FURTHER STEPS IN THE PROGRESS OF ORTHODONTIA.

By EDWARD H. ANGLE, M.D., D.D.S., New London, Conn.

(Read before the Alumni Society of the Angle School of Orthodontia, at its seventh annual meeting, September 5, 1912.)

MR. PRESIDENT AND MEMBERS OF THE ALUMNI SOCIETY:

AT our meeting one year ago, as you will recall, I presented a new plan of treatment of malocclusion of the teeth, with new forms of appliances for accomplishing the various tooth movements in accordance with this plan, a description of which was published in the DENTAL COSMOS for August last. A close study of that description is necessary for a full comprehension of what I shall present today.

As a result of wider observation, much thought, and careful experimenting, I think I can today not only greatly simplify the technique in the adjustment and operation of the appliances then presented, but lead you to a more intelligent appreciation of the possibilities and advantages to be gained by the employment of the new method of treatment.

NECESSITY OF EXACT DIAGNOSIS.

All of you here today are fully aware of the importance of a thorough knowledge of the normal occlusion of the teeth and normal facial balance as a guide to the intelligent direction of your efforts in the correction of malocclusion. Also you are aware of the importance of the full complement of teeth, and the very important part that each tooth plays in its relation to all the other teeth of the denture, that the denture may not only be in function most efficient, but that it may contribute its full part to the normal beauty and balance of the face according to the individual type, and also its normal part in the possibility of normal growth and development of the throat and nose, all of which are so essential to the health and growth of the individual.

For a number of years we have been able to classify malocclusion, to note quite accurately the degree of variation of position from the normal of the crown of each tooth, and to judge of its necessary movement in establishing normal occlusion. But heretofore the crowns of the teeth have received our chief attention, both in diagnosis and in tooth movement, and we have been largely dependent upon nature for the movement of the roots, the positions they will finally occupy being largely problematical—due chiefly to the limitations of the orthodontic appliances heretofore at our disposal. But a new era is before us, with far greater possibilities, but with these possibilities come, also, greater responsibilities as to diagnosis, knowledge of the tissues we operate upon, and technique. We must now study our cases so carefully in the beginning as to enable us to determine accurately not only how great are the variations of position from the normal of the crowns of the teeth, but the extent of the apical displacement and incorrect angle of inclination of each root, and also the extent of arrest in development of the alveolar process and co-related bone, that we may have a clear conception of the exact direction and extent each tooth should be moved and the amount of bone development necessary in order that nature may build the denture to full completion in accordance with the architectural design of the individual type.

STUDY OF BONE-GROWTH A PREREQUISITE TO SUCCESSFUL REGULATION.

Science discountenances guessing and exacts accuracy, and I believe it is now quite possible to fulfil the demands of science in orthodontic procedure; but this necessitates, as we have said, closer study and a more intimate knowledge of the habits of bone-growth and of the tissues we are to operate upon, for let us ever remember that we can do nothing of permanent value by ourselves in our efforts at treatment, but only as we work in conjunction with nature, studying her carefully, interpreting her wishes, and intelligently assisting her in her efforts of growth and development of the denture to be in harmony with the line of occlusion and the forces which govern occlusion.

Fortunate are we at this time in having access to those splendid chapters on bone life contained in Dr. Noyes' recently published book, and to the wonderful researches in bone-growth by another of our own number, Dr. Oppenheim of Vienna, together with the epoch-marking researches on the development and growth of bone by Dr. McEwen of the University of Glasgow, just issued, all of which will later be reviewed at this meeting.

DELICACY OF THE NEW APPLIANCES.

Having determined the exact requirements of crown and root movement, and the bone development necessary, our appliances should be such as will best fulfil these demands, namely, to exert pressure upon the teeth in the right direction and with only the proper force to normally stimulate the various bone cells in their work of absorption and rebuilding the bone. As we now know that this pressure should be very gentle, our appliances may be very delicate—far more delicate than we formerly believed practicable, and the new appliances have been designed with a view to fulfilling as nearly as possible these natural requirements.

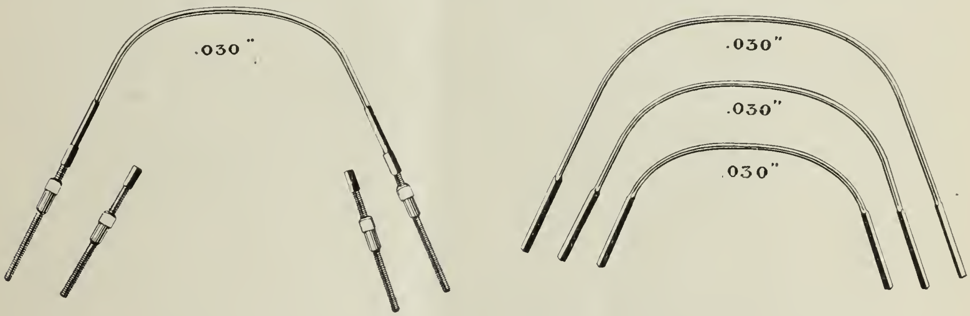
In order to refresh your memories regarding the new appliances let me briefly review the description of the more important of them, together with that of their adjustment and manner of operation.

THE EXPANSION ARCH IN ITS PRESENT PERFECTION.

The ideal principle in an orthodontic appliance, that of the expansion arch, is still employed, but the arch now used is of necessity of much greater delicacy than the one formerly employed, and it is also further modified for greater convenience in use. It is divided into three sections, a middle and two end sections. The middle section is very elastic, is smooth, round, and very delicate in size, being only .030″ in diameter. It has squared ends which accurately fit into square holes in the ends of the threaded end sections, Fig. 1. In operation the end sections are slipped into the sheaths of the anchor bands on the teeth used as anchorage. The middle section is carefully bent so that it will lie passively in close relation with the buccal and labial surfaces of the teeth in their malpositions, with its ends telescoping with the threaded end sections for about one-eighth of an inch.

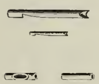
Instead of being attached to the teeth to be moved as heretofore by means of wire ligatures, bands, and spurs, the attachment of the arch is now made more direct and positive by means of delicate pins soldered to it, which engage delicate

FIG. 1.



tubes soldered to bands on the teeth to be moved. The pins and tubes are shown in Fig. 2, and the whole appliance, Fig. 3, is shown on the upper dental arch of an ordinary case belonging to class I, which requires much bodily movement of the

FIG. 2.



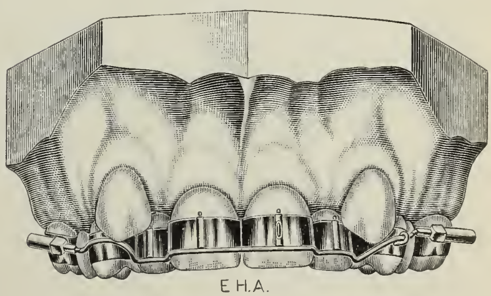
incisors, with a large amount of bone development.

Force is exerted on the teeth to be moved by the elasticity of the middle section of the arch and the pins, the middle section being occasionally removed from the teeth and one or more of the bends in it slightly straightened, after which it is again sprung into position on the teeth, and this is repeated at intervals until both crowns and roots of the teeth have been carried into their normal positions in the line of occlusion. It will thus be seen that the force derived from the elasticity of the arch and pins is so distributed to the teeth that the latter will be carried bodily, apices of roots as well as crowns, in the direction in which force is exerted.

PREDETERMINING ROOT MOVEMENT BY AN IMPROVED TECHNIQUE.

And here I wish to improve upon some of the technique that I gave you one year ago. I then said that the pins were occasionally to be bent forward or laterally to accelerate or change the direction of movement of the apices of the roots of the teeth, thus resorting to a considerable amount of guessing as to the amount and

FIG. 3.



direction of the force. I now believe we should have clearly fixed in our minds, before the adjustment of the appliances, the exact direction and extent that the apex of each root should be moved, and that we should so place our pins in the beginning, giving them the requisite inclination for the proper root movement, as to avoid the necessity for their subsequent bending, the only subsequent change in the mechanism then required being the straightening of the bends in the middle section of the arch and the proper adjustment of the end sections through the manipulation of the nuts. Only by this means can we avoid unnecessary disturbance of the tissues, with the resultant inflammation and injury. To make this clear, if it has been previously determined that the apices of the roots of one or both of the lateral incisors require more movement labially than those of the centrals, the pins should be given the necessary additional inclination when they are soldered to the arch. In like manner, other additional root movements should be anticipated, and the pins be placed for their accomplishment, thus reducing to the minimum the necessity for subsequent changes.

POSITION OF PINS AND TUBES.

In order that the force may best be exerted on the roots of the teeth, the pins and tubes should be made to line parallel with the axes of the teeth whenever possible, and at the same time they should be parallel with each other, in order to permit the telescoping of the pins with the tubes. But as the teeth are often found in such irregular positions, the first impression in such cases would probably be that if the tubes were placed parallel with the axes of the teeth, the tubes themselves would diverge so greatly from the parallel as to make the insertion of the pins impossible. But if you will study your models carefully, accurately noting the direction of the line of axis of each tooth, you will doubtless be surprised, as I have been, to find that when the tubes have been placed so that they align with the axes of the teeth, they will be parallel in nearly all cases, or sufficiently so as easily to permit, with gentleness and care, the telescoping of the pins with them, the slight divergence from the parallel being accommodated by the spring of pin and arch. In some instances, however, the irregularity of position of a tooth may be so great as to necessitate slightly varying the inclination of the tube from the parallel in its placing.

DEVICE FOR SOLDERING PINS TO ARCH WITH PERFECT ACCURACY.

According to the technique for placing the pin which I gave you one year ago, the pin was to be held while being soldered by means of a pin-holder (Fig. 4) in one hand, while the arch was supported by the other hand, thus relying on the skill and judgment of the operator for the inclination of the pin, and, while many of you are sufficiently skilful to place it with a considerable degree of accuracy by this method, yet the possibilities of inaccuracy are great, often requiring the re-soldering of the pin at a different angle, and its frequent final bending to give it the proper alignment, which often results in breaking it or weakening it at the point of its attachment. The importance of the accuracy of this operation I have already dwelt upon, and if you will observe care in the method I shall now give you, you may entirely eliminate inaccuracy in the operation.

FIG. 4.

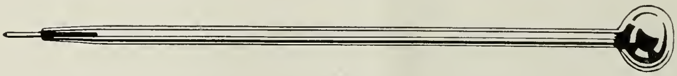


FIG. 5.

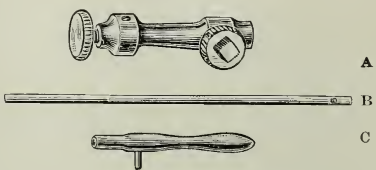


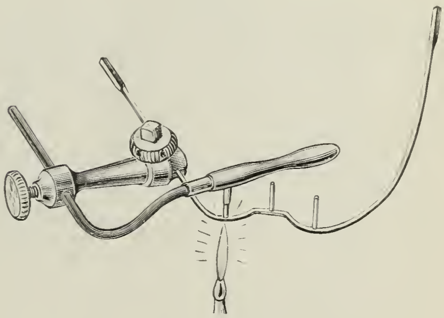
For supporting the pin in the proper

alignment while it is being soldered to the arch I have devised a peculiar form of soldering jig, shown in Fig. 5. It consists of a delicate vise, A, a section of soft copper wire, B, and a pin-carrier, C. In use the jaws of the vise are firmly clamped on the middle section of the arch at a point not more than half an inch from where the pin is to be soldered, the arch lying passively in contact with the buccal and labial surfaces of the teeth, and the opposite end of the vise projecting outward between the lips of the patient, for in practice the appliances should always be fitted directly to the natural teeth, never to plaster models. The round end of the copper wire telescopes a round hole near the outer end of the vise and is firmly clamped in position by a thumb-screw. The copper wire is then bent around so that its other end, slightly flattened on one side, is made to rest passively at the exact point that the head of the pin is to occupy after it is soldered to the arch. Usually this point is at the gingival end of the orifice of the tube on the tooth to be moved. If, however, it is desired to move the apex of the root of a tooth more than its crown in a certain direction, the pin must be given the necessary angle of inclination to accomplish this movement. The flattened end of the copper wire is therefore made to rest exactly at the point necessary to give this inclination, independent of the position of the mouth of the tube. Considerable care is necessary in the bending and manipulating of the copper wire that it may rest passively at the exact point desired, and this operation is made much easier by keeping the copper wire very soft by occasional annealing.

The wire is now gently disconnected from the vise without changing its form, and laid aside. The middle section of the arch is also carefully disconnected from the end section, and it and the vise are removed from the mouth without changing the form of the arch or its relation with the vise.

The round end of the copper wire is now replaced in its original position in the vise and reclamped, and the pin-carrier slipped over the flattened end of the copper wire to the full depth of the hole in its end. Then the pin is placed in the hole in the pin-carrier, with its hook pointing lingually, and the pin-carrier is turned to bring the chisel crescent end of the pin in a similarly formed delicate notch in the middle arch section, its position having been previously carefully determined and the notch carefully made at a point directly opposite the orifice of the tube on the band against which the middle section of the arch is to rest and into which the pin is to fit. By this means the pin is accurately aligned and supported and

FIG. 6.



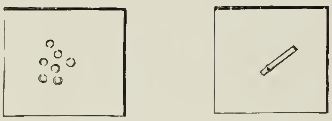
ready to be soldered in position, as shown in Fig. 6.

I am indebted to Drs. Gough and Lane for suggestions relative to the soldering jig—to Dr. Gough for suggesting the detached pin-carrier, and to Dr. Lane for the suggestion of the thumb-screw in the end of the vise for clamping the segment of copper wire in position.

CONVENIENT FORM OF SOLDER TO INSURE ACCURACY IN SOLDERING PINS TO ARCH.

Another point on which I wish to improve the suggested technique of one year ago is in the form of the solder to be used for making these attachments. I then said we should guess at the amount of solder, cutting it in the usual small squares, and either previously partially fusing it upon the middle section of the arch, or hoping it would remain in contact with pin and arch while being fused. The result, following this time-honored custom of soldering, was that too often the fragment of solder became displaced, or was found imperfectly distributed after it was fused, or that too little or too much had been used. All of these difficulties are now overcome by having

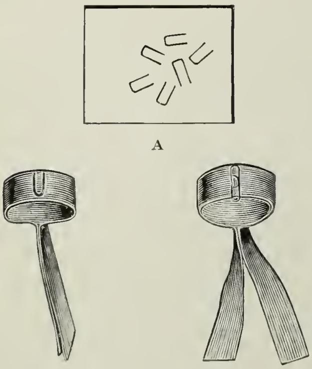
Fig. 7.



a *b*

the bits of solder of proper size and shape. This I have accomplished by first drawing the solder into very delicate wire and then forming it into minute rings, *a*, Fig. 7, the inner diameter of which is the same as the diameter of the pin over which one little ring is slipped before putting the pin in the carrier, as shown in *b*, Fig. 7. The sample rings which I shall

Fig. 8.



A B C

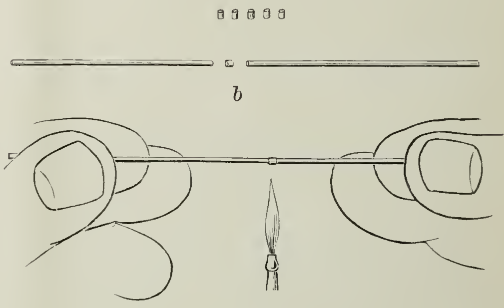
A, Staple form of solder. B, Staple of solder on band. C, Tube, solder, staple, and band.

pass around I believe will be found to contain just the proper amount of solder and of the correct karat, which result has been attained after considerable experimentation.

In fusing the solder it is held in contact with the delicate flame, the point of the flame striking the arch directly underneath the pin, as shown in Fig. 6, and I wish to impress upon you the importance of observing care in this operation. First, the notch in the arch must be delicate and of the proper shape to best engage the thin, crescent-shaped end of the pin. Just the requisite amount of flux should be used, and the ring of solder must not only encircle the end of the pin, but lie in actual contact with the arch, otherwise there will be no union be-

Fig. 9.

a



b

c

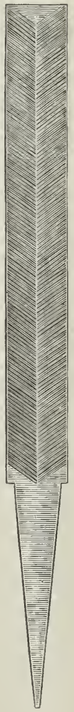
tween pin and arch. The flame must be very delicate. That from the Grünberg blowpipe is the best, and the heat must be applied slowly and very evenly so that the pin and arch will be equally heated, and the temperature very gradually raised to just the fusing-point of the solder. You will note how beautiful and how strong are the soldered joints (Fig. 6), and how evenly the solder has flowed. If a flame larger than necessary be used, as many of you will persist in employing, there is almost a certainty of injuring, if not of ruining, either the pin or the arch, or both.

STAPLE-SHAPED PIECES OF SOLDER FOR SOLDERING TUBES TO BANDS.

Taking advantage of this principle of soldering, I have applied it also to the attachment of the tubes to the bands, in which case the pieces of solder are made in the form of minute staples (A, Fig. 8), one of which is picked up with a very delicate camel's-hair brush, previously dipped in liquid flux, and carried to the desired position on the band, B, Fig. 8. The tube is then placed in position between the projections of the staple, C, Fig. 8, and carried to the flame, which should be even more delicate than the

FIG. 10.

FIG. 11.



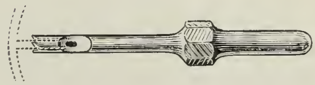
one used in soldering the pin, because there is less metal to be heated, and the temperature very slowly and evenly raised to the fusing-point of the solder. If good flux be used and the temperature be raised very slowly and be very evenly distributed, so that the tube and band and solder are equally heated, the most even and perfect distribution of the solder, without the least displacement of the tube, will result. On the other hand, if a large flame be used, the band and tube will be heated unequally and the solder fused on one side before it is on the other, which will always displace the tube to the side on which fusion first takes place. If, however, the tube is slightly displaced while the solder is melting, it may, before removal from the flame, be best teased back to its correct position with the point of an ordinary sewing needle, about No. 10, the needle being held in the fingers, not in a broach.

TUBES OF SOLDER FOR SOLDERING ACCURATE BUTT JOINTS.

And here is still another extension in the use of this novel method of soldering,

FIG. 12.

FIG. 13.



with which I believe you will be pleased: It is occasionally necessary to unite, end to end, a broken middle section of the arch, or to lengthen a middle section by adding to it a segment of wire of the same diameter, and you all know how difficult it is to make an accurate, even, soldered butt joint, but with the method I shall now give you it becomes a very simple operation. I have drawn the solder for the purpose into tubes, the bore of which is the same as the diameter of the middle sections of the arch, *i.e.* .030″. The wall of the tubes is very thin. This solder tubing is cut in short segments (*a*, Fig. 9). Flux is placed on the ends of the wires to be united and one of the little ferrules of solder is slipped for half its length over one of these ends (*b*, Fig. 9). The end of the other wire is then inserted in the other end of the ferrule (*c*, Fig. 9), and all carried to the flame, with the little ferrule making a sure and accurate support for the ends of the wires. The temperature is then slowly raised to the melting-point of the solder by applying heat, not directly to the solder, but to the wire on each side, alternating from one side to the other. The little ferrules of solder insure not only the accurate apposition of the ends of the wires, but the proper quantity and distribution of the solder for making a very strong and perfect joint. And if you will use thought and cultivate skill in this operation, you may make joints that are not easy to detect. Of course the ends of the wires to be united should be round and made to abut accurately—with, possibly, a very small groove across the end of one of them to take up any superfluous solder.

Fig. 14.

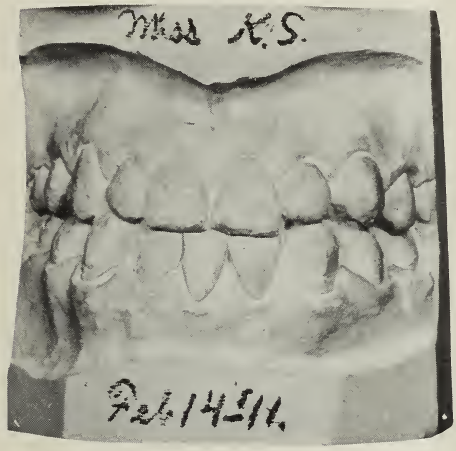
Fig. 15.

It is well worth while to cultivate judgment and skill in all our technique, and we all can easily do this. It will result not only in the saving of much time, but in real satisfaction in our work.

CAUTION IN STRAIGHTENING THE ARCH.

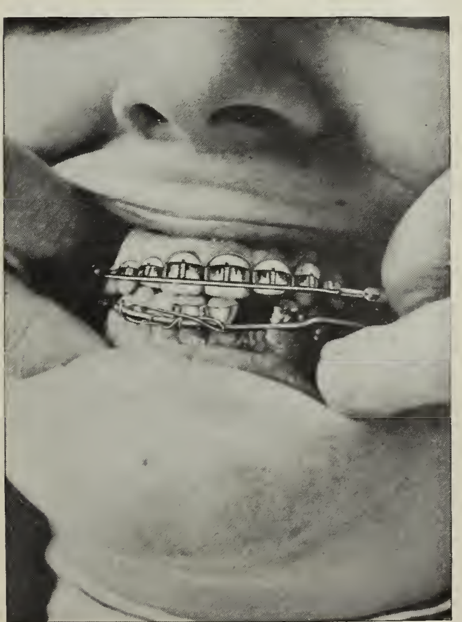
Now a word of caution. It should be remembered that there is practically no loss of energy with this method of treatment by slipping or displacement of parts, as compared with the probability of much loss of force in this way in the older method. So, in straightening the bends in the middle section of the arch from time to time, it is highly important that not too much force be given to the moving teeth, and that the orthodontist shall know quite accurately its amount and direction. Dr. Young, who has had much experience in the use of the new appliances, assures me that he is now convinced that rarely more than one, or at most two of the bends should be slightly straightened at any one appointment of the patient, leaving the balance of the arch as it is for control of the force, and that the amount of straightening

Fig. 16.



should never be more at any one time than would change the relation of the

Fig. 18.



pin with the tube the thickness of the wall of the tube.

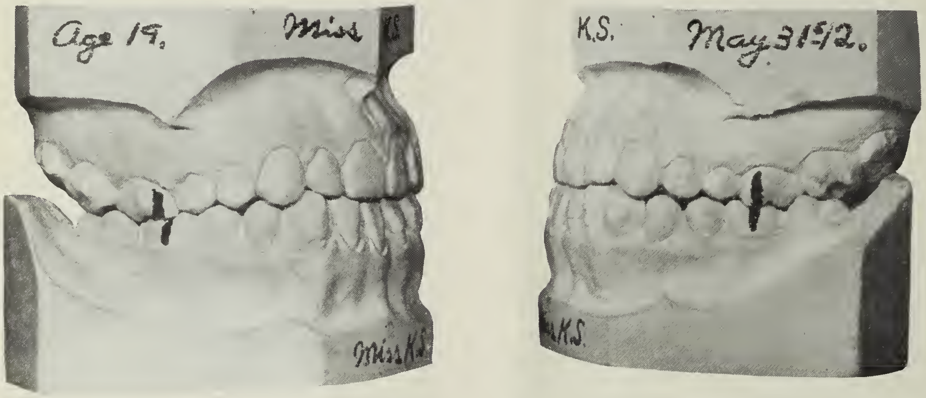
It is also important that the square ends of the middle section of the arch

Fig. 17.

shall be kept in proper relations with the holes in the screw sections. In other words, if slightly straightening one or more of the bends should result in giving the ends of the middle section of the arch too much buccal or lingual displacement to be in general harmony with the ends of the screw sections, the middle section, in the region of its ends, should receive additional modification of form to restore harmony with the anchorage when the middle section is again placed in position, so that unnecessary soreness or displacement of the anchor teeth may be avoided.

Dr. R. H. W. Strang, one of our number, has devised an ingenious instrument for recording the exact amount that the middle section of the arch is modified in the straightening at each appointment of the patient. Dr. Strang will later describe this instrument himself. If it is practical and will do what it so well promises, it will be a most valuable adjunct to orthodontic operations, for we can then for the first time actually measure the exact extent of movement of not only the crowns but the roots of any or all of the teeth, from appointment to

Fig. 19.



appointment. This is progress; this is science.

A FEW ACCESSORY INSTRUMENTS.

As a means for properly bending and straightening the middle section of the arch I have designed a pair of delicate pliers (Fig. 10), which I think you will find as efficient as they are simple.

I have already spoken of the importance of the form and position of the little notch in the middle section of the arch for the reception of the crescent end of the delicate pin during soldering. By far the most efficient instrument for this purpose I have yet found is the extremely delicate-edged file shown in Fig. 11. It should be kept for this purpose only.

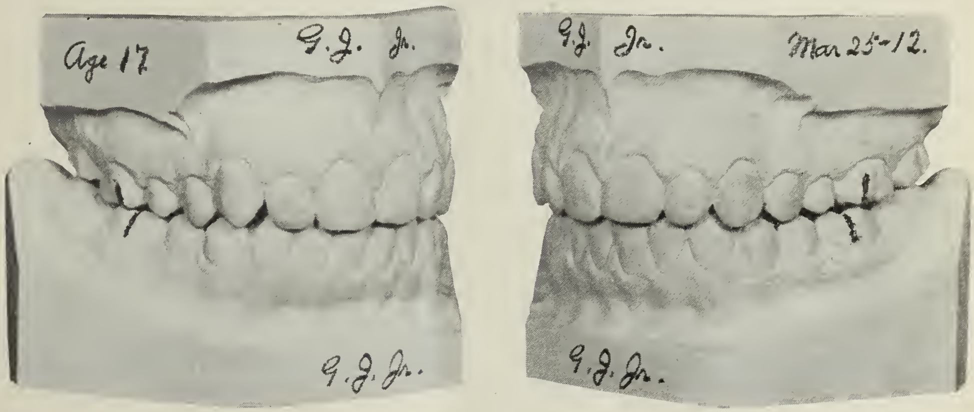
I have also designed two other delicate instruments to aid us in this work. That shown in Fig. 12 is a reamer for enlarging the mouth of the little tubes, and that shown in Fig. 13 is a solder trimmer for trimming away any excess solder around the base of the pin which would prevent the proper seating of the pin in the tube.

I am glad to be able to tell you that we will soon be able to procure the various parts of these appliances, together with the solder in the forms I have described, also the various instruments I have described, and others, for the orthodontic technique, and that all will be of the most excellent quality and of beautiful proportions and finish. Some of them have been sent us for use in the clinic today. I am greatly delighted with the accuracy

Fig. 20.

with which they have been manufactured, and I am still more delighted with the future possibilities for orthodontia in their intelligent use. But remember that at best the orthodontic appliances are only a factor in treatment—one of the means to an end, and let me incite you to a broader study of the basic principles of orthodontia, and especially of the tis-

Fig. 21.

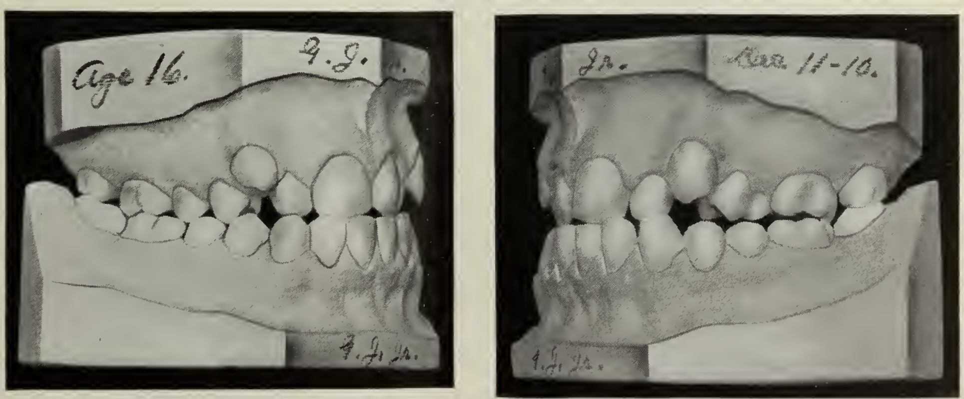


sues you operate upon, for orthodontia is no longer merely mechanics, but science.

PRACTICAL RESULTS OBTAINED WITH THE IMPROVED APPLIANCES.

And now I want to show you some splendid results in the use of these appli-

Fig. 22.



ances in a case treated by one of our number, Dr. A. H. Ketcham of Denver, who could not be with us today, but who has sent the report of this case. You will see that the results are such as could probably not have been accomplished by any other method of treatment heretofore employed.

The original conditions of occlusion and facial lines of the patient are shown in Figs. 14 and 15. The case was treated, up to a certain point, with the old appliances, exactly in the way in which we have all been treating similar cases, and very good results were accomplished, as you will see by the model and the face of the patient at this time, Figs. 16 and 17. We have all been quite happy over equal successes, but I do not think we will be content in the future to rest with such results. Dr. Ketcham was not satisfied with the occlusion nor with the resultant facial balance. So the new appliances were adjusted to the teeth of the upper arch with a view of inducing further bone growth and of gaining better angles of

Fig. 23.

inclination of the incisors and cuspids. The ordinary expansion arch was adjusted to the lower teeth, and through its means the lower dental arch was enlarged and space provided for the missing lateral incisor, all as shown in Fig. 18. Now, if you will please study the occlusion of the

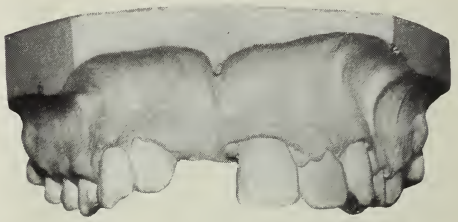
Fig. 24.

case shown in the models in Fig. 19, after the completion of tooth movement, together with the facial lines of the young lady at this time (Fig. 20), I am sure you will feel, with me, that the result is simply wonderful. Dr. Ketcham will doubtless later report this case more fully himself, but the point I wish to here bring out is what has been accomplished in bone-building by the new method of treatment.

Of course the new appliances might just as well have been employed from the beginning of the treatment, both on the upper and lower arches, and I believe the results would have thus been accomplished more easily and quickly, with decidedly fewer appointments and the consequent conservation of much time of both patient and orthodontist.

You will remember that one year ago, in connection with the explanation of the new appliances, I also reported another case then being treated by Dr. Ketcham. Although splendid progress was shown in the treatment of this case, it had not been completed when I gave the report

Fig. 25.



of it. So you will, I am sure, be pleased to see now the final results of Dr. Ketcham's work on this case, shown in Fig. 21, as compared with the original condition, shown in Fig. 22.

You will also be interested in the report of another case, treated by another of our members, Dr. Mendell of Minneapolis, wholly by means of the new appliances (Figs. 23, 24, and 25). Not only has there been extensive and pronounced bodily movement of the teeth, but most gratifying results in bone-growth.

Certainly the excellent results attained in these cases ought to be an inspiration to you all for deeper study and finer technique, and I sincerely hope that each and every one of you will be able to show equally gratifying results in the use of the new appliances in the reports of your cases at the meeting of this society one year hence.

PRACTICE CLINIC.

And now, gentlemen, in order that you may better familiarize yourselves with the various steps in the technique of adjusting the new appliances, I am going to give a clinic, but it will not be the kind of clinic that we have always been accustomed to, where men congregate around a chair or table to watch an operator do all the work. We will reverse this order and ask each of you to give the clinic himself, under the instruction of myself and Drs. Gough and Lane, who have been with me in my laboratory for several days specially fitting themselves to help you in this clinic. Every preparation has been made to enable you to do careful, thoughtful work in each detail of each operation, and I believe you will derive much practical benefit from this clinic.

Of course it would be impossible to provide actual patients for so many, and for our purpose this is not essential. Each will fit an appliance to a carefully made model of a practical case, but I repeat that the only true way in practice is to perform the operations directly upon the teeth of your patients.

There are many more interesting questions in regard to this method of treatment which cannot be brought out in a two days' clinic, but which we hope to reach at our next annual session.

DEFORMITY OF THE JAWS CAUSED BY THE EXTENSION BANDAGE IN THE TREATMENT OF SPONDYLITIS.

By G. LIND, D.D.S., Amsterdam, Holland.

IN the fall of 1911, I was called to one of the Amsterdam hospitals for consultation. The patient, who had been suffering from spondylitis for several years, complained of severe pain in the mouth, especially during eating and speaking.

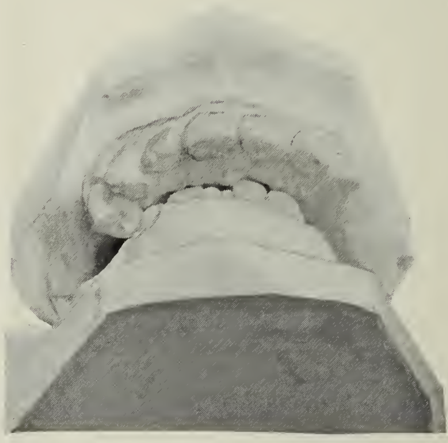
CASE HISTORY.

The aspect of the chin and lower jaw immediately convinced me that a mechanical injury had been done to the patient, imparting to the jaw an abnormal shape. The patient's history was as follows: Miss M., age thirty-five, became ill in the summer of 1904. After having been under observation for several months, the case was diagnosed as one of spondylitis, and the patient was immediately placed in the customary plaster bandage, extending around the neck and resting on the shoulders. This bandage was worn by the patient until 1906, when it became too uncomfortable, and was replaced by the Glisson extension bandage, which the patient wore until March 1911. Fig. 1 shows how this bandage is put on, a rather heavy weight being suspended by the cord from the iron bar, keeping the neck straight. In 1908, oral trouble first arose, which in 1911 became so severe that the patient could not tolerate the pressure of the bandage. Treatment with this bandage was subsequently abandoned, and the patient was placed with her head in a suspended position. In the meantime the patient's face had greatly changed, as evinced by photographs that were taken before her illness. The chin and lower jaw were small, and on either side of the jaw a depression was noted corresponding to the leather straps of the bandage. The skin and lips were normal. The upper anterior teeth were very much protruded and loose, several of them exhibiting pyorrhea alveolaris and caries. All the upper bicuspids and molars, with the exception of the upper right first bicuspid, were missing. The mucous membrane of the palate was ulcerated and sore from the bite of the lower teeth. In the mandible one central incisor, one bicuspid, and two molars were missing. Several of the remaining teeth were carious, but none of them was affected with pyorrhea. The patient said that the missing central

Fig. 1.

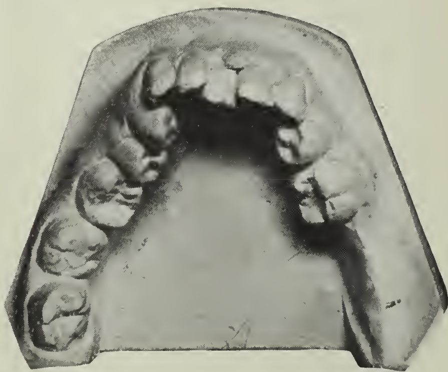
incisor had been pressed slowly out of alignment, and had been extracted in 1909, when it was very loose. The remaining five incisors were now bunched, while the bicuspids and first molars were tipped lingually, as shown in Fig. 3, leaving but little room for the movement of the tongue. The lower right bicuspids were in infra-occlusion with the remaining upper right first bicuspid. The patient asserted that she had had a normal denture just like her sister's, whose mouth I have examined. It was evident that the constant pressure of the extension bandage had caused this deformity of the jaws, viz, the pressing upward of the chin, the tipping and bunching of the lower teeth, and the

Fig. 2.



enormous protrusion of the upper ones, together with the concomitant complications, consisting in severe pain in the

Fig. 3.

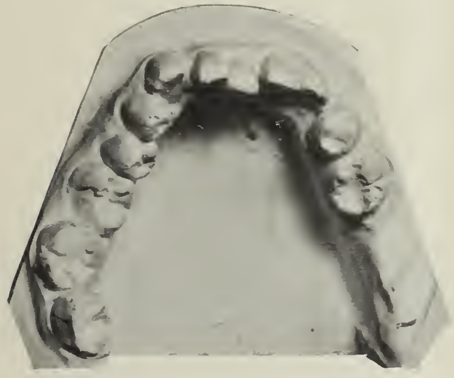


palatal region, inability to masticate food, and trouble in moving the tongue.

TREATMENT.

The patient's deplorable condition rendered rational treatment impossible. I therefore decided upon the following procedure: A bite-plate was made for the upper jaw to relieve the palate, the ulcerations of which were treated. The carious teeth were filled, and the pyorrheal condition combated, as well as possible, the suspended position of the head rendering these manipulations rather difficult. An old-style coffin plate was then constructed, to expand the lower jaw.

FIG. 4.



After four months' treatment, the jaw was expanded so far that the lower right bicuspids were in normal occlusion with the remaining upper right bicuspid, and the tongue could move freely. (See Fig. 4.) For the purpose of retention, a plate was made carrying one molar. The upper bite-plate was replaced by a partial denture. The protrusion in the upper jaw was not treated, as I only wished to relieve the patient of her suffering, and enable her to masticate her food better. The result was very satisfactory from the standpoints of both patient and operator.

SUGGESTED MODIFICATIONS IN THE USE OF THE EXTENSION BANDAGE.

I have been unable to find any literature on the ill effects of the extension bandage upon the jaws, etc., perhaps because this bandage is usually not worn for such a long time as in the case described. Still, if it is to be worn even for a shorter time, it would be advisable in my opinion to replace the chin support of leather with one of rigid metal, made after an impression and model of the patient's chin, thereby preventing the compression of the lower jaw. Furthermore, it is necessary to take into consideration the occlusion of the teeth. If the occlusion is abnormal, I should advise the construction of an upper vulcanite plate fashioned like a retention plate provided with the impressions of the incisal edges and masticating surfaces of the lower teeth, so as to guide them into proper occlusion. If such precautions are taken, I am sure that complications like the one described can be avoided, and the deplorable condition of sufferers from spondylitis will not be aggravated by pain in the oral cavity.

AN EROSION CAVITY IN A GOLD CROWN.

By H. JAMES MORRIS, L.D.S., Sheffield, Eng.

THE illustration shows a model of the bicuspid region in the mouth of a young married woman who came to consult the writer. The remarkable thing about it is that the upper left first bicuspid is a gold crown exhibiting a well-marked erosion cavity in the most prominent place. The edges of the gold have been worn very thin and the floor of the cavity consists of cement.

The lady said that she had brushed her teeth "twice a day for twenty years," and other erosion cavities, chiefly on the left side (as she is righthanded) tend to support this statement, as does the general condition of the mouth. The powder used during the last four years is a private recipe which the writer had no chance of examining.

This cavity in a gold crown in such a position on the buccal surface hardly admits of any explanation except that it was cut by a brush and powder, and lends strong support to the mechanical theory of the origin of many such cavities. The researches of the late Professor Miller

(See DENTAL COSMOS, 1904, vol. xlvi, p. 177; 1907, vol. xlix, pp. 1, 109, 225, 677) tended strongly to prove this, if they did not absolutely do so.

THE GREAT NEED OF IMPROVEMENT IN THE MANUFACTURE OF DENTAL ALLOYS.

By C. M. McCAULEY, B.S., D.D.S., Abilene, Texas.

(Read before Section I of the National Dental Association, at its annual meeting, Washington, D. C., September 10, 1912.)

THE subject of this paper will be treated under three headings, namely —(1) The present status of the amalgam situation. (2) What has been done toward the correction of existing evils. (3) Prospects for improvement in the future.

REITERATION OF A FEW STATEMENTS CONCERNING AMALGAMS.

My experience during the past year prompts me to emphasize certain points touched upon in my paper—which was read before Section III of this association last year and published in the February 1912 issue of the DENTAL COSMOS, p. 174. Namely:

I still maintain that the method of making and balancing alloys as discovered by Dr. G. V. Black is the only scientific and dependable method which has been introduced up to this time.

That shrinkage, flow, weakness, and excessive expansion are serious faults found in most amalgams, and that of these faults shrinkage is the worst.

That silver, tin, and copper are the only metals that should be used in alloys.

TWO MAJOR ELEMENTS IN THE MAKING OF EVERY GOOD AMALGAM.

There are two major elements which enter into the making of every good amalgam operation, namely, a good alloy and correctness of manipulation. Where either of these elements is lacking, even in a slight degree, the result fails to reach that degree of perfection which characterizes efficiency in any scientific undertaking. When one appreciates the importance of each of these elements, then considers the vast number of operations done with amalgam, and observes the large percentage of failures therein, no apology for presenting a paper on this subject at this time will be necessary.

IMPORTANCE OF THE SUBJECT OF AMALGAMS.

I do not hesitate to say that, in view of the remarkable deficiency of many commercial alloys, and the seeming indifference on the part of so many dentists, there is not a subject before us today that calls for closer study, better teaching, and more profound investigation than the subject of amalgam.

ONLY ONE OUT OF SIX ALLOYS FOUND GOOD.

According to tests which have been made up to the present time, only one out of six alloys has proved good. In other words, the man who is a capable amalgam operator and selects his alloy from the market stands one chance in six of securing good results! To make it still worse, many men believe in an alloy and earnestly advocate its supremacy when, as a matter of fact, it may be unfit for use as a filling material. For example, one man brought in a specimen of alloy, in which he had the utmost confidence, to be tested by the committee. He had been searching for several years for his ideal alloy, having tried a great many kinds, and the specimen presented he honestly believed to be the best of all. In making the tests, he watched the readings of the micrometer very closely. The first filling showed shrinkage. Not being satisfied, another was made, and then a third; still shrinkage occurred. Three months from that time these same fillings had expanded to an extreme degree. This operator was one of the leaders in his state, and the alloy tested is being sold in many states, thus bearing out my claim that the most vigilant observation of our best operators is insufficient to determine the quality of dental amalgams. No one should be blamed for such an attitude as is assumed by this man (and there are many just like him), because he has no means of knowing of such defects as can only be found by the micrometer, the microscope, or long years of clinical experience. No one will question the assertion that clinical experience throughout the country is far from satisfactory, and is of only secondary importance in determining the quality of alloys.

THE MANUFACTURERS' SHARE OF BLAME.

In bringing about a reform in the present amalgam situation we must give the manufacturer his share of the blame. Many of them seem to be lacking in knowledge of their business. And yet the strongest claims for superiority of their products are set forth in glaring advertisements; circulars are sent broadcast over the land, telling of the long years of experience, giving testimonials from the leading men, etc.

"NAMELESS" ALLOYS.

It is estimated that over two hundred different brands of alloys are made and sold in the United States today, of which less than one-fourth bear the name of the maker. In most states there are local dealers in dental supplies who have one or more alloys made, and give them some catchy name. The maker of these alloys is aware of the dealers' ignorance and perhaps indifference as to the quality of the alloy, and he, the maker, being in no way responsible to the dentist for the quality, the main incentive to honest and conscientious manufacture is utterly lost. This class of alloys composes practically three-fourths of the entire market. Not one of this class has been found to be up to the standard—nay, worse, all of them which have been tested in our experiments have been found bad.

UNSCIENTIFIC ALLOYS.

Of the remaining alloys, which bear the name of the maker, more than three-fourths are still made by unscientific and haphazard methods. Some adhere to the use of zinc, some to that of gold, and others to various modifying metals which are quite detrimental. One manufacturer claims to make twenty different alloys, each from a separate formula—none of which, judging from the formulæ he gives us, could be expected to stand the micrometer test. Some manufacturers not only use ingredients which are positively harmful, but some of them herald their use throughout the country in glaring headlines on advertising matter, claiming originality, new discovery, superior quality, and so forth—and the dentist believes, hence the sale of the article.

Of the remaining small number which are balanced by the micrometer and properly made, a few, a very few, are composed of the right materials. Is it any wonder that some of our best operators frown upon amalgam? Is it any wonder that results as a whole are so far from perfect?

The above conditions have produced innumerable unnecessary failures in our work, and have stood in the way of good being done in other lines. Some of our best operators will not use amalgam because they have failed to render the best service with it. The trouble was a defective alloy. The best efforts of our best operators will fall short of perfection unless the amalgam is perfect. Make the alloy right and put it in the hands of an efficient operator, and the result will be right.

What has been done toward the correction of existing evils? So far as the writer is aware there has never been a systematic examination made of any considerable number of alloys with a view of ascertaining their physical properties and reporting the same to the profession.

RESULT OF INVESTIGATIONS CARRIED ON IN SEVERAL STATES.

Such work was begun a year ago, when Section III of this association requested the writer to co-operate with a committee appointed for that purpose. Owing to an oversight the appointment of this committee was not officially confirmed. The work has consequently been deferred, pending confirmation of the committee appointed.

The writer was invited to the states of Iowa, Nebraska, and South Dakota in May of the present year to do some work along this line. At my request, a committee was appointed in each state to assist me, and to check up my notes. The plan adopted by each of these committees was to present the alloy to be tested in sealed envelopes, bearing only a number. The name was unknown to us until after the tests were made and recorded. Special effort was made to do all the work in a strictly fair and unbiased manner. The tests made in these states were highly significant, because the standard of efficiency among the members of these societies is very high, thus indicating that the highest-grade materials are in use. The specimens tested were supplied by the best men of these states. These specimens included many, in fact most, of the alloys which enjoy a wide reputation. We presume that the cream of the market was represented in the specimens thus secured. Added to these specimens are a few brands sent me from different sources and tested by me in my office, bringing the total number tested to thirty-seven. Out of this number only six or eight brands proved to be good, or medium good. All the rest should be eliminated from the usable class. Twenty-two out of the thirty-seven show excessive expansion, ranging from 5 points up to 342 points. Several fillings showed over 100 points expansion. Dr. Black says that 2 points expansion is desirable. We may safely say that expansion in excess of 5 points should be avoided, and that shrinkage in the slightest degree is harmful. To be on the safe side and to give every alloy a fair test, we regard 1 point in all tests as coming within the range of unavoidable error, hence where only 1 point shrinkage is shown, we do not place the alloy on the condemned list. The number of usable alloys taken from over the country would probably be less than one in twenty.

THE PROSPECTS.

The future of dental amalgam depends upon the action of the dental profession. We should take the initiative. If let alone, conditions will, in all probability, grow worse; if we take the aggressive, much good can be done. If the work is ever completed as it should be done, co-operation is imperative. A vast amount of work and considerable outlay of money will be required. Of the two hundred alloys on the market at least four specimens of each should be secured from different sources. Each of these should be carefully tested for shrinkage, expansion, strength and flow. If everything were in readiness to begin, this work would require the constant attention of one investigator for several months. Besides the time and expense, there is a responsibility attached to making such a report, which one man would not care to shoulder.

The accompanying brief report of partial tests* made is presented only to give this body an idea of the deplorable condition existing. It represents only a beginning.

The tests made are incomplete, therefore they cannot be absolutely relied upon.

Certainly the worst are condemned without further work, but those which appear good might not prove so if tests for flow and strength were made, and the tests were repeated a sufficient number of times. In view of the incompleteness of this report in some respects, I ask that it be accepted only for what it is, and that judgment be withheld pending further investigation, in the event that such action is officially taken by this association.

THE SIGNIFICANCE OF NORMAL OCCLUSION.

By LAWRENCE G. SINGLETON, D.D.S., Pittsburgh, Pa.

(Read before Section I of the National Dental Association, at its annual meeting, Washington, D. C., September 10, 1912.)

IN the presence of the naturalist an explanation of the value of the normality of a dentition would be equivalent to an effort to demonstrate the potency of a perfectly self-evident and well-known truth. As enlightenment for the dentist, it may appear like "employing a steam engine to crack a nut." But for the sake of humanity, it should prove itself an element of defense against deformity, disease, and the various disharmonies contingent upon perverted growth in the development of the individual.

Since the practitioner of dentistry renders expert testimony regarding all matters pertaining to the teeth, and in view of the fact that his decisions constitute the opinions of the court of last resort, it becomes necessary to occasionally classify the experiences of the past in order to standardize the verdicts of the future.

Owing to the practitioner's laudable success in the inauguration of methods for the attainment of much in the harmony of the human face, as well as his contributory responsibility for some of the disharmonies, it is clearly incumbent upon him to early recognize the fact that a mild indifference toward the importance of the normality of the dentition as regards the units and their relations, involves not less responsibility in the ultimate result than the failure to institute measures for their correction and prevention when such procedures are clearly indicated.

Mortal man, occupying as he does such an enviable position toward the other forms of life upon the earth, is apt to overestimate his importance in the economy of the universe. But with all his experience, and as the result of all his skill, there remains, as the issue of the aggregate of the combined efforts of the whole of mankind, nothing that is permanent, nothing that is fixed, which can resist the ravages of time and stand out as a permanent monument to his superior intelligence and skill in the operations of his functions.

There is abundant evidence to prove that for eons of time before man assumed the ascendancy on this planetary rib of the sun, those identical forces which shall have control of its ultimate destiny in the annals of time were in as complete operation, and were possessed of the same absolute certainty of effect, as has ever obtained during the period of his most phenomenal records of advance.

It is assuredly unnecessary to prove the precincts of our origin in order to enjoy the emoluments of our existence. But it is incumbent upon us to recognize the conditions of our existence, and place ourselves in conformity with those forces which govern the same, in order to derive the most benefit from their operation.

In this attitude we may direct our inquiries toward the significance of certain considerations involved in the study of teeth in their relation to the face, for the sake of a clearer interpretation of those problems which confront us in our daily pursuits. But it is frequently necessary to check our mad course among the lofty heights of the spectacular and drop to the level of mediocrity, by faithfully considering basic principles, in order to arrive at a substantial estimate of our progress.

Owing to their intimate relation to the necessities of nutrition and their formidable position in the matter of defense, the teeth have been inseparably associated with the history of animal life upon the earth for untold millions of years. In the matter of their significance in the functions of prehension and nutrition they have, even in the higher mammals, unmistakably antedated the uses of the hand. But with the advance of civilization, through discovery and invention, manual dexterity and skill has largely superseded the function of these pioneer organs of nutrition and defense, sacrificed, it may be, at the expense of some of their most valuable properties, as is evidenced by the ravages of disease with which we are so intimately concerned.

In the matter of evolution the forces of nature have been extremely prolific in the variety of designs effective in the purpose for which they have been evolved, and having traversed a wide range of possibilities in the adaptation of the mammalian forms for the uses of man, the human dentition represents a convenient apparatus for a generalized diet.

The problems of teeth have been most indelibly stamped upon the records of the past, and these organs, by virtue of the nature of their composition, have persisted as one of the most substantial evidences of pre-existing species. It is a significant fact that much of the mystery of the past has been satisfactorily unraveled by the careful interpretation of the characteristics of teeth.

Since nature has been creating designs and arranging teeth for a period of time sufficiently long to entitle her to respect, even before man entered the arena of combat, her precedents in regard to occlusion should receive the careful consideration that their importance demands. And it is a thought worthy of our most serious consideration, that as long as man has existed as a separate species in the zoölogical kingdom—which comprises a period of untold thousands of years—his typical dentition has been retained as a most persistent and dominant characteristic. Since this design has been in continuous service for a sufficient length of time to prove its utility and efficiency, it is manifestly an undertaking which borders upon presumption to set up artificial standards of occlusion as a substitute for the accredited plan of creation.

Neither are we justified in assuming that the human dentition is in a transitional stage because of occasional aberrant forms, discrepancies in number, and departures from the normal in position. There are undoubtedly conditions of "variation" from obscure causes, constantly arising, which according to the evidence of the past may be potent for the institution of new forms to come. That, however, will be a problem for the paleontologist of the future rather than a consideration for the anatomist of the present. But judging from her previous hesitating disposition toward the inauguration of new or spectacular forms, and before these processes of variation have culminated in the new and more perfect man, mother earth herself may have been separated into her elements, and then, having been shifted into the oblivion of time and space, may go drifting nonchalantly down some starry pathway, preparatory to beginning anew the cycle of her primordial existence.

According to a theory of heredity promulgated by Weisman, the germ plasm constitutes the physical basis of heredity, and only those characteristics which have been impressed upon this medium possess the potentialities for realization in the inheritance. The normal dentition, therefore, may be considered an expression of our ancestral inheritance. Aside from the "continuity of the germ plasm," there are other influences, immediately operative, which may deflect the course of development and retard or finally prevent the full expression of the inheritance in the individual. Irregularities of nutrition in the embryonic state, the effects of disease, and the absorption of drugs create conditions of environment which militate against the expression of the potential design, but these cannot in any sense be considered a part of the germinal inheritance.

We may therefore credit the malocclusion of teeth—including impactions as well—which are, in form and position, at variance with the type of the species, to the absence of appropriate environmental conditions and developmental stimuli. The function, therefore, of the orthodontist, and likewise the aim of the idealist, is not merely tooth alignment or the construction of ingenious appliances, not the reversal or obstruction of nature's processes, nor the creation or mutilation of types, but the endeavor to realize the purest expression of the inheritance in the individual.

The only scientific basis for the attainment of this goal consists in the application of the principles of normal occlusion as advocated by Dr. Angle; not as a dogmatic theory arbitrarily adopted, but as a natural standard most beautifully and continuously illustrated all through the records of the past, and enjoying the distinction of having been universally incorporated as a part of the architectural design in the creation of species.

The significance of normal occlusion loses a most potent motive in the absence of a genuine conception of the "line of occlusion," which has been defined as "the line with which, in form and position according to type, the teeth must be in harmony if in normal occlusion." Furthermore—"it is more than the tangible or material. It may be regarded as the basic ideal of the dental apparatus, the comprehension and appreciation of which will grow in proportion as our knowledge of the science of occlusion unfolds." (Angle.)

Without this basic principle, normal occlusion would represent nothing more than the mere contact of surfaces and the close approximation of the units in alignment, regardless of their number and denomination. In conformity with such a conception, the individual units lose their significance in the economy of the organism, and rank as accidental appurtenances, to be eradicated at will or left to destruction by default.

This virtually constitutes the parting of the ways, the slough of despond, where many an unwary traveler has struggled, and in the darkness has dismally met his Waterloo.

Each organism contains the potentialities for the completion of its cycle of existence in a perfectly characteristic and well-ordered fashion. The conditions of its environment form an absolutely essential complement for the innate peculiarities of its inheritance. Should the characteristic order of its development meet with unusual or disproportionate resistance, the perversion of its purpose constitutes the confused witness of its conflict.

In the event of such a contingency, and providing there exists sufficient inherent developmental vigor to induce the requisite activity, the rehabilitated forces proceed anew, from the point of interruption, to follow the remaining stages of the cycle to its ultimate termination.

In a technical sense, and in conformity with its ideal conception, orthodontia, based as it is upon the science of normal occlusion, affords no sanction for the mutilation of the dental apparatus. Extraction, therefore, has not been featured in the true science of orthodontia.

The most elementary conception of orthodontia demands the establishment of the "line of occlusion." The realization of this idea demands the full complement of teeth, characteristic in their form, position, and relations; and in this connection it may be stated that the standard of procedure for the dentist is not less rigid than for the orthodontist, inasmuch as the final verdict admits of no middle ground.

In this august presence a formal definition of normal occlusion would be superfluous, but an analysis of its significance would be manifestly incomplete in the absence of an explicit statement concerning its major premise in the form of its original interpretation. The value of much that has been written regarding the relations of the teeth might readily be determined by the measure of its conformity to this ideal conception of the line of occlusion.

There can be but one line of occlusion, and it must be the same as the architectural line on which the dental apparatus was constructed. This ideal line was intended to govern not only the length, breadth, and peculiar curve of the dental arches, but the size and pattern of each tooth, cusp, and inclined plane composing these arches. And more than this: That as the dental apparatus is only a part of the great structure—the human body—each part and organ of which was fashioned according to lines of design, it must have been intended that the line of occlusion should be in harmony in form and position with, and in proper relation to, all other parts of the great structure, according to the inherited type of the individual. (Angle.)

The phraseology—"fashioned after lines of design"—was probably not intended to indicate that natural forces work according to a preconceived plan, but rather that the design is the result of the operation of these forces. But since their operation has been observed to follow characteristic pathways, the result being a typical form, it was probably in this sense classified as architectural design.

In conformity with this interpretation of nature's plan, and as justification for the true science of orthodontia, it may be asserted that the sizes and shapes of teeth themselves, which are a distinct item of the inheritance, together with their growth-force, and these co-ordinating with the physiological stimulation of appropriate environmental conditions, determine the size, form, and position of the dental arches, in conformity with the typal design.

In recognizing the continuity of the cycle of development in regular and characteristic sequence, it becomes equally incumbent to concede its susceptibility to interruption, as well as to affirm the direction of its course. Its interruption constitutes a perversion proportionate to the force; its direction is forward, to the culmination of its purpose.

The inexcusable disregard of this natural condition leads to numerous embarrassing conclusions relative to the province of orthodontia. The contention that the results of the application of the principles of normal occlusion in orthodontic procedure do not justify the claims of its advocates is an evidence of a misconception of the very spirit of orthodontia. In view of the fact that orthodontia implies "the science which aims to assist nature in building the line of occlusion" (Angle), its advocates are not in accord with the idea that the dentition may be permitted to pursue a precarious course of development until the teeth have reached an uncertain position of latitude and longitude, and then, by the institution of some form of mechanical violence, pretend to eradicate all the evidences of perverted growth, and obtain a result comparable with the perfect correlation of parts in unrestricted development.

The forms of teeth, including their roots, are a continuation of characteristics which are a part of the heritage of the species, and are generated in conformity with the laws of heredity. And the weight of the evidence obtaining throughout the whole animal kingdom conclusively proves that normal occlusion of the teeth is the inevitable result of the operation of natural force in the presence of appropriate physiological stimulation and nutrition.

The course of development pursues characteristic pathways, but its full realization is susceptible to interruption and perversion. However, either in its perfection or its deviation, it comes fully within the bounds of natural laws.

And herein lies the value of orthodontic procedure. Not that we shall stand idly by, countenancing perverted efforts of growth, hoping to step in later on and invite nature to reverse her course. Her persistent refusal is an evidence of the astounding folly of such a course.

Rather should we fortify ourselves by familiarity with the architectural design, anticipate its requirements, and superintend the construction as indicated, in conformity with natural laws. Then only shall the structure be in full accord with the design; then asymmetry shall give place to symmetry, and harmony and balance shall rule supreme.

The significance of normal occlusion is therefore manifest, representing with all the eloquence of truth the culmination of natural force in the majesty and perfection of its design.

CHRONIC ALVEOLAR OSTEOMYELITIS (PYORRHEA ALVEOLARIS) —ITS CAUSES, AND TREATMENT WITH VACCINES:

With a Bacteriological Study and Report of 115 Cases.

By LEON S. MEDALIA, M.D,, Boston, Mass.,
LATE INSTRUCTOR IN PATHOLOGY AND BACTERIOLOGY, TUFTS COLLEGE MEDICAL AND DENTAL SCHOOLS, PATHOLOGIST AND VISITING PHYSICIAN FOR VACCINE THERAPY, MT. SINAI HOSPITAL, BOSTON, MASS.

(Read before the National Dental Association, Section I, at its sixteenth annual meeting, Washington, D. C., September 11, 1912.)

Introduction.

DURING my investigations of the opsonic index and the use of vaccines in the treatment of diseases due to bacterial infections, I was approached (in 1907) to find out if anything could be done with this new method of treatment for "pyorrhea." I have since had under my personal observation 115 cases, besides several other cases where I have acted as consultant. The cases here reported are all private patients, most of them sent to me by their respective dentists or physicians, while others applied for treatment of other diseases or for relief of other symptoms.

The laboratory work in connection with this study was carried out in the beginning at the pathological laboratory of Tufts medical and dental schools, and has continued, since 1910, in my private laboratory.

This work was carried out with the following objects in view:

(1) To help clear up, if possible, the etiology of this disease by means of the opsonic index, bacterial cultivations, and specific therapy.

(2) To establish the value of the vaccine method of treatment in this disease.

(3) To establish the relation of cause and effect of the bacteria isolated from the pus, by means of animal inoculation.

Etiology.

The understanding of the etiology of this disease depends upon a thorough knowledge of the true anatomical relation that the tissues surrounding the tooth bear to its socket, and what the alveolar process is.

Almost all authorities and text-books on dental pathology refer to the tissue between the root of the tooth and the alveolar bone as the periosteum, or peri-odontal or peridental *membrane.* According to Malassez(1), on the other hand—

> The so-called "alveolar-dental periosteum" or "peridental membrane" is nothing more than an alveolo-dental ligament, because of the fact that if one examines microscopically longitudinal or transverse sections comprising the tooth and the neighboring parts of the maxilla one does not find in the alveolar dental space anything that resembles a periosteum nor any other *enveloping membrane.* What one does find there are solid bundles of fibers which emanate from the wall of the alveolar cavity, go convergently to insert themselves into the surface of the dental root, thus forming a sort of circular ligament. They penetrate deeply in the form of fibers of Sharpey into the bone of the maxilla as well as into the cementum, similar to what takes place in the solid tendinous insertions (in other parts of the body). Some of the bundles, the most superficial ones, those which spring from the alveolar margin, gen-

erally speaking have their maxillary attachment higher or more superficial than the dental-root attachment, in such a way that the tooth finds itself suspended by these bundles on the inside of the alveolar cavity. Mastication, therefore, cannot produce painful compression—as it would if it were a "periosteum"—but simple traction, as is true of all ligaments. What is more, there exists between these tendinous bundles large spaces filled with a loose cellular tissue or medullary tissue communicating with other neighboring medullary spaces, and it is in these spaces that are found the voluminous blood-vessels and the numerous nerves of that region.

From a study of comparative anatomy(2), he says we learn that—"In many animals the teeth are not inclosed in alveolar sockets. They are simply found contained in the gingival mucosa, but they are also fastened to the maxilla by solid ligamentous bundles, which are analogous to our so-called 'alveolo-dental periosteum.'" Malassez quotes Ranvier and other observers as siding with him, and all his statements are backed up by drawings from microscopic specimens that are sufficiently clear for anyone to draw his own conclusions from.

Personally, I cannot help but side with Malassez and the other authorities whom he cites.

The alveolar process is not therefore a bone distinct from the maxilla, but is *part* of the maxilla. The socket is nothing more than an enlarged medullary space of the maxilla, and instead of being lined by a supposedly thin plate of compact bony substances as Talbot(3) would have us believe, it is simply made up of the thinned-out edges of the maxillary bones and their trabeculæ or bony offshoots, as seen on microscopic specimens. Also, instead of an elastic "peridental membrane," which is supposed to act as a cushion for the teeth, we really have an alveolo-dental ligament—a circular ligament—which keeps the tooth suspended in the alveolar cavity.

From the above short sketch of the anatomy of these parts it is very easy to understand the morbid changes that take place in this disease. According to Znamensky(4), whose microscopic studies of the pathological specimens are considered the best, the disease begins with an inflammatory process of the gum margin at the gingival space; it destroys the epithelial tissue and gradually involves the bones, which latter become necrotic. New bone formation (osteoid tissue) takes place and results in a partial involucrum (a partial encapsulation). It is the involvement of the bony socket which is considered by almost all the observers to be the characteristic feature of the disease.

Now, since the chief characteristic feature is the involvement of the alveolar bone and the tooth socket, the latter being nothing more than an enlarged medullary space of the maxillary bones, the only term it seems to me that we can properly apply to such a disease is CHRONIC ALVEOLAR OSTEOMYELITIS. This term, as you can see, is truly descriptive of the disease; it immediately suggests to one its morbid anatomy, its causes and the modes of its progressiveness, and, above all, its proper treatment, while the other terms—Riggs' disease, pyorrhea, or periodontal disease—do not describe the affection and are therefore misleading.

Having made the normal and morbid anatomy of these parts clear, the etiological factors of chronic alveolar osteomyelitis become apparent. They are local and general.

The local causes are (1) mechanical and (2) infectious.

The mechanical are by far the more important ones in starting the disease, but less so in keeping it up. It is the local infectious causes, on the other hand, that are the more important in keeping up the disease.

The local mechanical causes are the same that are responsible for ordinary gingivitis, and the most frequent of them are calculi or tartar deposits. Tartar as a cause of alveolar osteomyelitis was recognized by Ambroise Paré(5) (1550) and other early writers centuries ago. It has been recently emphasized by Fletcher(6), at the last meeting of the American Medical Association. In a previous communication(7) I called attention to the necessity for an albuminous or organic nucleus for the formation of calculi. The organic nucleus may be some food remains on the gingival space together with some epithelial cells and bacteria. The organic matter, if allowed to remain any length of time, will ferment. The products of the fermentation will cause the precipitation of salts from the saliva or other secretion and form a calculus in the same way as calculi form in other parts of the body.*

The local infectious causes comprise the bacteria, principally those capable of pus production. The important ones are the pneumococcus in chain or diplo forms, staphylococcus aureus, streptococcus, and M. catarrhalis. These organisms are recognized today as the infectious agents, affecting the tissues either spontaneously—due to disuse and the consequent improper blood supply—or following a mechanical injury. They are always responsible for keeping up the disease. (A careful review of this phase of the subject as found in the literature as well as my own findings will be described later.)

The careless use of infected instruments as a possible cause of alveolar osteomyelitis should be emphasized here. The same instrument used in scaling or cleaning an affected tooth, if used without being re-sterilized in treating other unaffected teeth in the same patient at the same sitting, might spread the disease to the healthy teeth.†

The general or systemic causes are more in the nature of predisposing causes—lowered resistance—as a rule, rather than exciting causes. It is conceivable that acute infectious diseases—pneumonia or typhoid fever—will render the general resistance of the patient to various organisms so low that a beginning of an alveolar osteomyelitis would follow, especially so if the cleanliness of the mouth be neglected, and if there be present some local irritant, rough edges of cavities, calculi, or artificial bridge work. As a general rule, however, the systemic disturbances met with during this disease, in my opinion, follow the local trouble, and in turn are responsible for keeping it up. The systemic importance of this disease, or rather its consequences, I will take up later.

* In the gall-bladder typhoid bacilli act as an organic nucleus. Living typhoid bacilli have been found in the center of gall-stones, and experimentally it was found that if typhoid bacilli were injected into the gall-bladder of healthy rabbits they would produce gall-stones. The necessity for an organic nucleus in the production of calculi is thus established.

† One of the best methods for sterilizing instruments during the progress of an operation is to dip them in a jar of alcohol and then burn off the alcohol. This can readily be done by bringing the alcohol-saturated instruments in contact with the flame of an alcohol lamp.

Brief Review of the Literature.

I shall limit myself to the discussion of that part of the literature which deals only with the relation of bacteria to this disease. The important bacteriological investigators on this subject are Galippe(8), who isolated two organisms from pyorrheal pus, one of which he described as a double bubble. He succeeded in causing suppuration by inoculating this organism under the skin and in the joints of guinea-pigs and rabbits. His attempts to produce pyorrhea by inoculations in the gums of rabbits were not conclusive.

W. D. Miller(9) isolated twenty different organisms from twelve cases of human pyorrhea. Among them he found staphylococcus aureus twice, staphylococcus albus once, and streptococcus once. The other sixteen were not identified by him. He therefore concludes that "Pyorrhea is not caused by a specific bacterium which occurs in every case, but various bacteria may participate in it." His attempts to produce pyorrhea in healthy dogs artificially were unsuccessful. He did succeed, however, in producing inflammation, and in one case a little suppuration, but inside of a week the lesions were completely healed. He recommends experiments to be carried out on old, emaciated, or sick dogs.

Personally I have tried the artificial

production of alveolar osteomyelitis in two dogs. The cultures used for the inoculations were those isolated from two patients. One was a streptococcus and the other a pneumococcus in chains. The only results I obtained from the gum inoculations was an acute inflammation which subsided within a week. I repeated the inoculation three times, with similar results each time, *i.e.* the gums were healed up at the end of one week.

I believe the negative results to be due (1) to the natural resistance of the dogs, both of them being in a very healthy condition, and (2) to the lack of sufficient injury done to the alveolar process at the time of inoculation—sufficient to produce an osteomyelitis. I must confess that I was not aware at the time I made the experiments that pyorrhea so called is in reality a chronic alveolar osteomyelitis. The negative results of the other investigators cited are probably due to the same reasons. In my future experiments I shall know better.

Kirk's (10) finding of a pure culture of diplococcus pneumoniæ in a few cases of freshly opened pericemental abscesses is of importance because of the minimal chances of contamination under such circumstances. Black (1), Von Arkövy (12), and others found bacteria in pyorrheal pus, but they failed to identify or properly describe them.

Simms (13) records the following bacteria in 10 cases of pyorrhea which he identified: Staphylococcus aureus 2, staphylococcus albus 1, streptococcus pyogenes longus 1, M. catarrhalis (?) 10; streptococcus brevis, spirilla, and fusiform bacilli occurred in every case.

All the investigators thus far cited approached the bacteriological study of the diseases merely from the standpoint of establishing the etiological relation of bacteria to pyorrhea. Goadby (14) (1905) was the first to study the relation of bacteria to pyorrhea both from the standpoint of etiology and that of treatment, making use of Wright's bacterial vaccines in this disease. According to Goadby (15) the streptococcus pyogenes, M. catarrhalis, and staphylococcus aureus and albus are the most frequent organisms met with in this disease. Apparently he left out of consideration the possibility of pneumococcus occurring in chain forms, and considered all the organisms occurring in chains as streptococci.

The confusing of the streptococcus with the pneumococcus in chains is met with in the literature and in a great number of text-books, to which I have already called attention in a previous communication (7). It has also been called attention to by Ricketts (16) and others.

In a recent article Goadby (17) reports 70 cases of early pyorrhea treated by vaccines; 45 of these he reports as cured, 13 relieved, 11 disappeared, and 1 died from an intercurrent disease. He therefore concludes that "The prognosis of early cases is 60 per cent. of cures, while without the vaccine treatment the majority will progress not only to the loss of the teeth, but to diseases of divers natures which have been shown to be associated with pyorrhea."

Jones and Humphreys (18) reported 5 cases treated by autogenous vaccines with good results. The organisms found by them in all of the cases they described as streptococcus, occurring often as a diplococcus in short chains or chains of diplococci. The organisms described by these authors correspond exactly to the one I found in most of my cases, but which I designated as pneumococcus in chains.

Eyre and Payne (19) (1909) reported the bacteriological findings in 33 cases of pyorrhea as follows: Staphylococcus aureus 2 cases, M. catarrhalis 9 cases, M. catarrhalis and streptococcus pyogenes longus 11, streptococcus pyogenes longus 7, streptococcus lanceolatus pneumoniæ 4. They treated with vaccine 26 of the above 33 cases, with the following results: 21 cured and remained cured from nine to fifteen months, 4 improved, and 1 died. All these were advanced cases of the worst type. They were all followed up with vaccine treatment as well as local and general treatment.

Beebe (20) reported 17 cases of pyorrhea treated with good results by vaccines: 6 of them showed a pure growth of pneumococcus both in chains and diplo forms, while the other 11 showed the same pneumococcus mixed with staphylococcus aureus.

The foregoing brief review of the literature indicates that observers in all parts of the world who have had any experience at all in the treatment of this disease by means of vaccine are unanimous as to the good results obtained with this method of treatment. It is to be remembered that the observers, be they bacteriologists or medical men, have always handled their cases together with the dental surgeons, and their reports are the conclusions reached by both the medical man and the dentist.

Personal Work.

The study of the 115 cases of "chronic alveolar osteomyelitis" or pyorrhea alveolaris, which makes up the subject-matter of this communication will best be described under three groups, divided according to their clinical appearance and chronicity into—I: *Incipient.* II: *Moderately Advanced.* III: *Far Advanced.* Before taking these groups up under their separate headings, it will be best to describe the method of procedure in handling the patients as a whole, the method of obtaining the cultures, and also in a general way the findings, treatment, and results.

METHOD OF PROCEDURE.

Each patient was given a thorough physical examination when he first applied for treatment, also a careful urine analysis and examination of feces, both chemical and bacteriological. Specimens of blood were obtained for the opsonic index. The blood was also tested by Talquist Hem. scale and smears of blood stained and examined microscopically. No further examination of the blood was made when the above were found negative. Cultures from the gums, nose, and throat were obtained, both for bacteriological examination and the preparation of vaccines.

Technique. Cultures from the gums were obtained in the following manner: The lips or buccal parts were kept away from the affected tooth by means of a sterile tongue-depressor by the patient or an assistant. The gums around the affected tooth were carefully wiped off with sterile cotton. The pus was then squeezed out by means of a sterile swab. This pus in turn was collected with a fresh swab and labeled No. 1. Further pressure would cause a second and third drop to ooze out, which were collected on a second and third swab respectively. The first drop of pus was smeared upon cover-slips for the direct microscopic examination, while the second and third drops of pus were used for cultural purposes. In cases where there was no visible pus present (incipient and some moderately advanced cases), the gums that showed the most sponginess, inflammation, or recession were used. A sterile, heavy platinum wire was used to obtain material for cultural purposes, alongside of the swabs, from the gingival space or from a pocket if any were present. Several culture tubes were inoculated at the same time and results compared. In a word, all efforts were made in each individual case to obtain cultures from the pus or affected places, as free from contaminating material or contaminating organisms as is possible under the strictest bacteriological methods.

Culture media used were glucose agar made of fresh meat, beef blood serum, plain and glucose bouillon, and Schottmüller's blood agar (prepared by mixing 2 cc. of fresh human blood obtained from a vein and 5 cc. plain agar). This latter medium was used for plating purposes in order to establish the hemolytic property of a streptococcus when found. The glucose agar was found to be the best medium for the growing of the bacteria for the preparation of autogenous vaccines.

BACTERIOLOGICAL FINDINGS.

(a) *Direct microscopic examination of smears.* The smears of pus were stained by my methylene-blue stain([21]), also by Gram's method, and at times Wright's modification of Leishman's blood stain. As the microscopic findings of the smears were practically the same in all cases, one description of the bacteria found will be given here which will be applicable to all.

The direct smears of pus when stained and examined microscopically showed, aside from a great many pus cells, a variety of bacteria, both bacilli and cocci, as well as spirochetes of all sizes and shapes. A few red blood corpuscles were also found, especially if bleeding occurred in collecting the pus.

The bacilli were very numerous, but rarely those identified as pathogens. They also rarely grew upon the artificial culture media known. A great many of the cocci, on the other hand, were those found associated with pus or disease production in other parts of the body, and grew readily on artificial culture media. Aside from a number of micrococci, varying in size and arrangement, which could not be identified, there were almost always present large masses of groups of staphylococci, diplococci resembling pneumococci, tetrads, a rare chain of diplococci, and at times a few short chains of streptococci. Masses of biscuit-shaped diplococci resembling M. catarrhalis were also met with at times.

Gram's stain helped to identify the various organisms; the bacilli only rarely stained by Gram, and a great many of the cocci were also found Gram negative, while the chains of diplococci (pneumococci) and the streptococci were almost always found Gram positive.

(b) *Cultural findings.* During the early part of the work it was at once apparent, both from the opsonic index and cultural findings as well as from results obtained by the administration of autogenous vaccine, that the bacteria to reckon with in this disease belong to the coccal group rather than the bacillary types. Among the cocci found, those that are known to be responsible for the production of pus in other parts of the body are the ones, and the only ones, that are of any importance in this infection. Specifically, they are pneumococci in chains or diplo forms, staphylococci, streptococci, and M. catarrhalis—either alone or in combinations. The most frequent of these, and the one that appeared in practically all the cultures—107 times out of 112—was the pneumococcus in chains, or the so-called "streptococcus lanceolatus pneumoniæ." The others were less frequent, and occurred rather in combination with this organism than alone. Thus in the whole series of cases I found—

	Times.
Pneumo. (strepto. lanceolatus pneumoniæ)	26
Pneumo. and staphylo.	67
" " strepto.	3
" staphylo., and strepto.	10
" and M. catarrhalis	1
Staphylo. " " "	2
" aureus	2
Strepto. and staphylo.	1
Sterile	3

These findings recall to one's mind the findings of Galippe (double bubble) and Kirk's findings of a pure culture of pneumococcus in freshly opened abscesses. Goadby, Humphreys, Jones, and other observers, as I have already pointed out, have apparently confused the streptococcus lanceolatus pneumoniæ, or pneumococcus in chain forms, with the true streptococcus.

Chronic alveolar osteomyelitis is therefore not due to a specific micro-organism present in all cases, in the same way as tuberculosis is always caused by the tubercle bacillus, but is due, according to my own findings and those of other investigators, to a mixed infection of different bacteria, and may vary according to the pathogenic organisms most prevalent in the oral cavity in the particular locality or part of the world.

OPSONIC INDEX AND IDENTIFICATION OF THE RESPONSIBLE MICRO-ORGANISMS.

A. E. Wright's discovery of the opsonic index and his development of bacterial vaccines for purposes of treatment gave us two new methods by means of which we could determine the causal relation of a given bacterium to a given disease.

In the beginning of this work I made it a point to test the opsonic index to as many stock or laboratory pathogenic bacteria as were found expedient, and in some cases also to the bacteria isolated from the patient's own pus. This, together with clinical results obtained from the use of autogenous vaccines, was the method by means of which the identification of the responsible organism and its relation to the disease was established. A detailed description of the opsonic method of treatment, also the technique as modified by myself, will be found in a previous publication (22).

In this series a number of cases were also followed up in the beginning with the opsonic index as a guide to treatment. Later, however, after a great deal of experience with this method of treatment, the clinical reaction of the patient at the point of the injection and the amelioration of the disease were considered sufficient guides to establish the causal relation of the organism found to the alveolar infection, without having to resort to the opsonic index.

FECES EXAMINATION.

The examination of the feces was (1) bacteriological, and (2) chemical.*

Technique. The bacteriological examination of the stool consisted of direct smear examination, stained by methylene blue and by Gram's method. Cultures were made upon glucose agar (stab and surface cultures), beef blood serum, and sterile milk. The milk media were used to detect the presence of the bacillus aerogenus capsulatus. The cultures were made use of for the purpose of determining the presence in the stool of the same organism that was found in the pus of the alveolar sockets, also for the preparation of vaccines to be used in combination with the gum vaccine in those cases that were suffering from intestinal disturbances.

The chemical analysis revealed the presence of excessive amounts of undigested meat remains, starch remains, or excess of fat. Also, by means of the Strassburger fermentation tube it was possible to detect whether the particular intestinal fermentation of which the patient complained was a carbohydrate fermentation or a meat putrefaction. This chemical examination was found of the utmost value in deciding upon the proper diet in the individual case.

TREATMENT.

All the cases were treated by (1) immuno-therapy or vaccine therapy; (2) general systemic treatment, and (3) local treatment by the dentist.

(1) *Immuno- or vaccine therapy.* I call this method of treatment immunotherapy because it consists of an active immunization of the patient against the bacterium with which he is infected. This treatment is carried out by means of bacterial vaccines, and is also known as the opsonic treatment. The bacteriological and opsonic investigations seemed to indicate that this disease was due to a bacterial infection plus a low resisting power to the particular bacterium. The treatment, then, according to these findings, would be along the lines of raising the resistance of the patient to the infecting agent, which could be accomplished by means of bacterial vaccines and attention to the general condition.

The technique for obtaining cultures for making the vaccine is the same as that described for the bacteriological examination. The vaccine, which consists of killed bacterial cultures, was prepared and standardized according to Wright's method as described in detail in the communication already referred to (22).

All the cases had autogenous vaccines made up which were used in combination with the corresponding stock vaccines, *i.e.* vaccines made of the same bacteria obtained from other similar cases. The combination of stock with autogenous vaccine was found to be more efficacious

---

* In order to obtain the specimen the patient was directed to sterilize a wide-mouthed jar ("lightning" or any other preserve jar) by boiling it for half an hour. The boiled empty jar was covered up while still hot and kept covered until used. The movement was passed directly into it. This gave a sterile specimen which could be used for bacteriological as well as chemical purposes.

than either alone. (The combined vaccines were used in one injection.) The dose varied from 50 to 100 million of pneumo. vaccine and from 50 to 300 million of staphylo. aureus vaccine, except where the latter was used at the same time for a staphylo. skin infection (acne, furunculosis), when its dose was increased. The dose of the strepto. vaccine varied from 15 to 75 million. The interval varied from five days in the beginning to eight and fourteen days or longer later, according to the local amelioration of the condition. The vaccines were injected in the upper arm, deep-subcutaneously or intra-muscularly. A marked local reaction was met with only rarely; a general reaction was never present.

(2) *Systemic treatment.* Systemic treatment was principally attention to diet, the developing of a water-drinking habit (two quarts daily), proper personal hygiene, and attention to proper elimination. Tonics were found to be needed only rarely. Emphasis was put chiefly upon the diet and personal hygiene, and the results, in my opinion, justified the procedure.

The gastro-intestinal symptoms as a rule yielded to the appropriate diet, while the intestinal flatulence and fermentation responded best by addition to the diet of lactic acid milk prepared at home with the bacillus acidi lactici — Medalia([23]). Any other pure culture of a good lactic acid bacillus may be used.

(3) *Local treatment.* The local treatment was left entirely in the hands of the dentist, who removed calculi and necrotic bone when present, kept the teeth free from tartar, established free drainage of the pockets, and instructed the patient in the home care of the teeth. He found it necessary to delay local treatment in many cases where the teeth were too loose and the gums too tender for instrumentation. Such patients were first followed up by vaccine treatment until the teeth were rendered tighter and the gums less inflamed and less tender. These cases helped to establish the value of the vaccine treatment independent of local treatment.

I wish to say here that local surgical treatment by the dentist is absolutely necessary in conjunction with vaccine treatment for the final successful outcome of the case. It is not to be expected of vaccine treatment to supplant, but rather to supplement, surgical treatment. Similarly we cannot expect local treatment alone to do it all, because, as long as the resistance of the blood of the patient remains low to that particular infecting agent, just so long will the disease persist.

In connection with local treatment it may be of interest to quote from a letter of Dr. H. S. Draper (dentist) of Boston. He says in part:

> A number of years ago it seemed to me that "pyorrhea" was only a symptom of a constitutional disorder, and that local treatment alone would be of no avail, or only palliative. Consequently I have not urged local treatment unless the patient would also try systemic remedies, which most patients did not seem inclined to do. I attached so little faith to the purely local treatment that I told patients so, and sent them to specialists in local treatment who did have faith in it. The cases usually resulted in a return to me to have artificial substitutes for the teeth, which they finally lost, or in being turned over by the local-treatment specialist to someone who practiced vaccine therapy. The only cases which I feel I have helped by local treatment were cases where the teeth had been neglected and tartar allowed to accumulate—the inflammatory condition disappearing after thorough scaling and treatment. In the worst cases there oftentimes is no deposit present, and in these cases I have no faith in treatment locally only.

The above is the opinion on local treatment alone as expressed by a man for whose observation and conservative judgment I have a great deal of respect.

Besides the local treatment, mild antiseptics were also advised, most of them for purposes of calling attention to the cleaning of the teeth and tartar deposits. A favorite prescription was the following:

℞—Liquor iod. comp. (U.S.P.).
Glycerin, āā ℥ss.
Aquæ destil., ad ℥ij.

Sig.—Apply on gums each morning or at bedtime, with a cotton pellet wound round a toothpick, or with a camel's-hair brush.

This iodin preparation was advised to be applied at the junction of tooth and gum. The patient was told it would not stain the enamel, but would stain any foreign matter or tartar. Hence, as soon as there was much staining the patient knew that he had to go to his dentist to have it removed. This worked well for the purpose of attracting attention to the teeth and gums. Its antiseptic property is of course very mild, especially under the circumstances, where it is washed off by the saliva as soon as applied.

Results.

The results of the treatment have been classified as "cured," "improved," and "no improvement." It might be well to state here what I mean by the term "cured." I considered a case cured when the local condition of the gums became healthy as to color and firmness, when no pus could be squeezed out of the sockets, when loose teeth had tightened up, and when no inflammatory condition was found; also when symptoms such as bad metallic taste in the mouth, soreness and bleeding of gums, and tenderness during mastication disappeared. The recession, of course, that took place before treatment was begun could not be mended by this or any other treatment; further recession, however, was checked. Finally, when any systemic symptoms present, such as rheumatism, gastro-intestinal disturbances, and neuralgic pains, also disappeared or were relieved, and the patient considered himself as feeling "quite well." When these changes for the better in the patient's condition lasted for several months without a recurrence, I thought I had a right to consider such a case as cured.

We will now discuss the cases under their respective groupings:

Group I: *Incipient Stage* (14 *cases*).

Description. The cases grouped under this heading are those where the disease was in its incipience. The gums and teeth taken as a whole appeared in fair condition, but here and there the gum margin of individual teeth showed signs of inflammation. There was congestion and swelling, distinct discoloration, or slight recession of gum margin. The gums around the affected teeth were found to have lost their elasticity. In some cases the congestion was so marked that bleeding occurred at the slightest touch. Visible pus was rarely present, but smears made from these affected parts showed microscopically the presence of pus corpuscles, also dead epithelial débris and a large number of bacteria.

The teeth in these cases were not found loose, but the necks of the affected teeth were always found uncleanly, surrounded by food débris and tartar deposits. Some of the patients complained of a local discomfort and a dull ache on mastication, while others were not aware that there was anything wrong with their teeth and gums, except perhaps for some bleeding caused by the use of the brush.

Bacteriological findings. The direct smear findings already described are applicable to this as well as to the other groups. The cultural findings of this group are as follows:

Pneumo. and staphylo.	10 cases.
"	2 "
Staphylo. and strepto.	1 case.
Sterile	1 "

The predominating organism culturally was the pneumococcus in chains; the staphylococci were as a rule less abundant.

The *opsonic index* was tested in 3 cases; they were all below normal to pneumo.; 2 were found normal to staphylo., and 2 below normal to colon. One of them was normal to strepto. and colon.

Treatment. The average number of treatments was six—the maximum being eleven and the minimum two, at an interval of from once a week to once in two weeks or less often.

The average duration of treatment was six and one-half weeks, with a maximum of twelve weeks and a minimum of three weeks.

Results. Of 14 cases 13 were cured, while the remaining 1 was greatly benefited. Even in the fourteenth case, where improvement was noted only at the time she discontinued treatment, the gums were still in good condition when she was last seen—about a year later. The progress of the disease was apparently checked.

The permanence of the cure can only be judged from the length of time that the cured cases remained cured. Two remained cured for from twenty-four to twenty-seven months; three from twenty to twenty-three months; five from ten to fifteen months; and three from three to seven months.

Systemic disorders. In this group of 14 cases, 4 suffered from rheumatism and gastro-intestinal disturbances, 1 had rheumatism and asthma, 2 had acne and intestinal fermentation, 1 chronic catarrh and chronic bronchitis, 1 secondary anemia (menorrhagia, low coagulability of the blood), 1 had severe headaches (neuralgias?), 1 had empyema of the antrum and facial eczema, and 3 had gastro-intestinal disorders. Almost all of them complained of a lack of energy and general debility. They were all cured or relieved of the systemic symptoms while under treatment for their local conditions. Nor is this my experience alone; other observers have reported similar results (Eyre and Payne, Goadby, Lewin Payne).

Urinalysis. The urine analysis showed in 9 of the 14 cases an increased amount of indican, probably due to the intestinal fermentation. In none of these cases was there any albumin or sugar. The reaction was found neutral in 3 cases and acid in 11. The acidity was not markedly abnormal, and the only thing that attracts attention in the urinalysis is the indicanuria.

Feces examination. The bacteriological findings of the feces in this group was colon (B. coli) in 9 cases; B. coli and diplo. (pneumo.) in 3 cases; no record in 2 cases. We might infer that the diplo. (pneumo.) found in the stool were swallowed with the pus from the gums, escaped the injurious effects of the gastric juice, and finally landed in the intestines.

The chemical examinations were made in 9 of the 14 cases; 6 showed undigested meat remains; 2 of these 6 had in addition undigested starch remains. The remaining 3 of the 9 cases had an excess of undigested starch remains.

Carbohydrate fermentation was present in 3 cases, meat fermentation or putrefaction in 4 cases, while 2 others had a combination of meat and carbohydrate fermentation. These cases showed a tendency to an improper digestion of meat foods rather than of starchy foods, in the proportion of 6 to 3. The old idea of eliminating meat in this disease, which was found empirically to be of value, is here corroborated by actual analysis.

GROUP II: *Moderately Advanced Stage* (16 *cases*).

Description. The cases under this heading are those in which the disease was much farther advanced than in the previous group. The gums on the whole were found congested and inflamed at the margins. Around most of the teeth they were either spongy (hypertrophied) or showed marked recession (atrophied). Bleeding was producible in all cases by the slightest touch. Visible pus was present in all cases, and it could easily be squeezed out by pressure over the affected part. The number of teeth affected in this group ranged from one to several, but the looseness was not very marked, and only in a few of the teeth. All the patients in this group complained of local discomfort and tenderness and difficulty in chewing. All of them were definitely aware that they had gum trouble which they wanted to have treated.

Bacteriological findings. The direct smear findings have already been described. Cultural findings are—

Pneumo. and staphylo.	8 cases.
"	6 "
Staphylo.	1 case.
Sterile	1 "

In this group, as in the preceding, the predominating organism found culturally was the pneumo. in chains. The number of cases that showed a pure growth of pneumo. was greater than in the incipient cases. No definite explanation could be given for the case that was found sterile culturally.

Opsonic findings. Of the 16 cases, 9 were tested opsonically; 7 were found below normal to pneumo. and one above normal. Of these 8 with an abnormal opsonic index to pneumo., 4 were also low to staphylo., 1 to strepto., and 3 to B. coli, while they were normal to the other pathogenic organisms tested. Of the 9 cases tested, 1 was normal to

TABLE I.—

No.	Initials.	Sex and age.	Date.	Teeth affected.	Treatments.	Duration of treatments.
1	C. O. B.	F. 48	7-22-11	Left lateral incisors.	2	1 month.

Pneumo. in chains. Few staphylo.					Cured. 2 years.	Muscular rheumatism. Intestinal flatulence.
Pneumo.	.59	.73	.85	.62	Cured. 3 years.	Intestinal flatulence.
Sterile.	.66	.82		.83	Cured. 19 months.	Gastritis + rheumatism.
Pneumo. + yeast fungi. Many long thin bacilli.					Cured. 14 months.	Chronic furunculosis. Intestinal flatulence.
Pneumo.	.75	.83			Cured. 20 months.	
Pneumo. + staphylo.					Cured. 1 year.	Marked intestinal fermentation.
Pure staphylo.	1.18	.67	.73	1.16	Cured. 2 years.	Intestinal fermentation. Chronic furunculosis.
Pneumo. + staphylo.	.68	.75	1.13	.68	Cured. 2 years.	Chronic sore throat.
Pneumo. + macrococci.	.52	.88	.96		Cured. 23 months.	Rheumatism. Indigestion.
Pneumo. + staphylo.					Cured. 8 months.	Intestinal flatulence.
Pneumo.	1.30	1.04			Improved.	Asthma. Intestinal flatulence.

these charts refers to staphylococcus aureus.

this case (No. 26, J.M.) was very low (0.67), slightly low to strepto. (0.73), and normal to colon (1.16).

Treatment. The average number of in the beginning, to two weeks or longer later, according to the amelioration of the condition. The average duration of treatment was three and one-half months

—with a maximum of seven months and a minimum of two weeks.

Results. Of the 16 cases, 15 were cured and one was benefited. This last patient discontinued treatment at the end of five weeks, after he had received four treatments. The teeth stopped troubling him, and he thought that he had done his share toward them.

Of the cured cases, 2 remained cured for from thirty to thirty-six months, 7 from twenty to twenty-three months, 4 from fourteen to nineteen months, and 2 from eight to twelve months. The process, apparently, even in these cases did not as yet reach to necrosis of bone, at least not to any extensive necrosis. Of course this is merely a supposition, as no pathological specimens could have been examined, for obvious reasons.

Systemic disorders. Of the 16 cases in this group, 2 suffered from rheumatism, 4 from rheumatism and gastro-intestinal disturbances, 3 had gastro-intestinal disorders, 1 had asthma and intestinal flatulence, 2 had chronic furunculosis and intestinal fermentation, 1 chronic sore throat, and 1 a nervous break-down (psychasthenia); 2 had no general symptoms.

The rheumatic disturbances were muscular as well as joint affections. The pain in these cases yielded promptly to the vaccine treatment, while the ultimate good results may also be ascribed to the overcoming of the local affection.

Urinalysis. The urine was examined in 13 of the 16 cases. In none was there found any albumin or sugar. The reaction was found acid in all, and the indican abnormally high in 4. Here, too, the presence of indicanuria is the only thing to be commented upon.

Feces examination. The stool was examined bacteriologically in 12 of the 16 cases. The cultural findings were: Pure colon in 9 cases, colon and diplo. (pneumo.) in 3 cases. The pneumococci were found in this group in about the same percentage—33 per cent.—as in the preceding group.

The feces were examined chemically in only 5 of the 16 cases, 4 of which showed a great excess of undigested meat remains, while the 5th was found normal in all respects. The fermentation test in these 4 cases was marked by a violent gas fermentation, acid change, and a typical picture of carbohydrate fermentation. No deductions, of course, can be made from the small number examined.

(To be continued.)

EXPERIMENTS SHOWING THE EXCRETION OF MEDICINAL SUBSTANCES THROUGH THE SALIVARY GLANDS.

By PERCY R. HOWE, D.M.D., Boston, Mass.

IT is a matter of great interest and importance for those making a study of the oral secretions to note that many medicinal substances, when taken internally, are secreted through the salivary glands. These same substances are, as is well known, eliminated through other secretions of the body, but it is their appearance in the mouth that immediately concerns us.

The study of this topic discloses the fact that the majority of these remedial agents give to tests capable of identifying them a positive result in about twenty minutes after administration. This I believe to be much sooner than many are aware of, and shows that such remedies do not follow the metabolic processes involved in the from-food-to-tissue changes, but that they are early absorbed and carried on to the eliminating organs and surfaces. In this connection it is well to mention that some of these foreign bodies have been found in the tears and in the perspiration, while urinary analysis shows the presence of the greater part, if not all of them.

Another point brought out by these investigations is that it is a matter of several hours before they are so completely eliminated as not to be chemically detected; for after nine hours, when the tests were discontinued, their determination was as distinct as at the commencement of the experiment. The following morning, however, tests gave negative results.

Such a number of these preparations, when taken internally, give a positive reaction to tests for their presence in the saliva, that we may reasonably infer it to be generally true of the class.

We have, then, a means of bringing into intimate relation with oral conditions demanding them substances that have antiseptic, oxidation, reduction, and many other properties. Their effect is a constant one extending over a period of hours, in contradistinction to the transitory effects of the usual methods. Here, too, is additional information respecting the deleterious action of certain compounds upon the teeth, notably iron preparations, for as I will show farther on, ferric chlorid is no exception to the principle spoken of.

One other important thing for consideration advanced by these experiments is that the glandular system of the mouth becomes at times an eliminating organ. To this I have previously called attention in an article in the DENTAL COSMOS for May 1912, entitled "The Accelerating and Inhibiting Agents in the Oral Secretions." So that we may go a step farther, and conclude that substances foreign to the system are so eliminated, whether introduced into the system or produced within it by nutritional disturbance, by bacterial proliferation, or by other systemic derangements. In support of this idea the case reported by Dr. Combe in his work on Auto-intoxication is given, showing that a child during crises of intestinal fermentations eliminated several liters of saliva daily. I myself have found indican present in the saliva in acute cases of this trouble, and accompanying large amounts of sulfoethers in the urine.

The importance of this lies in the fact that the salivary secretions become abnormal under various systemic derangements, and either contain products which are directly injurious to tooth or to tissue, or which so modify the saliva that it loses its natural protective quality and thus engenders the very requirements best suited for bacterial growth.

The method of procedure together with some of the analyses adapted to the work will be described, in order to show the accuracy of the findings.

The medicaments were taken in gelatin capsules, the saliva being at once tested, when it should give a negative result; then, drawn directly from the glands by the apparatus described in the DENTAL COSMOS for April 1912, it was tested at five-minute intervals for the appearance of the substance. It developed that saliva allowed to run directly into a beaker answered all the requirements for this analytical work.

It is a well-known fact that halogens have a decided antiseptic action, and the following, together with a general and sensitive test, are reported: Iodin tincture, five drops with milk; iodids of sodium, potassium, mercury, hydriodic acid taken in sealed capsules, gave a positive test in about twenty minutes, and at the expiration of nine hours were still present in the saliva.

Test: To a small amount of saliva (one-half cc.) add directly one or two drops of nitrosyl-sulfate solution (preparation described in Mulliken's work on Carbohydrates) and shake with one-half cc. carbon disulfid. Deep amethyst purple indicates the presence of iodin.

The bromids of sodium and of potassium administered gave a positive reaction in the same time and were present over a similar period.

Test: Add to saliva freshly drawn 0.05 to 0.1 gm. potassium dichromate (free from chlorid) and 1 cc. dilute sulfuric acid; boil in a large test tube and place over the mouth a piece of fluoresceïn paper. A pink color means the formation of eosin and the presence of bromin.

It seems, therefore, that these are typical of the class, and it is safe to conclude that all iodids and bromids are excreted through the salivary glands.

The chlorids, being natural constituents of the saliva, require a volumetric estimation, the process for which I have described in the DENTAL COSMOS for April 1912. I do not, however, propose to enter upon the discussion of the chlorids here. Ammonium chlorid, being a medicinal agent, was taken internally and tested for in the saliva with Nessler's reagent, and gave a fair indication of its presence.

Tests were tried following the administration of other antiseptics in use in general medicine, such as sodium salicylate, sodium benzoate, guaiacol cinnamate, benzoic acid and salicylic acid, menthol, oil of peppermint, etc. Menthol, guaiacol, and oil of peppermint gave indication of their presence. The salicylates did not give the characteristic color with ferric chlorid, but compared with a control gave a deep change in color that approached it—in fact, being the nearest in tint according to Mulliken's color tables. These substances would, however, be in such dilution that their effect would amount to nothing, except possibly in the cases of menthol and guaiacol.

These results naturally lead us to test for iron preparations, to find if they act in the same way and hence explain the destructive action that so often accompanies their administration. Here we get a positive reaction which clearly shows that iron appears in the saliva in twenty minutes, as with the halogens, and remains as long. The usual preparations of iron were taken in a capsule with the above-indicated results; hence it is not so much the coming of the medicament into contact with the teeth during the act of swallowing, but the fact that it is soon secreted back into the mouth through the saliva, that accounts for its action. It is secreted as ferric or ferrous chlorid whether taken as such or as carbonate, for the carbonate is converted into the chlorid by the hydrochloric acid of the stomach.

Test: Evaporate 10 cc. of the saliva to dryness and redness, using a porcelain crucible. Dissolve in a little dilute HCl, add five drops of dilute HNO to oxidize any ferrous to ferric chlorid. Add excess of KCNS. One cc. of a saturated solution gives a deep red color and shows presence as ferric sulfocyanate.

For quantitative result, titrate against titanous chlorid until color disappears. Control test gives a slight amber color or none.

That ferric chlorid is very destructive of tooth structure is to be seen by placing tooth sections in a solution of it. This has been long known, and the experiments of Dr. Weld have been often quoted to show that this is so in great dilutions.

It has been shown repeatedly that KCNS appears in the saliva when given internally. Its time of appearance is twenty minutes and its duration as with the halogens. This substance has been administered on the supposition that it is a natural constituent of the saliva, but in this respect it acts as do the foreign bodies. I find that it slightly augments lactic bacterial growth. Its attributed effect of dissolving bacterial plaques is the common property of any neutral salt, as may be learned from any physiology. The iodids have a real inhibitory effect on lactic cultures, as I have demonstrated in my laboratory.

The points brought out, then, are—First, that foreign substances given medicinally appear in one form or another in the saliva; second, that those capable of passing through the system in their original form appear within twenty minutes; third, that they are secreted over a period of nine hours but are absent the following morning; fourth, here is the explanation of the injurious effect of iron upon the teeth during its administration; fifth, that the salivary apparatus becomes an eliminating organ; sixth, that we may reasonably conclude that deleterious substances of bacterial origin, of nutritional error, or of other systemic derangement are so eliminated; and last, that a specific compound of intestinal fermentation has been determined to be present in the saliva during acute cases, viz, indican.

These experiments serve to establish principles concerning the nature of salivary secretions and to strengthen the views of those investigators who hold to the opinion that these secretions are a very great factor in all oral disturbance It is true that bacteriologists have not considered that the saliva had much to do with microbic life. The writer has proved, however, by many experiments that salivas that contain much phosphates furnish most excellent media for bacterial growth, while saliva with a high sodium chlorid content and low phosphates is a very poor culture media. Here I speak of lactic cultures. Ammonium chlorid is an augmenting factor according to my experiments. The phosphates and the ammonia evidently supply a nutritional demand on the part of the micro-organisms.

These facts are not given in the expectation of their involving the full explanation of oral bacterial troubles, but as being decided conditions for or against bacterial proliferation.

From my studies, I do not feel as do those investigators who report that the salivary secretions have nothing to do with tooth decay. It may be true that our information on the subject is limited and imperfect, but these very experiments serve to strengthen the opinion that sufficient study of the topic will produce the most practical results yet seen exclusive of mechanics.

AN INQUIRY INTO THE POSSIBLE RELATION OF SULFOCYANATE TO DENTAL CARIES.

By WILLIAM J. GIES, M.S., Ph.D., New York, N. Y.,

WITH THE COLLABORATION OF

MAX KAHN, M.D., Ph.D., New York, N. Y.

(Address before the Dental Society of the State of New York, at its annual meeting, at Albany, May 9, 1912.)

Mr. President, Members of the Society, Ladies and Gentlemen:

It gives me great pleasure to present, informally, today a summary of the results of research that we have been conducting recently under your auspices.*

Scope of Research.

Investigation, as you know, is not the acquisition of predetermined or desired results; it is the search for and establishment of truth, irrespective of preference or prejudice. Sulfocyanate has excited much more debate than research. It was my privilege to suggest to your Research Committee that special attention be given to salivary sulfocyanate, because sulfocyanate, in one phase or another, has occupied a prominent place in your discussions for some years. I felt that we might be of special service if, as biological chemists working under your auspices and having no prejudices regarding possible dental relationships of sulfocyanate, we should review and analyze the available data on this general subject, and then report such additional chemical and physiological facts as might be established by experiment. When I offered my suggestions in response to your committee's invitation, it seemed opportune to correlate and summarize, and if possible to clarify, past findings, and at the same time to go forward so far as time and facilities would permit.

Let me remind you of the program suggested in my original proposal to your committee. In a letter to Dr. Dunning, which was subsequently printed as a part of the committee's report last year,* I called attention to a number of general facts pertaining to sulfocyanate and summarized them under twelve heads. I need not now repeat the details in that connection, but, after briefly indicating generalities of past findings on sulfocyanate, the following suggestion was offered:

> With the foregoing facts in mind, I believe that a thorough investigation of salivary sulfocyanate is now called for under the auspices of your society, because of the past efforts of its committees to solve related problems.

In the same letter I outlined the nature of the experimental work that I felt we could undertake to advantage. The three proposals at the head of the list, which I shall now read, are those toward which we were able to direct our experimental attention:

> (A) Devise *new methods* [or establish the validity of available ones] for the qualitative and quantitative estimation of sulfocyanate in saliva and animal liquids in general —methods which would not be influenced by diacetic acid and other extraneous substances.

* Previous contributions in this series were made by Seaman and Gies, Dental Cosmos, 1910, lii, p. 1141; Gies, *ibid.*, 1911, liii, p. 1324.

* Dunning: Dental Cosmos (Proc. Dental Society of the State of New York, forty-third annual meeting), 1911, liii, p. 1324.

Bunting's recent experiments in this connection should be very carefully and critically duplicated—[because of the fact that the whole matter of sulfocyanate values has been thrown into more or less confusion by his findings, provided they are accurate].

(B) Ascertain in experiments on mammals the full story of the *origin* of sulfocyanate and the reasons for its quantitative *fluctuations* in the saliva, urine, blood, and other parts that may contain it. [It is necessary to establish additional physiological facts regarding the biological occurrence of sulfocyanate.]

(C) Determine the *toxic and pharmacologic effects* of sulfocyanate for the purpose of establishing principles of dosage [provided the therapeutic use of sulfocyanate is indicated].

It seemed that this was the climax toward which we should direct our efforts—to ascertain whether the administration of sulfocyanate for prophylactic purposes might be productive of any harmful effects.

We have followed this general program as closely as possible, with as much detail as possible, with as much thoroughness as possible, and with as much skepticism as possible. We have declined to believe any of our own results until repetitions of the respective experiments offered no other alternative. We have had no desire to prove or disprove anything. We aimed to learn the truth and to establish the facts. We have adhered faithfully to that purpose.

Recently your president requested me to send him copies of a synopsis of our findings for the use of Dr. Low and others who intended to discuss our report. It gave me pleasure to do so. For the convenience of all concerned, I shall now use one of the copies of that synopsis as my guide in discussing the results of our work.

SYNOPSIS OF FINDINGS.

I.

SELECTION OF THE MOST RELIABLE METHOD FOR THE QUANTITATIVE DETERMINATION OF SULFOCYANATE.

(1) We began our research with a purpose to ascertain, if possible, which of the available methods is most reliable for the quantitative determination of sulfocyanate. The classical ferric chlorid process was naturally first in our thoughts in this connection, and Bunting's recent criticism* and proposed modification of the ferric chlorid process was first in our inquiry.

A CRITIQUE OF BUNTING'S PROPOSED MODIFICATION OF THE FERRIC CHLORID TEST.

Bunting's most significant conclusions regarding the method which has been employed by your Research Committees, and by many other previous workers, may be briefly summarized in the following statement: The test is "very delicate," but it may be made "more distinct, if the liquid [containing sulfocyanate and treated with ferric chlorid] is shaken with ether." It is possible, however, that "there may be present in the saliva some substance other than potassium sulfocyanate† which is capable of giving a red color with ferric chlorid; for example, diacetic acid."

Aiming to determine the "reliability of the ferric chlorid test for potassium (!) sulfocyanate"‡ Bunting sought to refine the usual method by carefully desiccating 5 cc. portions of saliva, then stirring "one drop of water and one or two drops of ferric chlorid solution"§ into each dry residue, and treating each *wet* mixture with 5 cc. of ether. Bunting believed that in this particular treatment the resultant ferric sulfocyanate would remain wholly *undissociated,* and that the ether would extract *all* of that colored

---

* Bunting: DENTAL COSMOS, 1910, lii, p. 1346.

† No one has shown that sulfocyanate occurs in saliva as the *potassium* salt.

‡ *Soluble* sulfocyanate is evidently intended in this remark, for there is no such thing as a test for "*potassium* sulfocyanate."

§ *Water was returned* in this way, of course. In his concluding statement Bunting recommends the addition of "*one or two* drops of water and *one or two* drops of ferric chlorid solution. The disturbing influence of this water did not appear to impress Bunting.

substance from the moistened residue. He did not recognize the fact, however, that his addition of "a drop of water" and of the water in "one or two drops of ferric chlorid solution" prevented such a consummation, by markedly dissociating the ferric sulfocyanate, the sulfocyanate *ions* being insoluble in ether.

In discussing the supposed advantage of the proposed use of ether, Bunting says (regarding the effect of adding ether to the colored liquid of the *ordinary positive test*): "Ferric sulfocyanate, in the *undissociated* state, is soluble in ether; the undissociated portion, therefore, passes for the *greater part* [!] into the ether, a fresh amount of the undissociated compound is formed [?] in the *aqueous* solution, and this also goes into the ether. When the equilibrium is finally established, *there is much more undissociated ferric sulfocyanate in the ether than there was [in undissociated form?] in the water solution [originally?].*" These statements do not seem to be based on experience. Bunting has apparently not noted the fact that, if saliva-acid-ferric chlorid mixtures exhibiting the ordinary *positive* sulfocyanate reactions of average intensity are shaken with ether, the supernatant ether may fail to acquire a reddish tint and the intensity of the original color underneath may be very greatly diminished (in some cases to the vanishing point). Ether may render the classical test *less delicate* than ordinarily! On the other hand, 5 cc. of an ethereal solution of ferric sulfocyanate containing a proportion of the colored substance approximately equal to the proportion of sulfocyanate in saliva, when shaken with a few drops of water loses its color, *i.e.* undissociated colored ferric sulfocyanate is transformed into the *dissociated* colorless material that passes from the ether to the water. Bunting's conclusion that his ether-modification is a more delicate process than the classical method itself was not established by him.

In Bunting's tests, and in our own, the more accurate indications appeared to be obtained by the classical method rather than by the proposed ether-modification of it. Bunting's assumption that this *particular difference* in favor of the classical method is due to *something important in saliva that is not sulfocyanate,* and which occurs in saliva quite regularly, cannot, therefore, be regarded as probable. Bunting suggests diacetic acid as a substance of such confusing influence in the classical test for sulfocyanate. But Bunting ignores, in this connection, the fact that diacetic acid does not normally occur in saliva in detectable amounts. Then, too, while diacetic acid is reactive in an aqueous solution, in a way to stimulate sulfocyanate, it does not react in this way under the conditions prescribed for the classical test, *i.e.* in the presence of a chemical excess of hydrochloric acid.

Bunting states that "The salivas of several diabetic patients who had been excreting diacetic acid in their urine were examined, and in every case a ferric chlorid test was positive in water and negative in ether."* "Should *potassium* (!) sulfocyanate have been present in these cases," he adds, "it would have reacted in both water and ether solutions." The latter conclusion, as I have already indicated, cannot be correct. In careful tests of saliva from fifteen different persons, five of them typically diabetic, we found that the Arnold-Lipliawsky test for diacetic acid was wholly negative in each instance.

Although Bunting has not shown that his modified method is more reliable, as a rule, than the process he criticized, his general conclusion, that *various substances in saliva may prevent, modify, or simulate sulfocyanate in the ferric chlorid test,* accords with a well-known and long recognized fact—even ferric phosphate (and phosphate occurs in saliva) may cause confusion. It is this general fact, however, which makes it impossible to accomplish accurate quantitative work with the ferric chlorid test in

* From our point of view this shows merely that the ether-modification was less accurate than the classical process. Bunting should have gone further and determined by other methods whether sulfocyanate or diacetic acid, or both, were present.

any form, without due regard for the possible presence of various confusing substances; and even "clinical" work must be carefully safeguarded from the influence of many factors of interference in order to secure results of some reliability. Our own study of the ferric chlorid method led us to reject it as wholly unsuitable for the accurate quantitative analysis which is required for an investigation under your auspices by professional biological chemists.

THE RUPP, SCHIED, AND THIEL IODOMETRIC METHOD FOR QUANTITATIVE DETERMINATION OF SULFOCYANATE.

(2) Quantitative chemistry deals chiefly with masses that cannot be continuously perceived. In many cases it is impossible to determine quantities accurately by noting merely the appearance or disappearance of colors or precipitates, by ascertaining the volumes of masses, distinguishing shades of colors, or by obtaining any other direct result. Quantitative chemistry must be more precise, more detailed, more technical than the acquisition of such data requires. After several months of careful study in strictly technical comparisons, we found that it would be impossible to do accurate work on the content of sulfocyanate in tissues and parts of the body in general, if we did not employ a laborious, tedious, detailed and thoroughly accurate quantitative method. There are quite a number of accurate methods for the determination of sulfocyanate. Some of these methods are just as accurate as the finely detailed methods in use for the determination of atonic weights. We found, for instance, that Munk's method is very accurate. It involves the removal of sulfocyanate from its solution by precipitation with silver nitrate solution, the conversion of the sulfur of the precipitate into sulfate, and the calculation of sulfocyanate from the sulfur in the sulfate precipitated with barium chlorid solution. We finally adopted a method which, while not possessing the simplicity and facility of a clinical process, is apparently the most accurate now available. I refer to the iodometric method suggested by Rupp and Schied, and improved by Thiel.*. This method, in spite of its complicated character, is justly regarded generally as the best and most accurate for the quantitative determination of sulfocyanate in tissues and fluids.

The *Rupp, Schied, and Thiel iodometric method* is based on the fact that sulfocyanate solutions containing excesses of bicarbonate decolorize large amounts of iodin solution, cyanogen iodid (CNI) being formed with hydriodic acid (iodid) and sulfuric acid (sulfate). Typical equation:

$$KSCN + 4I_2 + 4H_2O = H_2SO_4 + 6HI + KI + CNI$$

The reaction is completed in about four hours at ordinary temperatures. By cautious acidification with hydrochloric acid, the iodid which results as a step in the first reaction is changed to chlorid and hydriodic acid, the latter converting the cyanogen iodid into hydrocyanic acid (cyanid)—

$$CNI + HI = HCN + I_2$$

The *essential* steps in the whole process may be indicated directly by the following typical equation:

$$KSCN + 3I_2 + 4H_2O = H_2SO_4 + 5HI + KI + HCN$$

i.e. one molecule of sulfocyanate is equivalent to six atoms of iodin (as iodid).

The reagents for the method are nitric acid solution (1 per cent.), silver nitrate solution (3 per cent.), iodin solution (N/10), sodium thiosulfate solution (N/10), hydrochloric acid solution (10 per cent.), starch paste (2 per cent.), infusorial earth (clean, washed in acid), sodium bicarbonate, and potassium iodid.

The method may be conducted as follows: The liquid under analysis is filtered. If the material to be analyzed is solid, it is finely minced, thoroughly extracted with water for twenty-four hours,

* Rupp and Schied, *Berichte d. d. chem. Gesell.*, 1902, xxxv, p. 2191; Thiel, *ibid.*. p. 2766; Edinger and Clemens, *Zeitschr. f. klin. Medizin*, 1906, lix, p. 223.

the extract freed from coagulable protein in the usual way, and the liquid filtered. The clear filtrate is acidified with nitric acid and then treated with a chemical excess of silver nitrate solution for the precipitation of the sulfocyanate as the silver compound. In order to cause complete sedimentation, a little infusorial earth is thoroughly stirred into the liquid and the mixture warmed over a water-bath for about ten minutes. The liquid is then filtered, preferably under pressure, through a filter in a perforated platinum cone. The filtrate must be perfectly clear. The precipitate is thoroughly washed with dilute nitric acid solution, when the filter and precipitate are transferred to a wide-necked Erlenmeyer flask (1 liter), there treated with a little water, 3 gm. or more of sodium bicarbonate (alkaline reaction) and 3 gm. of potassium iodid are added, and the solution is stirred until the bicarbonate and iodid wholly dissolve, and the filter paper is thoroughly disintegrated. Iodin solution (N/10) is then added until a permanent brown color is imparted to the mixture. The liquid is next carefully shaken and allowed to stand in a dark place for at least four hours. After cautious acidification with 10 per cent. hydrochloric acid solution (strong evolution of carbon dioxid may cause loss of volatile iodid), a few cubic centimeters of freshly prepared starch paste are added. Titration with sodium thiosulfate solution (N/10) in the usual way, and the customary calculations, complete the determination. In calculating the result, the number of cubic centimeters of N/10 iodin solution required multiplied by the factor 0.9847 gives the amount of sulfocyanate as hydrosulfocyanic acid, in milligrams, or, multiplied by the factor 1.6203, expresses the content as *potassium* sulfocyanate in milligrams.

II.

THE FUNCTIONAL SIGNIFICANCE OF SULFOCYANATE IN SALIVA.

(1) Sulfocyanate is a normal constituent of human saliva. What is the explanation of its occurrence in saliva? Where and how does salivary sulfocyanate originate chemically? *What is its functional significance?* It is obvious that precise knowledge of the place and circumstances of its production may throw a bright light on the functional import of salivary sulfocyanate—something no one has succeeded in explaining.

Sulfocyanate occurs in saliva in the form, presumably, of simple salts of hydrosulfocyanic acid, or as the sulfocyanate ion.* For the sake of convenience it is often assumed that *all* the sulfocyanate in saliva exists there in the form of *potassium* sulfocyanate. Whatever the form or forms may be in the saliva, chemists indicate the nature of hydrosulfocyanic acid by the formula $H—S—C\equiv N$, and of sulfocyanates in general by the chemical symbol $R—S—C\equiv N$, in which R signifies potassium or any other base, and SCN represents the sulfocyanate radical or anion. The formula $R—S—C\equiv N$ suggests that a sulfocyanate is a compound of sulfid and cyanogen radicals. Chemical analysis has established the truth conveyed by these formulas. It is plain, then, that the biological production of sulfocyanate depends upon the availability of *sulfur, nitrogen* and *carbon* atoms in one form or another, together with atoms like those of *potassium,* or radicals like those of *ammonium,* to complete the salt formation.

SUBSTANCES OR RADICALS YIELDING SULFOCYANATE IN THE LABORATORY.

Assuming for the moment that salivary sulfocyanate does not originate from preformed sulfocyanate in the food, it is natural to conclude that salivary sulfocyanate is *made* in the oral cavity, or is *produced* in, or *excreted* by, the salivary glands. In any event we should expect to gain an insight into the biological production of sulfocyanate, in any of the imaginable environments, from an inquiry into the processes by

* It has not been shown that more complex forms do not occur.

which it may be obtained in the chemical laboratory. It would be natural to conclude that the substances or radicals that yield sulfocyanate in the laboratory *might* be the same as, or analogous to, the substances or radicals that yield sulfocyanate in organisms. Permit me to summarize briefly certain well-known facts in this connection:

(A) When cyanid is fused with sulfur, sulfocyanate is formed. Typical equation:

$$\mathrm{K{-}C{\equiv}N + S = K{-}S{-}C{\equiv}N}$$

(B) A similar result may be obtained when a solution of cyanid and *yellow* ammonium sulfid is boiled. Typical equation:

$$\mathrm{K{-}C{\equiv}N + (NH_4)_2S_2 = K{-}S{-}C{\equiv}N + 2NH_3 + H_2S}$$

(C) Sulfocyanate is produced when carbon bisulfid and an alcoholic solution of ammonia are heated. Equation:

$$\mathrm{S{=}C{=}S + 4NH_3 = NH_4{-}S{-}C{\equiv}N + (NH_4)_2S}$$

(D) Sulfocyanate may be formed by decomposing a mixture of cyanid and protein (which readily yields *sulfid* radicals).

The foregoing simple facts suggest that sulfocyanate may be produced in organisms from sulfur-containing and cyanogen radicals. We know that such radicals are produced in organisms in the metabolism of proteins and other substances. We might expect, therefore, that sulfocyanate is not only produced biologically from such radicals, but that it is made from them in such active parts of the body as the liver, and that it is not peculiar to the salivary glands or the saliva. Let us consider this matter of *distribution* of sulfocyanate in the mammalian body before we proceed farther with our inquiry into the *origin* of sulfocyanate.

DISTRIBUTION OF SULFOCYANATE IN THE MAMMALIAN BODY.

(2) A thorough review of the literature on sulfocyanate warrants the general assertion that sulfocyanate occurs in the blood and lymph and in *practically all parts of the mammalian organism.* Although we have respected the evidence to this effect from the literature, we have conducted many analyses of our own, with the method I have already described, for the purpose of directly testing the matter.

Finding that blood invariably contains sulfocyanate, we felt it necessary, in our work on the *distribution* of sulfocyanate, to remove the blood from the body of the animal whose tissues were intended for analysis. For this part of the investigation, normal dogs were kept in cages, under preliminary observation, for several days. The daily food of the dogs consisted of hashed lean beef, cracker-meal, lard, bone-ash, and water—a mixture which in ordinary amounts is very nourishing, which we have used for years in our nutrition studies, and *which is free from sulfocyanate.* After we had learned that the dogs were normal in behavior and character, so far as that can be determined by superficial observation, we bled each to death from a femoral artery under local cocain anesthesia. Exsanguination was made as complete as possible, so that the volume of retained blood in any part was negligible in this connection. The parts that were intended for analysis were immediately removed very carefully, one at a time, without intermixture of liquids or juices, and without introduction of any extraneous matter. The entire part was subjected to analysis in nearly every case.

Table I presents the results of our analyses under these particular conditions. The data in Table II were obtained in the analyses of materials from normal animals—the *tissues,* from animals which had been bled to death.

Our analytic data in this particular part of the work indicate strongly that, in dogs, sulfocyanate is produced in and excreted from the liver; that sulfocyanate circulates in the blood to all the usual channels of excretion; that sulfocyanate is eliminated from the blood in bile and urine. Our failure to detect sulfocyanate

in the combined salivary glands from six dogs accords with previous observations to the effect that dog *saliva* does not contain sulfocyanate. The excellent condition of the average dog's teeth is an interesting fact for consideration by those who believe that caries in people is due to the absence (or reduction in the proportion) of salivary sulfocyanate. It is highly probable that the quantity of sulfocyanate (produced?) in the liver, and the proportion of that substance in the blood, of people is much greater than in dogs and that, on this account, the salivary glands in people are able to participate in the process of *excreting* sulfocyanate *from the blood.**

The foregoing facts regarding the *distribution* of sulfocyanate in exsanguinated dogs—very typical mammals—are not sufficient to warrant dogmatic assertions about the origin of sulfocyanate, although my inferences regarding its production in the liver, as stated above, are strongly indicated.

CHEMICAL ORIGIN OF SULFOCYANATE.

(3) Returning, now, from our digression into general facts of its distribution, to our inquiry into the chemical *origin* of sulfocyanate, let me remind you of my suggestion that sulfocyanate results in the body from a union of cyanogen

* Such a difference would be analogous to a number of dissimilarities between human and canine metabolism which are illustrated by the well-known discordance in the metabolism of nucleoproteins (and purins in general).

TABLE II.—MISCELLANEOUS DATA PERTAINING TO THE CONTENT OF SULFOCYANATE IN PARTS OF MAMMALS.

and sulfid radicals. With this belief as a guiding influence, we sought to ascertain the truth about the chemical origin of sulfocyanate by studying the distribution and elimination (production) of sulfocyanate in dogs, after the administration of various substances that contain or yield sulfid radicals or cyanogen radicals.

The experiments were performed on a large number of normal dogs. During the progress of each experiment the animal was confined in a metabolism cage of the kind I have described elsewhere.* The daily food was uniform in character and amount, consisting of sufficient amounts of the mixture of hashed lean beef, cracker-meal, lard, bone-ash, and water, which we have been using for years in nutrition experiments on dogs, to the greatest advantage in the work and to the highest satisfaction of the animals.† During a preliminary period for each animal the total amounts of daily urine and feces were carefully determined and recorded, and the amounts of sulfocyanate in these excreta ascertained. In this way the normal elimination of sulfocyanate under the initial conditions of the experiment was established. Dosage with the substance under investigation was then begun and was continued in increased quantity daily. Sulfocyanate, as before, was determined in the urine and feces, for the purpose of ascertaining whether the dosage increased or affected its quantitative output. Finally, sufficient time having presumably elapsed for the registration of effects of the dosage on the elimination of sulfocyanate, the animal was bled to death from a femoral artery under local cocain anesthesia, and, after complete exsanguination, some of the blood and certain other carefully isolated parts of the body of the animal were analyzed for sulfocyanate, to determine whether the dosage had increased any local production or retention of such substance. The results of this part of the work are summarized in Table III.

Our data show that there were slight, though unimportant increases in the average daily excretion of sulfocyanate in urine and feces after administration of sulfur, sodium sulfid, and taurin. Thiourea and cystin did not induce elimination of quantities above normal average. The doses of each of these sulfur containers were comparatively large. Both the sulfur and the sodium sulfid certainly added appreciably to the usual amount of sulfid radicals in the body. Our observations in this connection suggest that added amounts of simple substances containing or yielding sulfid radicals do not markedly affect the sulfocyanate excretion. Since considerable HS sulfur results from ordinary metabolic transformations of proteins, it is probable that sulfur in such radicals is freely available at all times for any sulfocyanate synthesis that may tend to occur. On the other hand, the exceptionally violent toxicity of the CN radical suggests that this radical never occurs normally in proportions comparable with those of the HS radical. Our experi-

* Sulfocyanate contents are given in terms of potassium sulfocyanate. † Experiments 1 and 2 were "controls." Experiments 3-11 were planned to determine effects of sulfur and sulfur-containing substances. Experiments 12-15 tested effects of a CN container and two typical amino acids (products of protein metabolism—CN yielders). ‡ Crude cystin.

mental data accord with the opinion that the amount of sulfocyanate depends primarily on the available supply of the constituent radical which happens to occur in the body in the smaller proportion, namely, the CN radical.

Acetonitril, alanin, and glycocol had an apparently marked effect on the elimination of sulfocyanate in the urine. The doses of alanin were comparatively large. The first of these two substances contains a CN radical, the second is capable of yielding such a radical. Direct addition of CN-yielding material to the small available supply of such substance in the body induced a notable increase in the elimination of sulfocyanate.

So far as production and retention (distribution) of sulfocyanate are concerned, the data in Table III indicate that the effects on the quantity of sulfocyanate in the blood were much the same as those in urine and feces, as might be expected. The amounts of sulfocyanate in the liver and the small and large intestines, with their contents, were above normal in most cases. The effects on the amounts of sulfocyanate in the bile and the small intestine with its contents were especially striking after administration of acetonitril, alanin, and glycocol. Sodium sulfid was the only substance whose administration was followed by the occurrence of sulfocyanate in the stomach. The results with taurin were anomalous, and additional experiments with that substance are especially required. Glycocol seemed to be responsible for the production of considerable sulfocyanate in the alimentary tract. Our experiments are now in process of extension along these lines. Further work in this direction promises to be particularly instructive.

Our experimental data on the origin of sulfocyanate suggest strongly that sulfocyanate results from the metabolism of protein, that the liver is the organ chiefly concerned in the production of sulfocyanate,* and that the salivary glands *excrete* rather than secrete sulfocyanate in saliva. Let me summarize the inferences in this connection to which our results lead us.

* It is probable that the sulfocyanate in the alimentary tract is derived from bile, and that the quantities found in the tract are the amounts which were not reabsorbed.

INFERENCES TO BE DRAWN FROM THE EXPERIMENTS ON ANIMALS.

Protein yields HS and CN radicals in the laboratory and in the organism. Hydrogen sulfid, methyl-mercaptan and cystin are among the ordinary HS-containing products of protein transformation. Amino acids, such as glycocol and alanin, arise from protein in the digestive processes, and nitrils (similar to acetonitril in significance) result in small proportion from amino acids in the bodily oxidative processes. These cyanogen products, in spite of their slight proportions, are very toxic. The chemical defenses of the organism are presumably just as effectively operative in this connection as in any other. The liver combines the HSO_3 radical with putrefactive indol from the intestine (after oxidizing the indol to indoxyl), thus converting the toxic indol into a much less toxic substance (indican) prior to its elimination in the urine and in other excretions.

In like manner, our data suggest, the toxic CN products of metabolism or extraneous introduction are suitably modified and combined, in part at least, with freely available, normally occurrent, HS radicals, apparently in the liver, into much less toxic sulfocyanate prior to elimination of the latter in the urine and in other excretions.* These deductions are in full accord with many previous observations, with our own findings, with analogous facts, and with the logic of present metabolic knowledge. If these views are correct, they suggest, further, why no one has shown that sulfocyanate, a waste product, bears any functional relation whatever to the teeth or oral membranes.

* Ordinary cyanid, such as the potassium compound, is transformed, in part at least, into sulfocyanate after its introduction into the body.

EFFECT OF FASTING ON ELIMINATION OF SULFOCYANATE.

If sulfocyanate is produced from CN radicals that are released in protein metabolism, the tissues and excretions would probably contain smaller proportions of sulfocyanate during a fast, because protein metabolism is thereby reduced to a minimum. We tested this matter by subjecting a normal dog weighing 8.46 kilos to a seven-day fast. At the end of that period the animal was completely exsanguinated by the method already described. There was marked diminution in the amounts of sulfocyanate in the urine, feces, and tissues, in some cases to 50 per cent. of the "normal" values.

SALIVARY GLANDS IN DOGS NOT PRODUCERS OF SULFOCYANATE.

Although we were unable to detect sulfocyanate in salivary glands from dogs, we concluded that slight proportions might be produced there and secreted into the saliva, and by passing into the stomach enter the blood, accumulate in the blood, and account for some of our observations. We then determined the effect of preventing the saliva from entering the stomach, upon the distribution and excretion of sulfocyanate.

A normal dog, weighing 10.4 kilos, was successfully subjected to an operation for the institution of an esophageal fistula. The dog was fed twice daily through a stomach tube in the gastric end of the esophagus, the food mixture, which was free from sulfocyanate, consisting of milk, cracker-meal, bone-ash, beef extract, Witte peptone, and gelatin. Suitable bandages prevented saliva from passing into the stomach. All samples of saliva collected from the oral end of the esophagus were free from sulfocyanate. The urine contained approximately the usual proportion of sulfocyanate. The experiment was continued for about two weeks. The blood contained about 5 mg. of sulfocyanate (calculated as KSCN) per 100 cc. The liver (272 gm.) contained 17.8 mg.; the bile (27 gm.), 5.4 mg. These facts further emphasize our conviction that the salivary glands are not producers of sulfocyanate—merely the outlets for its ejection from the blood in some animals; for other animals the salivary glands are not even excretory channels.

INHIBITING ACTION ON DENTAL CARIES OF SULFOCYANATE IN SALIVA DOUBTFUL.

Your society has given considerable attention to sulfocyanate, chiefly from the standpoint of the possibility that salivary sulfocyanate prevents, inhibits, retards, or delays the onset and progress of dental caries. If salivary sulfocyanate is an *excretory* product, as I have suggested, such a prophylactic relation to dental caries is improbable. The available experimental data on the subject of an inhibitory influence of sulfocyanate on plaque formation are not only discordant, but cannot be applied satisfactorily to oral conditions. No *rational* explanation has been offered for the supposed effects of sulfocyanate, in salivary proportions, on the formation of bacterial plaques or on bacterial growth or activity. Our studies under your auspices* have convinced me that sulfocyanate does not, and, in the proportions of its occurrence in saliva, *cannot* appreciably retard the growth of oral bacteria, or impair their nutrition, or reduce their capacity to produce acid from carbohydrate. I believe that the ease with which sulfocyanate may be detected in the saliva, and the striking and attractive nature of the test, have given sulfocyanate an importance it does not deserve.

Michel, who claims to have been the first to suggest sulfocyanate prophylaxis against dental caries, who complains that his European colleagues have declined to take seriously his suggestions at the Munich Congress in 1902, but who notes with pleasure the development of the sulfocyanate propaganda among Ameri-

* Seaman and Gies, DENTAL COSMOS, 1910, lii, p. 1141.

can dentists, has recently suggested* that the prophylactic value of sulfocyanate is due to its oral decomposition into prussic (hydrocyanic) acid, with consequent "extraordinary" local *bactericidal* action! Michel says nothing about any other effect of the resultant prussic acid. This opinion of the leader in the sulfocyanate crusade is a very stunning conception when considered in the light of reports to your society that sulfocyanate, in some way or other, restrains the carious activity of the oral bacteria without injuring, though perhaps by "stimulating," the organisms.

III.

INDISCRIMINATE INTERNAL ADMINISTRATION OF SULFOCYANATE BY DENTISTS UNSCIENTIFIC.

Earnest students of the problem of dental caries, who entered this field long before we did, and whose desire to explain and prevent the disease are quite as sincere as ours, believe the results of their work indicate that the internal administration of sulfocyanate is preventive, alleviative, and curative of dental caries. They attribute the therapeutic value of sulfocyanate to the smaller portion of the administered substance which reappears in the saliva, and seemingly ignore the influence and fate of the larger portion of the dose which does not pass into the saliva. In spite of the fact that the pharmacology of sulfocyanate has not been effectively studied, some dentists recommend the internal administration of comparatively large doses of sulfocyanate and have been administering such doses without any apparent regard for effects, good or bad, that may be registered on any other part of the body than the teeth. If it were impossible to ascertain the pharmacologic effects of sulfocyanate, this empirical treatment might be excusable, but the present concentration of attention on the effects of sulfocyanate on the teeth and the disregard for systemic influences it may exercise, is contrary to the spirit of modern medicine and a reflection on the practice of dentistry.

I say this without reference to the ultimate outcome of investigation of this matter. I cannot declare that the internal administration of sulfocyanate in certain doses is without therapeutic advantage—that such doses do not possess curative or palliative effects in dental caries—for I do not know. I cannot say that such doses, if valuable in dental caries, are appreciably harmful in other respects—for I do not know this either. I wish merely to insist that our profound ignorance of the pharmacology of sulfocyanate should prevent us from proceeding empirically in its therapeutic use without due regard for considerations more immediately important, possibly, than those of preventing or curing or alleviating dental caries by such dubious means.

I wish especially to urge you to note the difference between a harmony of coincidental circumstances on the one hand and the accord between cause and effect on the other. We might prescribe "sugar-water" for each of fifty cancer patients daily for some time. It is quite possible that one "*spontaneous* cure" would occur in such a group of cancer patients in a given period of time. Did the sugar-water bring about the one cure observed? Certainly it did—was it not our purpose and expectation to do that very thing with sugar-water? Isn't it evident that sugar-water could do that, especially since we desired it to do so?

How can there be any doubt of the wonderful power of sugar-water under such circumstances? We might very happily exhibit our "cured" patient before such a convention as this. An uncritical convention, unlike this one, might "raise the roof" in its celebration of the wonder of the sugar-water cure for cancer. But if, besides exhibiting the one "cure," we also presented the history of the remaining forty-nine patients—with its dismal commentary on the negative phase of the sugar-water cure—would even an uncritical convention get excited about the curative powers of sugar-

* Michel, *Ergebnisse der gesamten Zahnheilkunde,* 1910, i, p. 436.

water? How much information do we have about the sulfocyanate treatments which have accomplished nothing? How much that is claimed for sulfocyanate is comparable to the sugar-water wonder I have just brought to your imaginative attention. How much that is "prevention of dental caries by sulfocyanate" is coincidental circumstance?—how much is effect due to a definitely established cause? Who knows? It is to your interest and to the interest of your patients, and to the interest of advancement in dental art and science, that you insist upon judicial presentation of every claim, in this and every other connection, that may be offered for your personal and professional attention; and it is equally important that your reception of every such claim be characterized by judicial fairness, thoroughness, and poise. Science is a matter of fact, not a state of emotion.

PRELIMINARY OBSERVATIONS ON POISONOUS QUALITIES OF SULFOCYANATE.

What I have just stated in criticism of the empirical use of sulfocyanate internally for some assumed benefits orally is due, in part, to the results of our experiments on the toxicity of sulfocyanate. We worked forward in our research, step by step, along the lines indicated in my preliminary statement. A few minutes ago I remarked that additional experiments will be performed with acetonitril, alanin, and similar substances, in our effort to establish the origin of sulfocyanate. We are now in the early stages of a series of experiments on the poisonous qualities of sulfocyanate. I can report today only the results of preliminary observations. That being the case, I shall merely summarize briefly the conclusions our results suggest, and postpone, for a future report, presentation of the details of our work to date and any extension of it that we may be able to carry forward.

The growth of lupin seedlings in water cultures, and of timothy seedlings on wet blotting-paper, was strikingly impaired by potassium sulfocyanate in dilutions of 0.01 per cent. or even less. Fungi appeared under such conditions and grew luxuriantly in spite of the toxicity of the media for the green plants. Lupin seeds, soaked for eighteen hours in 0.02 per cent. potassium sulfocyanate solution, lost all power of germination; similar treatment of such seeds in 0.01 per cent. solution did not prevent germination in a favorable environment.

Tubes containing gelatin and gelatin-peptone media, were inoculated with mixtures of common bacteria and fungi. The growth of bacteria in such media, containing 3 per cent. or less of potassium sulfocyanate, was not inhibited. Concentrations of the sulfocyanate greater than 3 per cent. inhibited bacterial development, but the growth of fungi was luxuriant in tubes containing as much as 10 per cent. The growth of yeast in a 5 per cent. glucose solution, and the rate of fermentation, were not decreased by such large proportions of potassium sulfocyanate. The curdling of milk (lactic acid fermentation) was prevented for four days or more by potassium sulfocyanate in proportions equal to or greater than 0.5 per cent. The sulfocyanate interfered with the growth of the lactic acid bacilli and markedly prevented the development of lactic acid.

Subcutaneous doses of 5 mg. of potassium sulfocyanate in frogs weighing 20 grams caused hyperesthesia, convulsions, and sometimes death. The hyperesthesia lasted for several days in the frogs that recovered. Larger doses (7.5 mg. and more) caused violent death, sometimes in a few hours, the main feature of the symptoms being convulsions.

Subcutaneous injections of 50 mg. or more in guinea-pigs weighing from 350 to 450 grams, caused death in convulsions in about twenty-four hours or less. A subcutaneous dose of 25 mg. in a guinea-pig weighing 335 grams was without *visible* effect.

A dog weighing 8.1 kilos was given 0.61 gram of potassium sulfocyanate (75 mg. per kilo) in hashed meat on each of three successive days. After the second dose the dog refused to eat, vomited, and exhibited general tremor. The dog died in convulsions twenty-four hours after receiving the third dose.

A dog weighing 6.1 kilos was given 0.2 gram of potassium sulfocyanate (33 mg. per kilo) in hashed meat on each of five successive days. The treatment caused depression, tremor, diarrhea, and vomiting. The dog appeared to recover promptly after the treatment was stopped.

In a similar experiment on another dog, doses equal to 25 mg. of potassium sulfocyanate per kilo produced no *discernible* toxic effects.

In an extension of these experiments we are planning to include a study of possible influences of small doses as registered on blood pressure, heart-beat, respiration, kidney normality, digestive functions, nervous co-ordinations, and other important vital phenomena whose disturbance, even when not discernible in gross symptoms, may lead to abnormality and disease.

CAUTION IN INTERNAL ADMINISTRATION OF SULFOCYANATE ADVISED.

These results suggest that dosage with sulfocyanate may be a dangerous procedure. They certainly indicate that the pharmacology of sulfocyanate should be thoroughly understood by those who determine how much and how often sulfocyanate shall be administered.

Sulfocyanic acid is produced from its salts by mineral acid. Such a change doubtless occurs to some extent in the stomach after the administration of sulfocyanate. When heated, sulfocyanic acid changes readily into persulfocyanic acid, $H_2C_2N_2S_3$, and hydrocyanic (prussic) acid, HCN. By oxidation, sulfocyanates are convertible into sulfates and hydrocyanic acid. By reduction, hydrogen sulfid, ammonia, and hydrocyanic acid or methyl amin (CH_3NH_2) and trithioformaldehyd result $(CH_2S)_3$. Alkyl sulfocyanates are converted by reduction into mercaptans and hydrocyanic acid or methyl amin. These chemical facts suggest that the oxidations and reductions in organisms tend to produce one or more of these *poisonous* derivatives—derivatives which might be produced abundantly enough after dosage with sulfocyanate under one nutritive condition or another to cause harmful influences similar to, if not as decided as, those exhibited by our frogs, guinea-pigs and dogs in the few experiments I have just described.

I have not noted any statement, by those who used sulfocyanate therapeutically, that the products employed by them were free from hydrocyanic acid (cyanid). In all our work we used an imported product—potassium sulfocyanate—made by Kahlbaum. Large portions of the material, tested by the Noyes method,* were found to be free from cyanid.

Our results strongly suggest an extension of this work along the several lines I have indicated. They emphasize especially the need for thorough determinations of the hidden effects of doses of sulfocyanate that produce no gross toxic symptoms—doses given to mammals, and particularly to men who would volunteer to submit to such treatment after its possible dangers were clearly and fairly indicated.

I regret that we could not finish all that we planned to do, and I am sorry that I have had to take so much of your time to explain the little we have accomplished.

THE QUESTION OF EXTRACTION: AN ANSWER TO DR. FERRIS' DISCUSSION.

By CALVIN S. CASE, M.D., D.D.S., Chicago, Ill.

I WISH to correct two misleading statements in Dr. Ferris' discussion of my paper published in the DENTAL COSMOS for February and March, 1912. First: On page 349 he says: "I have lived long enough to have practiced the essayist's methods of extracting the first premolars in cases of class II, division 1, and to see these patients grow to maturity. Likewise I have treated cases of the same class upon the principles set forth by Dr. Edward H. Angle's teachings. I have had the uncomfortable experience of having to undo a case started after Dr. Case's method, and having to introduce artificial teeth to fill the space that had partially closed."

I have endeavored in my papers, as in all my teachings for the last fifteen years, to explain the very wide difference in facial effect and demands of treatment in Dr. Angle's class II, division 1, and to show that in fully one-half the cases of this division—which is characterized by the upper denture occluding about the width of a cusp in front of a normal occlusion in relation to the lower—that extraction is decided malpractice, because the disto-mesial malrelation is due to a retrusion of the lower denture rather than a protrusion of the upper. Such cases demand a decided forward movement of the entire lower denture, with perhaps a slight retrusion of the upper to harmonize the facial outlines by thus placing the dentures in normal occlusion—the whole being easily accomplished with the intermaxillary force.

It unhappily is quite customary for the Angle men, who do not seem to recognize this marked difference in the two characters of this class, to exhibit all cases having this malocclusion with the statement or inference that these are the kinds of cases for which I advocate tooth extraction; whereas it is quite as likely as not that nothing could be farther from the truth. If they have fallen into the inexcusable error of extracting upper teeth in cases where the uppers were not decidedly protruded, I think it would be quite as well to try to gain something more than a superficial and prejudiced understanding of my teaching before claiming that they had followed my methods of treatment.

I wish to say further, that even in those cases of marked upper protrusion for which in my practice extraction is demanded, I should hesitate before advising an Angle orthodontist to extract, because in all probability the employment of the commercial single-molar-clamp-band-anchorage and arch—which it seems impossible for him to get away from—could not help but result in a decided mesial inclination movement of the crowns of the back teeth, as much if not more than a retruding movement of the front. It is not strange that men who wholly employ these appliances are disgusted with the extracting proposition.

Orthodontists who employ no other appliances than those advocated by Dr. Angle in his recently published text-book knew practically nothing of many of the most scientific and most important methods of moving teeth—nothing about absolutely stationary anchorages, composed of two and three bands, Nos. 35 and 36 gage in thickness, contoured and perfectly fitted to the teeth, soldered together with reinforcements for rigidity, and carrying long-bearing *rootwise* extension tubes for retruding bars for the movement of the canines alone; other tubes being attached for the incisor retruding bow, for the employment of the occipital force, and for the attachment of intermaxillary elastics to similar stationary anchorages on the lower—thus utilizing every possible means of distributing the force of reaction so that all the movement, if desired, may be confined to a retrusion of the six upper front teeth. When a bodily retruding movement is demanded, special methods of a positive and adequate nature are employed.

I speak of these things now because I resent the statement from any man that he has followed my methods and failed, when it is very likely he has gone exactly contrary to my teaching in extracting; or if the case is one in which extracting is demanded, he evidently has not followed my methods for retruding the front teeth after extracting, else there would have been no failure.

Second: On page 352 he says: "There are exceptional cases which demand exceptional treatment, but that 20 per cent. of this class of cases in the essayist's practice demand extraction seems to me extraordinary."

On page 140 I say: "To sum up the number of cases in which teeth are extracted by all skilled rational orthodontists as compared to the whole number of cases presented for treatment: There arises about one case in thirty or thirty-five in Dr. Angle's class I, and in his class II about one case in every twenty, making on the whole only about one case in every twelve or fifteen." In other words, about 3 per cent. of Dr. Angle's class I, and 5 per cent. of his class II, demand extraction, and practically 0 per cent. of his class III. Therefore, in an average of 100 cases in practice there will be only about six or seven cases in which extraction is demanded. This is quite different from Dr. Ferris' statement that I would extract in 20 cases out of every 100.

May it not be possible that the "exceptional cases" for which Dr. Ferris tacitly admits extracting is demanded, amount to 6 or 7 per cent. of all the cases he treats? It is certainly not a far-fetched belief, as stated in my paper (if the truth could be known), that nearly all experienced orthodontists of whatever school extract teeth in the correction of all the marked protrusions for which I claim extraction is demanded. Then why not come out frankly, and openly acknowledge, in their papers and on the floors of conventions, that which they feel they must do in private practice for their patients and for their own reputations.

When the whole question of extraction in orthodontia is summed up and the full truth is grasped, it seems a most senseless thing for men to fight over, when the truth is so self-evident; and then to quibble and cast untruthful slurs —among men whose main object in life should be for the development of truth, true principles, and true methods of practice for the advancement of their profession and the relief of suffering humanity!

Proceedings of Societies.

NATIONAL DENTAL ASSOCIATION.

Sixteenth Annual Meeting, held at Washington, D. C., September 10 to 13, 1912.

SECTION I: Prosthetic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

Chairman—Weston A. Price, Cleveland, Ohio.
Vice-chairman—Harry E. Kelsey, Baltimore, Md.
Secretary—Marcus L. Ward, Ann Arbor, Mich.

(Continued from vol. liv, page 1372.)

Tuesday—*First Session.*

(Continued.)

The next order of business as announced by the Chairman was the reading of a paper by Dr. C. M. McCauley, Abilene, Texas, entitled "The Great Need of Improvement in the Manufacture of Dental Alloys."

[This paper is printed in full at page 16 of the present issue of the Cosmos.]

Discussion.

Dr. C. M. McCauley. I have here a table of results of experiments made with a few alloys, and I will read portions of it to give you an idea as to what the committees in the states visited have done. I have arranged the report in such a way as to show where the testing was done, the amount of shrinkage, the amount of expansion, and the time that the movement was followed up.

One point in the table means one ten-thousandth of an inch. The fillings were made in Wedelstaedt steel tubes. The cavity in each was 33/100 of an inch in diameter, and 38/100 of an inch in depth. At the bottom of the cavity is a groove, in which the amalgam is packed to prevent movement toward the orifice of the cavity. In other words, the filling is held in the bottom of the cavity so that the expansion is indicated by the protrusion of the filling from the cavity, and the shrinkage is indicated by its drawing into the cavity or away from the margins, either of which movements may be detected by the micrometer or microscope. The microscope is used to verify the work of the micrometer in both expansion and shrinkage movements.

The first test I will mention is that of a specimen of *Rego*, which showed no shrinkage, 4 points expansion, time ten days. Two other specimens showed practically the same result.

Crandall's Alloy. No shrinkage, 1½ points expansion, time seven days. Another specimen of Crandall's showed no shrinkage, no expansion, time one and one-half months. Another specimen showed no shrinkage, 3 points expansion, time one and one-half months. Another specimen showed 1 point shrinkage and 1 point expansion, three months' time.

A specimen of *Fellowship* tested in Lincoln showed no shrinkage, 2 points expansion, and read for two months. A specimen of Fellowship tested in Des Moines showed no shrinkage, 4 points expansion, three months' time.

Twentieth Century. Shrinkage 1 point, expansion 1 point, time ten days. Another specimen (test made at Lincoln), 1 point shrinkage, 20 points expansion, two months' time. Another specimen, 1 point shrinkage, 2 points expansion, three months' time.

Science Alloy. Shrinkage 1 point, expansion 6 points, four months' time. Another specimen, no shrinkage, 2 points expansion, two days' time.

Absolute Alloy. Shrinkage 1 point, 3½ points expansion.

All of these that I have read show only slight movement, and, if repeated tests showed similar movement, they could be relied upon in practice.

Dr. Conzett. Will you explain how you have expansion and shrinkage in the same filling?

Dr. McCauley. I have found in testing amalgam fillings that most of those that shrink at first show subsequent expansion. The greater part of shrinkage takes place in the first two hours. When expansion follows, it is sometimes slight, and again it reaches an enormous degree. In doing this work we made it a point to measure each filling in the micrometer, two or three times the first two hours; after that every two or three hours for the first day, then every day for eight or ten days if possible, and about once a week after that.

Dr. Moffitt. Will you tell how you verify the micrometer with the microscope?

Dr. McCauley. When the expansion or shrinkage reaches as much as 4 points, the binocular microscope will detect it very readily, the shrinkage being shown by the amalgam drawing away from the margins or into the cavity, and expansion by protrusion therefrom.

Dr. Moffitt. What size cavity?

Dr. McCauley. 33/100 of an inch in diameter.

Dr. Moffitt. What is the magnification?

Dr. McCauley. Fifty diameters. Under such a microscope 4 points can be seen by the untrained observer.

Next we have a specimen of *True Dentalloy,* which showed no shrinkage, 35½ points expansion. Another specimen, no shrinkage, 2 points expansion. Another specimen, 1 point shrinkage, 20 points expansion, two months' time. Another specimen, 1½ points shrinkage, 5½ points expansion.

Globe Alloy. Shrinkage 11 points, 1½ points expansion, time ten days. Another specimen of Globe, 6½ points shrinkage, 1½ points expansion.

Dr. Tileston. Do you count the expansion from the minimum or rest point?

Dr. McCauley. We count from the point of maximum shrinkage. For instance, we have a shrinkage of 6½ points, and after that the material expands 1½ points, leaving 4 points of shrinkage from where it started.

We have a specimen of what is called *Fox White Alloy,* which showed a shrinkage of 5½ points, and expansion of 2½ points, in ten days. *Standard,* shrinkage 6½, expansion ½, in six days. *Sterion White,* shrinkage 3½, expansion ½, in seven days. *Pure Dentalloy,* no shrinkage, 12 points expansion, in two months' time.

It is not intended that the practitioner should accept the above figures as conclusive and select his alloy therefrom, but they are submitted here only to give dentists an idea of the necessity of a thorough and exhaustive series of tests covering the entire alloy market. Many tests of each kind must be made before a reliable conclusion can be reached.

Dr. J. A. Bliss, Ruthven, Iowa. I had the pleasure of being the chairman of the committee which tested these alloys in Iowa. The results were very surprising. We should remember in this connection the statement of Dr. Black in regard to alloys, mentioned by Dr. McCauley, that they should show no shrinkage, and not above from four to five points of expansion. Even though you realize that of this list of alloys tested very few come near to what alloys should be, still we must remember that the formula of many of those that seem to have reached the point of excellence demanded by the profession shows up improperly, no matter what the tests have shown; and when that is true, that alloy must be changed. For example, Dr. Black makes the statement that the only three elements that should enter into a perfectly good alloy are silver, tin, and copper. He emphasizes that any zinc introduced into an alloy is detrimental, owing to the fact that it does not alloy uniformly with other metals, and consequently, in one portion of one and the same ingot there may be a percentage of zinc above what is intended, and in another portion of that ingot there will be less zinc than intended, and this necessarily results in an uneven alloy. Dr. Black therefore excludes zinc as being detrimental and undesirable, and we are forced to the view that any alloy that contains zinc should be excluded from our tests, which means all but about two or three. This is alarming, when we consider the fact that of all the fillings made in the United States, at least seventy-five per cent. are made with amalgam. The investigation of this question is merely begun. I would be more than pleased, and Dr. McCauley no doubt concurs with me, if the National Dental Association would take some action, and that a committee be appointed and an appropriation set aside for further careful investigation of alloys with an eye to perfect fairness and justice. If the alloys that we are using are of no use to us, we want to know it; and if there are alloys that are what they should be, we want to know that.

Very recently we have received circulars from alloy-makers, who evidently have been stirred up by this movement, and it is amusing to read the many various statements of different makers in substantiation of the claim that their alloys are perfect. These circulars consist mostly of testimonials from prominent dentists, who state that they have been using such and such an alloy for a number of years with perfect results. With all deference to the operators who give such testimonials, I wish to go on record as saying that these recommendations are not worth the paper they are written on, for the reason that any such tests made clinically in the mouth are not scientific, and not dependable. We cannot depend on tests made by dentists in the mouths of patients. The only tests that can be relied upon are those made scientifically with the aid of accurate instruments. These tests are valuable, but anything outside of that is absolutely valueless.

We also must bear in mind, when any of these alloy-makers tell us that their alloy contains gold or platinum, that Dr. Black makes the statement that these metals are a detriment to an alloy, and of no advantage whatever. With regard to gold, I happen to know an alloy that contains a large percentage of gold, and we have made tests of this alloy, which brought out the fact that it shows a large amount of shrinkage, and fails to respond with the proper amount of expansion.

Regarding gold and platinum alloys, the statement is being made that these metals improve the color of the amalgam. All we have to do to dispose of that point—aside from the fact that it causes more shrinkage—is merely to remember that anything less than 18-karat gold will not be free from discoloration in the mouth.

Dr. Conzett. Twenty-four karat will discolor when mixed with mercury.

Dr. Bliss. That is a good point. We want to remember the plain fact that we, as the dental profession, should stop paying for stuff that is not worth anything as a filling material, and make the manufacturers furnish us with a suitable material. It seems to me that our way is clear. We are merely at the beginning, and it is unfair to condemn any alloy, or any maker who acknowledges the shortcomings of his product and stops furnishing such material.

Dr. McCauley speaks of the responsibility of making these tests. I assure you that it is a great responsibility, and if you knew some of the persecutions endured by him since he began these investigations, you would be indignant. It is a shame that one man should bear the brunt of these attacks. In justice, therefore, to Dr. McCauley and his fellow investigators, these tests should be made under the supervision of the National Dental Association or some state society, as a part of the society's work, thus relieving the investigators of any personal responsibility.

In closing, I wish to repeat that this work is merely begun, and I am sure that all appreciate what Dr. McCauley has done, and I hope in the future the society may see its way clear to lend assistance in this task.

Dr. R. E. L. Strickler, Bridgewater, Va. I would like to ask which of the alloys mentioned are the best to be used. I made some notes as best I could, while Dr. McCauley was reading, but he has the full report, and perhaps he may have in his mind several that he could recommend as the best.

Dr. McCauley. The question, as I understand it, is—What is the best alloy to use? I have been asked this question a number of times wherever I have spoken on amalgams, and I never have been able to answer it. I give you the figures and let you form your own conclusion. Any degree of shrinkage and any degree of expansion exceeding 5 points is detrimental. Those alloys in this list which come within that range of shrinkage and expansion may be easily determined by anyone in going over the list. Yet here is a case of four or five tests being made of a certain alloy, and all but one showed the alloy up well, that is, no shrinkage and less than 5 points of expansion; yet, in one of these tests, a specimen of the same alloy showed expansion of 20 points. I should hesitate, therefore, to say that this is not a good alloy, after such a small number of tests. If, after having made many careful tests of this same alloy, I find that the expansion and shrinkage will reappear time and again, and that the results are varying in different fillings, I shall be able to say that this alloy is not dependable. Again, if I find, in test after test, that this alloy shows no shrinkage and little expansion, then I shall be able to say that this alloy is good, and no better can be found. But we have not reached that point, because the tests I have made are incomplete. I have made only a few tests and none of these tests are complete. It would, therefore, be an injustice to other manufacturers, who perhaps are producing a good article, to point out five or six alloys as being satisfactory and recommendable. We must obtain results in the best way possible, without any undue hurry, and wait until thorough and conclusive tests have been made, and until we have enough data before us to determine whether or not a certain amalgam is good or bad.

A Member. Tell us what proportion of mercury you use, and how you mix amalgam?

Dr. McCauley. That varies with the alloy used. A balanced alloy, composed of silver, tin, and copper, requires about 55 per cent. of mercury and 45 per cent. of alloy. This proportion varies in that alloy as it grows older.

A Member. Do you get the proportions by weighing?

Dr. McCauley. Yes, by weighing, and observing the working properties of the alloy.

Dr. Kozer, Harrisburg. What attention do you give to the amalgamation of the alloy? Say you make three tests, do you try to give the same attention to amalgamation in each test?

Dr. McCauley. Yes, the idea being to obtain uniform results, if such can be obtained with the alloy in question. Of course, if we use varying proportions of mercury and a varying technique, we should not expect uniform results. In order to make tests and tabulate the results, we have to determine whether or not these tests will repeat themselves, and must therefore use as nearly as possible the same technique.

Member. What effect has age on the alloy?

Dr. McCauley. Age makes no difference in shrinkage or expansion. It affects, however, the amount of flow and strength; as it grows older, the alloy grows weaker. In my paper of last year (Dental Cosmos for February 1912, p. 174) I said that every alloy should be dated by the manufacturer, viz, the date should be placed on every batch before it leaves the manufacturer, so that the dentist may know whether or not the alloy has grown old.

Dr. Conzett. Dr. Ward found years ago that fillings made up a certain length of time increased in strength, but after a certain time began to decrease in strength. Have you made any tests along that line?

Dr. McCauley. The question is whether amalgam deteriorates in strength as it advances in age. I have not made any tests in that direction, but I am sure as to Dr. Black's opinion on that point. He says that amalgam does not lose its strength with age, but that alloy does lose its strength with age.

Dr. Mausteller. In one alloy you give five results, and the shrinkage in all was favorable; in two the expansion results were favorable; in one good, and in two bad. How do you account for that difference in the same alloy?

Before you answer that question, I should like to ask in addition, In amalgamating the alloy, how do you apply the mercury? Do you apply it all at once and attempt to incorporate the proper amount of alloy and expel no mercury, or do you expel mercury or add alloy after the amalgamation is started?

Dr. McCauley. The result that you mention in the first case, where three of the five tests showed favorable results, and two others showed unfavorable results, could be produced by errors in the alloying process, viz, either by not heating enough, so as thoroughly to dissolve the metals in each other, or by overheating and producing what is known as eutectica. Any failure to alloy the metals thoroughly, you can understand would leave an uneven distribution of those metals throughout the mass, and a filling made from a certain part of that ingot would be differently constituted from one made from another part of the same ingot. On the other hand, if you produce a eutectic formation by overheating, and that appears in one part of the ingot and not in another, you obtain a result that is not uniform.

As to mixing mercury with the alloy, it is better to start with the correct amount of mercury. The amounts of mercury and alloy should be carefully weighed, and only the amount should be used required to produce desirable plasticity of the mass. This is a point that should always be stressed in the manipulation of amalgam, *i.e.* the proper plasticity of the mass. Unless the amalgam has the proper plasticity it cannot be placed in any part of the cavity desired and kept there.

Dr. W. A. Smith, Denton, Md. In expressing mercury, would the tin leave the amalgam in greater excess than other metals?

Dr. McCauley. Not if you have a perfect alloy to begin with. If you have a mass that is improperly alloyed or in which the metals have not gone into accurate solution, you may lose more tin in the expression of mercury than other metals, but not so if you have an accurate solution or union between these metals.

I have been impressed with the importance of carrying on this work to a successful end. There is no doubt that the profession is being imposed upon, that we are getting inferior materials without knowing it, and we have no means of telling except by careful research work. We have to take what the manufacturers give us, and, as stated in my paper, ninety-five out of every hundred of the alloys that are offered to save teeth with are unfit. Are we going to sit still and let this state of affairs continue, and grow worse, or shall we take up the matter and see that we get the right kind of materials?

Dr. LUNDY. Have you any plan to suggest, so that we may make a motion to have it carried out at this time?

Dr. McCAULEY. I have no definite plan to suggest, further than that this association is the proper body to take this matter in hand; men of ability and integrity should be selected from this association, men who are above a purchasing price, men who have the ability to do the work accurately, and who will make a *bona fide* report of their findings to this association. This work must be done by such a committee, because it is too much for one man. A man cannot conduct a practice and do this work as it should be done. Your Research Committee would perhaps be a good one to which to assign this investigation, if they are willing to undertake it. At least this association should appoint a committee to take this matter up and complete the work as soon as possible. The business heads of the association are better prepared to lay out plans than I am, but this is a work that we must do before we can come to an understanding, and it should be done in such a way that everybody may get justice, and every manufacturer be condemned who should be condemned, because they have no right to supply the profession with such trash as many of the alloys now on the market represent.

Dr. W. E. LUNDY, Memphis, Tenn. I move that this section appoint a committee to meet with the Executive Council, take up this matter, and do what can be done to get the results we desire. And further, that this section request the Council to co-operate with the committee. [Motion carried.]

Dr. PRICE. I will appoint this committee later.

The section was then declared adjourned until a later session.

WEDNESDAY—*Afternoon Session.*

The second session of Section I was called to order on Wednesday afternoon, September 11th, at 2.30 o'clock, by the chairman, Dr. W. A. Price, Cleveland, Ohio.

Before proceeding with the regular program of the section, Dr. Price introduced to the section Dr. G. H. Watson, Berlin, Germany, secretary of the American Dental Society of Europe.

Dr. WATSON. *Mr. Chairman and Gentlemen,*—This is a little bit sudden. I am very grateful for the compliment and the courtesy which your chairman is conferring upon me in allowing me to bring to you the greetings of the American Dental Society of Europe. We extend to you an invitation to visit our meeting next year in Europe—which will be held at Easter time in Florence, one of the most beautiful cities of Italy and Europe. If we can have the pleasure of having any of you with us, we will be very glad to see you and will treat you as well as we can—and some of the men over there know how to do that.

The first order of business before the section was the reading of a paper by Dr. L. G. SINGLETON, Pittsburgh, Pa., entitled "The Significance of Normal Occlusion."

[This paper is printed in full at page 20 of the present issue of the COSMOS.]

Discussion.

Dr. J. A. GORMAN, New Orleans, La. The question of normal occlusion is most vital, not only for the orthodontist and the prosthodontist, but for every practicing dentist. The operator often wonders why his fillings do not remain in position, and if he stops to analyze the reason, he will find that normal occlusion plays a very important part in filling operations.

The essayist states that normal occlusion can obtain only if all the teeth are present. The day has come when the importance of preserving all the teeth and keeping them in normal occlusion is being more and more fully recognized. The extraction of teeth, in my opinion, is very much like a jeweler's statement that a watch which he is to repair has too many wheels in it. Would the manufacturer put too many wheels in a watch? This is an argument which I use every day in my practice, and this very question is a good start for educating the public, to say nothing of the dentist.

One of the greatest difficulties that the orthodontist encounters is when the patient has lost some of his teeth and the orthodontist is called upon to place the remaining teeth in their proper positions and retain them there. This maintaining of the spaces where teeth have been lost is one of most difficult tasks, and one that could be profitably discussed by the general practitioner.

Dr. H. C. Ferris, New York. From an orthodontic standpoint, I consider the paper we have just listened to a classic. Those who have made a close study of histology, embryology, and anatomy, will find on careful perusal of Dr. Singleton's paper that he has most ably covered every phase of the subject. He has treated this most scientific subject of the line of occlusion in a delicate and comprehensive manner. This line of occlusion is a mystery that we frequently consider solved when we present a record case of models showing the original condition and the finished product. That finished occlusion, as we see it in the plaster cast, although it may be perfect mechanically, and answer our definition of normal, does not represent the line of occlusion. We have to consider that occlusion in conjunction with the whole animal, with the development of the whole cranium, and it is in that particular that the true orthodontist will develop the ability to treat the individual case that comes before him. No man is able, in the present development of science, to set a plan for us to follow; the method of procedure must be based upon a knowledge and an artistic consideration of the whole anatomical structure.

The subject of heredity, which the essayist touches upon, is also far-reaching in its influence. We are now trying to apply Mendel's law in the interpretation of irregularities and the explanation of deformities, lost structures, etc. It must be considered in this connection that the human being is a much more difficult subject to study than the lower animals. I believe that on a second reading of this paper, you will all be edified.

Dr. R. A. Day, San Francisco, Cal. I wish to compliment Dr. Singleton upon this excellent paper. He has presented the subject so clearly that the orthodontist, as well as the general practitioner, cannot but fully appreciate its importance. We all should understand occlusion, and should devote a great deal of study to it. It is of great importance in every way, not only from the standpoint of the orthodontist, but from that of the general practitioner, as Dr. Gorman has said.

The dentist should recognize the principles set forth by the essayist early enough in life to be able to diagnose conditions and appreciate the necessity for correcting irregularities. This paper will give us much food for thought.

Dr. V. H. Jackson, New York. I have given this subject considerable thought, and wish to congratulate the essayist upon having covered it in such a concise manner. I firmly believe and advocate that every dentist should have very thorough instruction in this subject and know the consequence of the loss of each individual tooth, and practice accordingly. I wish I might be able to discuss this paper at greater length, but I am not at all prepared to do so.

Professor Subirana, Madrid, Spain. No puede haber ningún ortodoncista que no tenga ideas propias sobre la significación de la oclusión que constituye la base de la Ortodoncia? Creemos en las leyes de evolución orgánica establecidas por Darwin? Creo que no habrá ninguno de los que me escuchan que no comulgue en ellas. Con decir pués que la oclusión humana es el resultado de la sucesiva adaptación del sistema dentario animal á las necesidades por ese sentidas á través de las edades desde que apareció el primer diente en los peces, queda hecha su apología; y así como más descendemos en la escala zoológica vemos más uniforme y simplificado el sistema dentario, más vario y especializado lo encontramos á medida que ascendemos en la escala animal, hasta llegar al hombre, cuyo sistema es la cúspide de lo perfecto precisamente por ser el resultado de la adaptación, y así vemos cómo él tiene muelas, bicúspides, caninos, etc., variedad dentaria que responde á su cualidad de omnívoro. Quien mutile en una ó dos piezas esa oclusión, desde aquel momento deja de ser ortodoncista para convertirse en cirujano como dijo el Sr. Singleton, porque precisamente esa es la misión ortodóncica, la de restituir la normal oclusión alterada. Es qué solo tiene importancia esa oclusión bajo el punto de vista de la digestión? No; todos sabemos lo que representa en el orden biológico la *excitación funcional*, y ahí está precisamente su importancia, en el estímulo mecánico que representa, ejercida normalmente millones de veces, en la sangre, en la linfa, en los músculos, en los huesos é indudablemente en el cerebro. No solamente no hay diente que no cumpla su función excitadora, sino que no hay cúspide, ni plano inclinado que no ejercite su modesto papel, y quien al corregir un diente no lo considere así, merma la eficiencia de la oclusión.

Yo llego más allá; he dicho ya y repetiré aquí que por no ejercitarse la función masticatoria y por mutilarse la fórmula dentaria normal, y en consecuencia la oclusión, desde millones de generaciones, los niños que sufren de erupción dentaria dolorosa y difícil, es debido á que la herencia ha ido transmitiendo cambios de fórmula por falta de excitación funcional y los folículos dentarios han perdido su potencialidad de erupción.

La carencia del conocimiento de vuestro idioma me impide continuar, pido mil perdones al auditorio.

[Translation.]

Prof. SUBIRANA, Madrid, Spain. Can there be an orthodontist who has no ideas of his own as to the meaning of occlusion, which constitutes the basic principle of orthodontia? Do we believe in the laws of organic evolution established by Darwin? I do not think there is a man in this audience who is not influenced by them. By saying, therefore, that human occlusion is the result of the successive adaptation of the animal dental system to the needs developing through the ages since the appearance of the first tooth in the fish, its apology is made; and in the same way, the farther we descend in the zoölogical scale the more uniform and simplified a dental system we find. This system is the more varied and specialized as we ascend the animal scale until we reach man, whose system is the most perfect on account of its being the result of adaptation, and thus we see how he has molars, bicuspids, canines, etc., a dental variety necessary for its purpose of serving an omnivorous animal. He who mutilates that occlusion in one or two instances ceases to be an orthodontist and becomes a surgeon, as Dr. Singleton has said, because the orthodontist's mission is that of restoring the altered conditions of normal occlusion. Is this occlusion important only from the viewpoint of digestion? No; we all know what part the *functional stimulation* plays in the biological order, and on this depends exactly its importance, viz, in the mechanical stimulus that it represents, normally exercised millions of times in the blood, in the lymph, in the muscles, in the bones, and undoubtedly in the brains. Not only is there not one tooth which does not fulfil its exciting or stimulating function, but there is not a pyramid or an inclined plane which does not play its modest part, and the practitioner who, in correcting or restoring a tooth, disregards these rules entirely, will minimize the efficiency of occlusion.

I go further than that. I have already said that owing to the lack of exercise of the masticatory function and to the mutilation of the normal denture, and, with it, the mutilation of normal occlusion, which has been going on for millions of generations, the modern child suffers from painful and difficult eruption of its teeth, owing to the influence of heredity, by which changes in the denture have been transmitted owing to lack of functional stimulation, and the dental follicles have lost their potentiality of eruption.

I should like to proceed, but must now close, as I am not sufficiently familiar with your language to address you in it.

Dr. E. A. Bogue, New York. It is certainly with pleasure that, after two or three minutes' perusal of Dr. Singleton's paper, I take up the subject where he left off, and with your permission, go backward a little in its early history. Orthodontia, as I understand it, does not mean mutilation in any sense. Not long ago I received a letter from a friend in Europe who is an orthodontist and who made use of the following notable sentence: "Isn't it grand that, instead of repairing a few broken-down teeth, we undertake to repair or put in order the masticating apparatus of man and make it complete." The thought of mutilation had never entered his head, and I feel thankful to him for his mode of expression.

The title of this paper is, "The Significance of Normal Occlusion." Mr. Chairman, may I be permitted to modify it so as to read: "The Significance of Abnormal Occlusion"?

There are two sharp critics here, Dr. Ferris and Dr. Jackson, and when they find me wrong I hope they will correct my mistakes. Abnormal occlusion means, I think, almost always a diminution of the lumen of the air-passages. When, how, and why does that diminution take place? It often takes place before the first year of the child's life is completed. How does it take place? It very often—although I cannot give any statistics—is due to the presence of adenoids. At once we are confronted with the questions, What are adenoids, where do they come from, and why are they present? It is singular that adenoids should have existed always as far as we know. Canova made a statue of himself and represented himself as a mouth-breather with a stupid look, which, we know, did not belong to a man of his mental ability; yet in the lasting marble he has put himself down as a sufferer from adenoids.

There is the so-called tonsillar ring. We have heard it said many times that every baby is born with adenoids. This statement, I think, is a misuse of terms. Every baby is born with five little nodules, two of which become tonsils, while the other three are waiting perhaps for mischief. Most mothers, when their children catch cold, do not think much of it; they do not realize that by a single attack of cold the baby may be laying the foundation for shortening its days. The baby catches cold, and the irritation and inflammation perhaps extend into the nasal passages, down the naso-pharynx and beyond, to those nodules of the tonsillar ring, and these enlarge and become inflamed and form what we call adenoids, situated between the other two nodules and behind the pendulous portion of the soft palate. The child subsequently breathes through the mouth instead of the nose, because of this obstruction. Many mothers do not realize the seriousness of this condition. The adenoids become a mechanical obstruction to the child's breathing. When the child opens the mouth in order to breathe the muscles of the mouth are drawn against the row of teeth which are inside of the gum and not yet developed; the tongue is distracted from the roof of the mouth and no longer pushes upward and outward, and anterior protrusion ensues owing to lack of lateral growth. If no attention is paid to that condition, the air-passages will not be wide enough to allow a free flow of air to fill the lungs, and the lungs do not fully develop. If the lungs are not developed, the thorax cannot be developed, and instead of growing up straight, the child becomes round-shouldered, the spinal column becomes distorted, generally anteriorly. Very often a lateral curvature of the spinal column occurs, a weakness of the heart follows the diminution of lung capacity, a diminution of the thorax cavity ensues, and the child is manifestly an invalid. Many times when expressing before my professional brethren my views that I have yet to see a single case of saddle-shaped arch which was not accompanied by curvature of the spinal column, I have noted their utter surprise.

We are just beginning to realize that it is the dentist's duty to warn the mother that her child, though it be beautiful and perfect apparently, may belong to that seventy-one per cent. of defectives mentioned today by Dr. Ebersole, as found by the New York State Board of Health. If we are able to discover these defects and remedy them at an early age, we shall be of greatest service to the child. I am treating children from three and a half to five years of age, and I hope that the rest of my practice will be made up of that class of patients. Then I shall be able to say to many parents, as I said to a professor in a medical college yesterday: "I am glad that your baby has every prospect of having its life prolonged for years by what has been done. He breathes better, catches no more colds, and the prospects are that he will be a healthy child instead of a sick one."

Dr. M. C. SMITH, Lynn, Mass. I would like to say a few words on this vital question, also to call Dr. Bogue's attention to one error he has made when he spoke of the three nodules looking for mischief. They are not there looking for mischief, but for a physiological purpose, and in order to assist the economy of the body in supplying a deficiency. We are not getting at our patients early enough. We are only doing repair work, and the orthodontist does the most repair work of any. We must get at our patients earlier and not have so much repair work. The vital principle is to avoid delay of treatment. We may not know today just what all these enlargements of the glands of the throat mean, but there are a few facts which we know about them, and we should work on the basis of those.

We know, for instance, that, if we treat a cretin child with thyroid extract, the growth of the teeth is remarkably stimulated. We know also that the pituitary body has some influence in the fixation of lime salts in the body, and that the parathyroid glands have something to do with the lime salts in the blood-current. Let us, then, study these ductless glands and learn which one is controlling that part of the economy of the human body called the mouth. If the pituitary gland in a young person is diseased, giantism will result. Disease or enlargement of the pituitary body in adults causes a malady which is very rare in America but common in other countries—acromegaly, enlarged growth of the long bones, and especially of the lower jaw. A careful study of these glands should reveal which one is to blame for deformities in the mouth.

These nodules which Dr. Bogue spoke about have a physiological function to perform. They are not diseased glands, but by sympathetic enlargement they help supply what is lacking in the thyroid gland as the fixation agent of lime salts in the body. We have to go farther back, to the very first months of fetal life. If a pregnant mother seeks relief from nausea and morning sickness, she is given thyroid extract. If the nursing mother fails in the milk supply, she is given thyroid extract to stimulate the milk supply. Nursing is the physiological action of the child necessary for the development of the pharynx, the lungs, the spinal column, and the maxillary bones, and is one of the vital principles underlying orthodontia. The child must nurse in the way that nature intended it to, and if it does not receive its supply of milk from the mother, it cannot develop properly.

We must get down to the vital underlying principle and find out what is the reason for the sympathetic enlargement of the glands to supply the thyroid extract deficiency in the fixation of the lime salts in the body. The parathyroids are generally acknowledged as controlling the lime salts in the blood-stream, and the thyroid the fixation of the lime salts in the body. The pituitary body may have something to do therewith, but we must investigate and study, in order to ascertain which one of the ductless glands is at fault.

Dr. SINGLETON (closing the discussion). I will not take any more of your time in closing the discussion. My views have probably been expressed as carefully in the paper as I can express them. I wish, however, to thank those gentlemen who have assisted me in the effort to interpret the significance of normal occlusion. I think we are all beginning to realize that this significance is a very great one.

(To be continued.)

DENTAL SOCIETY OF THE STATE OF NEW YORK.

Forty-fourth Annual Meeting.

(Continued from vol. liv, page 1160.)

FRIDAY—*Afternoon Session.*

The society was called to order Friday afternoon at 2 o'clock, by the president, Dr. Hillyer.

The first order of business was the report of the Committee on Scientific Research, by the chairman, Dr. W. B. DUNNING, New York, as follows:

REPORT OF COMMITTEE ON SCIENTIFIC RESEARCH.

Your committee in its last report urged strongly the need of directing its work along some line of research which would have a definite value in the broad study of the causes underlying dental caries, and of possible measures to prevent the inception of that disease. It was suggested that a sum of money sufficient to pay a trained investigator be appropriated for that purpose, and that the work be placed in hands competent to carry out the most approved methods under the best laboratory facilities. It was hoped that such results, however scanty in extent, might be reached in a manner as nearly determinate as the nature of the problem admits, in order that future investigators might depend upon those findings as a groundwork for further inquiry. The importance of reducing to a minimum the necessity for duplicating work is self-evident.

It was voted that five hundred dollars be expended for this purpose during the year. Prof. William J. Gies of Columbia University, who for two years has conducted the experimental work of the committee, decided that an inquiry into the sulfocyanate question, as a whole, would be a contribution of essential value at this time. Your committee therefore placed this subject in his hands, and his report will speak for itself. The actual experimental work has been performed by Dr. Max Kahn, under the direction and with the co-operation of Dr. Gies, and this work has occupied Dr. Kahn's entire working time throughout the last winter. Dr. Gies has received no recompense for his personal work, and the very moderate charge of forty dollars was the only tax for supplies, many of the standard preparations being supplied by the university laboratory. The committee is sure that the society at large will appreciate this distinterested attitude of Dr. Gies and the authorities of Columbia University, who thus indicate their desire to further an inquiry of such public utility as the one in hand.

Respectfully submitted,
WM. B. DUNNING,
Chairman.

The next order of business was the reading of a paper by Dr. WILLIAM J. GIES, M.S., Ph.D., New York, entitled "An Inquiry into the Relation of Potassium Sulfocyanate to Dental Caries."

[This paper is printed in full at page 40 of the present issue of the COSMOS.]

Discussion.

Dr. E. C. KIRK, Philadelphia, Pa. I must as graciously as possible decline to open the discussion on this paper, for the reason that I do not regard it as discussable in its present stage. If I remember correctly it is recorded in the Old Testament scriptures somewhere of a horse in battle, that he said "Ha, Ha!" I heard of a little girl being asked about that equine incident, and she answered that what the horse said was, "Hay, hay!" I am rather inclined to the latter view myself, but I want to say "Ha, ha!" first for the presentation which Professor Gies has made here of the scientific attitude of mind toward this question. We have been heretofore dealing with it empirically and with prejudice—I want to put it just that way, in just those terms. The reaction of ferric chlorid with the saliva, containing what we believe to be sulfocyanate, is the most striking salivary reaction we have, and the tendency has been to jump to the conclusion that it must be as important as it looks. The ferric chlorid reaction is the most dramatic thing in a chemical and physical sense that the saliva happens to do with any reagent, and therefore we have concluded that it must be a very important thing. Doubtless scientifically it is important, bút I think we have attributed to that particular reaction an importance which is not as yet justified.

I want to thank Professor Gies for saying another thing with which I am in hearty accord, and that is that literally we know nothing about the meaning of the sulfocyanate reaction in saliva—that what we know about it is almost a minus quantity. In a clinical way I have studied the question somewhat, and I have been unable to trace any relation whatever between the occurrence or non-occurrence of sulfocyanates in the saliva, as indicated by the ferric chlorid reaction, with any activity or non-activity of the carious process. I have come to the general feeling—I do not want to dignify it with the name of a conclusion, because I have not reached any conclusion—but I have come to the feeling, which is entirely in sympathy with the statement made by Dr. Gies, that this substance is principally a waste product of metabolism, an excretory subtance that may be coincident with various observations made in a clinical way either for or against the caries problem, but that it has any causal relation to immunity or susceptibility itself I doubt very much. On the chemical side, the various lines of research as indicated by the experimentation which has been here reported are intensely interesting. I should like to ask Professor Gies to tell us in closing the discussion whether he has made any experiments to discover, if possible, the relation of the liver metabolism to potassium sulfocyanate or any basic sulfocyanate formation. That is to say, whether the blood entering the liver and leaving the liver has been examined to see what difference exists in the sulfocyanate content. I would like to ask him also as a physiological chemist whether he has any data or thought regarding the possible relationship of the existence of sulfocyanates in the blood or in the bodily secretions or excretions to urea formation. That, it seems to me, is of interest in view of the close relation of ammonium cyanate in its chemical composition to urea; whether it may not be one of those side products along the line of urea formation which has occurred incidentally as the result of an error in the metabolic processes.

I want further to congratulate the Dental Society of the State of New York for having gotten into relationship with a source of scientific activity that has, from my point of view, demonstrated its capacity and ability to ultimately solve this problem, and I want to express my pleasure in witnessing the laying of the scientific foundation, here, under the auspices of Professor Gies, that is, I believe, ultimately to bring us to the apex where that question which I know we as practical men want answered, shall be answered—that is, What has this dramatic chemical reaction of the sulfocyanates in the saliva in a practical way to do with the problems we are meeting in the effort to combat the ravages of dental caries? I may incidentally report from memory only one experiment that I made in this connection. In Professor Gies' report of his experiments I was constantly looking for my friend the rabbit in the list of animals as having been put through the sulfocyanate poisoning test. Some years ago I began feeding half a dozen rabbits on sulfocyanate of potassium in increasing step doses. I did not conduct the investigation with scientific accuracy, so that I can give you no figures. I was simply endeavoring to find what the obvious reactions to the drug were in the animal, and this I distinctly noticed—that it increased the arterial pressure and increased the frequency of the pulse beat, and that it produced a condition of hypersensitiveness or hyperesthesia upon the rabbits. It was interesting to note that, in the rabbits under the influence of potassium sulfocyanate, simply taking firm hold of the ear was sufficient to make them squeal. The rabbit is a timid animal, yet it takes much to make him squeal from pain, and this hyperesthetic state was related distinctly to the increase in the dosage of the sulfocyanate. It would seem, then, that nervous and vascular stimulation of that sort could not occur without some definite functional effect that might or might not be productive of harm.

I want to thank Dr. Gies for his emphasis on the possible physiological effect of this drug when internally administered, and for his verification of the work of other observers—confirming the view that, within the limits in which we find this substance in the saliva, it is practically without any antiseptic value whatever through the fluids of the mouth.

I do not offer this as a discussion, but merely as a running comment on what I regard as a most admirable presentation.

Dr. H. C. Ferris, New York, N. Y. I have learned more in the last hour than I have learned in five years' reading on this subject, and I believe that the scientific world can congratulate us upon the fact that we have Columbia College interested in this field. The National Dental Association has been undertaking this work in their scientific committee, and we have been endeavoring to bring out a technique which would be of practical diagnostic value. We have submitted our technique to criticism, but have been unable to get expert experience or expert experimental work in this particular field, so that I for one feel very grateful to Professor Gies for his efforts.

I want to cite my experience with thiocyanates from the clinical standpoint, and also the method which I have adopted to determine the quantitative value of thiocyanates in the saliva. Many are familiar with the technique adopted by the National Dental Association committee. Of course, we have used there the ferric chlorid as our reagent. As Dr. Gies said, ferric chlorid may be proved faulty in a certain percentage of cases where drugs have been administered to the patient, but in the majority of cases, from a personal experience of eight or nine years, during which I have been building up data upon this particular subject, I find that by this simple method of procedure I am able to obtain definite physiological results which are comparable with the blood pressure. The systolic pressure is registered by a most perfect machine, and the effects upon the cases in which the drug has been used in conjunction with the medical adviser have been remarkable, and I am only anxious to have the Columbia University investigators reach that point in their investigations. The method that we are utilizing to determine the percentage of thiocyanate requires the aid of these two little tubes [illustrating]. We utilize thiocyanate of ammonia as the basis or indicating carrier, as the thiocyanate of ammonia seems to strike a more normal color with that of saliva, using ferric chlorid as the reagent. In tube A we have 1 cc. of the specimen, and in tube B 1 cc. of a 1:2000 aqueous solution of thiocyanate of ammonia. In one tube we have a known quantity and in the other an unknown, and by adding one drop of dilute hydrochloric acid solution to the specimen, we precipitate the mucins and the albumins immediately, which also combine with any small quantity of diacetic acid if present, and that leaves a comparatively clear solution. Then by adding ferric chlorid, two drops to each tube, we strike colors. To this tube of known quantity we add water to reduce the color until it matches the specimen; then read the scale in thousandths. It is evident that there is a very small quantity of thiocyanate in this specimen [illustrating]. We then match these, and, if I think the eye is not sufficiently accurate, the specimen is placed in the colorimetric box, and the color determined by artificial light. In this instance it might read 18 thousandths, so we would consider that we have 1 part in 18,000 of thiocyanate in this test. I believe this method to be the most accurate and simple of any advanced today. By its use sufficiently accurate findings for diagnostic purposes can be made, and the accumulation of the drug in the patient's saliva under treatment observed. It is my practice to take blood pressure and record it when I undertake the administration of thiocyanate internally.

In order to bring this more potently to your attention, I would relate the effects of the treatment of a case which in its entirety is worthy of physiological notice. After listening to a paper read before the New York Institute of Dental Technique, by Dr. Bernard R. LeRoy of Athens, Ohio, on this subject, I was encouraged to recommend the treatment to a physician who was treating a male patient of seventy-five years for "chalk eye," or blindness due to an exudate in the anterior chamber of the eye following an operation for cataract. Dr. Peter Callan of New York performed the operation. In three weeks the trouble reappeared, and Dr. Callan performed a second operation and removed the exudate from back of the anterior chamber—which resulted in no value, as the exudate formed the second time. The man had no treatment for five years, and was totally blind.

At first examination I found with the aid of my colorimeter that the patient had 1 in 9600 parts of thiocyanates in the saliva. By centrifuging there developed 50 per cent. of solid matter in 20 cc. The blood pressure was 135, and the urine was as thick as molasses. This patient was given one grain of sodium thiocyanate in water per day, in three doses *t. i. d.* under the observation of C. E. Scofield, M.D. Four days afterward an examination was made for thiocyanates, and the scale read 1 in 9000, increasing 600 points. In nine days it increased to 1 in 7500. The blood pressure ran up to 190. We then reduced the dose to a half-grain per day, and at the end of two days took a specimen of the saliva, which showed a decrease in the strength of thiocyanate, making the figures 1 in 8500, and the blood pressure 150. We then put the patient on the original dose, and the results were as follows:

In seventeen days we took the blood pressure, which stood at 175; in twenty-one days it went down to 145; in thirty days it jumped again to 160; in forty-one days the thiocyanates showed 1 in 6000 parts, and the blood pressure stood at 195. The patient was then suffering with a bilious attack, which resulted in a second accumulation of the drug, and the treatment was reduced to one-half grain. The case went for seventeen days, and was examined again; we found 1 in 5000 parts, and the blood pressure stood at 180, when we stopped treatment. In a week's time, another finding resulted in 1 in 7800 parts, being reduced by 2800 in that time, and the blood pressure had come down to 160. Going over this you can see the definite relation of this drug to the blood pressure. This is heavy dosage, but the man's advanced age and the fact that he had arteriosclerosis, made it possible. I have noticed that, with a physiological dose of this drug, 1 in 2000 parts given one grain *t. i. d.*, in a week's time would raise the blood pressure from 140 to 149, and the thiocyanate would rise from 1 in 18,000 to 1 in 12,000.

At the completion of the treatment of the first case, the saliva was examined for its centrifuged sediment, which showed a reduction of 50 per cent. of the original, and at the end of nine days after the treatment was started, the urine became perfectly clear, all the phosphates having gone into solution, there being no albumin or sugar present; and while the man could not see when we started, the eye had cleared sufficiently so that he could note the passage of a dark object between his eye and a gas jet four feet distant. It is my belief that his vision would have been restored had he been willing to persevere in the treatment, but he became alarmed after a slight attack of indigestion, and, knowing the work to be experimental, he would not permit us to continue.

This case gives us a great deal of material for serious consideration, and would surely lead us to be cautious in the constitutional administration of this drug. It also demonstrates that, if these serious physiological changes are notable, a potency and influence of the drug upon caries must be recognized, and it remains for us to determine the manner of its action.

Dr. F. W. Low, New York. I am laboring under a considerable disadvantage, for two reasons, in attempting to discuss the presentation to which we have just listened with so much interest—first, because, concerning matters pertaining to biological chemistry, I am densely ignorant, and second, because no opportunity could be afforded that I might study or investigate concerning the conclusions and findings arrived at by Professor Gies, later than his 1911 report. My approach to the question as to what may be the effect, upon superficial enamel decay, of the presence or absence of potassium sulfocyanate in saliva, has been made mainly from the physical and clinical standpoints.

When your Committee on Scientific Research declared in 1910 that potassium sulfocyanate had no appreciable influence upon plaque formation that could be termed prohibitory, I immediately made a pilgrimage to New York, where I found that Professor Gies and I apparently were not viewing the same pictures.

Though the 1911 report was in no sense so positive concerning conclusions generally, and asked for an additional appropriation for continuance of the work, still I was not altogether satisfied, feeling that Professor Gies, even with considerably modified opinions, was even yet somewhat severe in his criticism of the behavior of us poor empirics; and since I am presumably the chief offender, I feel warranted in attempting some defense of our precipitate procedure.

The world is under many obligations to empiricism, yea, to the very fact that "Fools rush in where angels fear to tread." Dr. Butler* says:

> I recognize the use of the conservative element. It keeps the ignoramus, the charlatan, the therapeutic enthusiast from turning the medical world upside down too fast; it is well to remember, however, that every great advance of truth passes through the stage at which men call it heresy. The introduction of cinchona was at first most bitterly opposed, not only by the medical profession in England, but by the English church. To the impudent and presumptuous quack Paracelsus is the medical profession indebted for mercury as an internal specific remedy. The success of a patent medicine is responsible for colchicum. Arsenic was introduced into England as a remedy for intermittents in consequence of the success of a patent medicine. Iodin was discovered by a saltpeter manufacturer, sulfur was first used by the common people for scabies, and it took a long time for the "profession" to acknowledge that there was any virtue in it. Nearly every one of our indigenous medicinal drugs used today by the regular profession has been forced upon us by the eclectics. The use of lobelia was taught us by the American Indian. A dairy-maid gave Jenner the idea of vaccination. A marketwoman taught us how to catch the itch insect, and we borrowed acupuncture and moxa from the "heathen" Japanese. A monk taught us how to use antimony, a friar how to cut for the stone, and a postmaster how to sound the Eustachian tube.

---

* Geo. F. Butler, A.M., M.D., professor and head of the Department of Therapeutics and professor of preventive and clinical medicine, Chicago College of Medicine and Surgery, in an article that appeared in the September 1909 issue of the *Medical Standard*.

And how had it been, gentlemen, about the crowning achievement of empiricism, if Horace Wells, the comparatively uneducated but venturesome empiric had failed to have the courage, simply because he saw a neighbor bark his shin and bleed into his boot while half intoxicated? If, for want of courage, Wells had failed to challenge anesthesia, even the while she wore the mask that dissembled the look of death, this priceless boon which we enjoy today might still be awaiting—some other Horace Wells, some other venturesome empiric.

If I am to be considered among "the venturesome"—to quote from Professor Gies' report of 1911*—"who have been prescribing sulfocyanate internally, in comparatively large doses—without reporting or seeming to know or even caring anything about the pharmacology of the quantities thus administered," yet let me say that I began as Professor Gies himself has recommended, by "trying it on the dog"—that is, upon myself; but lacking somewhat in courage, I first consulted Professor Hill, who at the time occupied the chair in chemistry at our Buffalo university, and who told me that personally he would not be afraid to self-administer ten grains at a single dose so far as toxic consequences were concerned.

As to the therapeutic properties of KCNS, I knew that Squibb's *Materia Medica* of 1906 had this to say: "Antispasmodic, nerve sedative, in dyspnea, spasmodic cough, mania, etc. Dose, 1 to 5 grs.," and this I had reported to this society.

Before advocating stomachic medication among my *confrères,* I knew also that Merck's 1907 *Index* recommended such administration as a sedative, antispasmodic, anodyne, to be prescribed in cases of phthisis, cough, catarrh, dyspnea, mania, etc., in doses of from three-fourths of a grain to three grains, the maximum dose being given as five grains at one single administration, and twenty-four grains as maximum *per diem.* To be sure, for our purpose such dosage is not necessary, but, even if in error others should so consider it, I have heard or read of no dentist exceeding these safe limitations.

So far as I know, none of my *confrères* have observed any untoward consequences following the administration of this drug. One highly excited gentleman only—he came from the sunny South—wrote to urge me to abandon sulfocyanate, saying that he had given—I am not quite positive whether it was one or two ounces—to a rat, and the rat died. I replied that I felt quite confident that his finding was correct, but that I had no doubt that, had he poisoned the poor rat with an equal quantity of common table salt, he would have attained the same result. I think that at least it may truthfully be said: "If it does no good, it will do no harm," and "will serve very well as a good placebo remedy."

It *is* true, even as Professor Gies avers, that "Observers in the past have not agreed" as to the value of potassium sulfocyanate in saliva as a deterrent to plaque formation on the enamel of the teeth, but that was before the advocacy of the iodin stain experiment which I suggested in my paper read before the National Dental Association last July.

In several instances, when I have made inquiries concerning methods of procedure and the number of retrials, I have been satisfied that adverse criticisms were unwarranted, and at least in one instance I cannot escape the conviction that your distinguished essayist permitted himself to be sponsor to an error. I refer to his conclusions after experimenting upon the students in Columbia College.

If each of you will picture in your mind's eye a series of experiments conducted upon some forty-odd college students varying in age anywhere from twenty-one to forty, most of whom were more or less addicted to the smoking habit, and few of whom within the range of the ages I have mentioned would probably be afflicted greatly with what we as dentists would designate *rapid superficial enamel decay,* and with the conditions in their mouths largely dependent upon the character and value of dental operations performed by practitioners of widely vary-

* *Journal of the Allied Societies,* vol. iv, No. 4, December 1911.

ing skill, you can easily comprehend the difficulty of arriving at any just conclusions as to whether the natural presence of potassium sulfocyanate had any deterrent influence.

Compare conclusions arrived at under such circumstances with that other series of experiments conducted by your essayist at about the same time, in which he had the co-operation of several of New York's most distinguished operators, both as to selection of cases and as to diagnoses, in which series Professor Gies himself reported that among immunes there was, on an average, just twice as much potassium sulfocyanate as among susceptibles.

In the latter series the diagnosticians knew whether superficial enamel decay was actively present at the time of examination; whereas, in the other series, this condition very likely *may* formerly have been active, but may have entirely or materially diminished even two or three years previous to the date of examination.

As you often have heard a learned advocate plead, "I object to the admission of the evidence"—the college student evidence—on the ground that it is unreliable, misleading, prejudicial, and irrelevant. And furthermore, I submit that my pet sulfocyanate theory is proved —by the "testimony of the most trustworthy and reliable witness for the prosecution."

That, even as upon sowing a tiny mustard-seed, the sulfocyanate theory is growing and spreading is attested by returns from far-off South Australia, from "sunny" England, and from benighted India. In the *Commonwealth Dental Review* for July 1911, published in Sydney, the leading article is the essay of one F. M. Bradshaw, L.D.S., B.D.S.Vic., which was read before the Odontological Society of South Australia. The paper is too long to be read at this time *in toto,* and I shall therefore make mention of only a few of its most interesting statements:

The observations of Dr. Lohmann show that at certain times and in certain diseases caries makes rapid progress, and during such periods no sulfocyanids could be found in the saliva, while caries is retarded as soon as sulfocyanids are again present.

At the present time research on this subject is in its infancy, and there are no definite conclusions to be drawn. From clinical experience, however, the administration of KCNS has been found to exert a decidedly favorable action on the secretions, and is especially beneficial in mouths where a thick and ropy saliva is present, . . . for deciduous teeth that are carious beyond any hope of repair, especially in nervous children. With hypersensitive dentin it renders excellent service. The presence of sulfocyanates also keeps the mucous membrane in a healthy condition. In many constitutional disorders it is found that sulfocyanates are absent from the saliva. . . . To verify the statement of Dr. Michaels that a very constant relationship exists between the absence of KCNS and the prevalence of caries at that period, Levy treated patients during pregnancy, whose saliva contained none or only a very slight trace of KCNS, with tablets containing 0.1 gm. malt, 0.05 gm. malt diastase, 0.008 gm. KCNS. The results were most gratifying. There had been no fresh occurrence of caries in any case, although several of the patients had suffered extremely from their teeth during previous confinements. In cases where caries had supervened before treatment was commenced, the extreme sensitiveness of the cavities had been relieved.

KCNS is especially indicated for boys and girls at the attainment of puberty, when the teeth suffer so much, and in women during pregnancy. An alkaline purge should also be advised to increase the fluidity of the blood and stimulate the kidneys to functionate normally, thereby assisting the metabolism. KCNS is often given by physicians in diseases which are associated with periods of rapid tooth decay.

From Bombay, India, we have the assurance, as late as December 7, 1911, that clinical observation leads L. H. Wirt, D.D.S., to believe that KCNS tends to restrain the growth not only of the plaque of Black, but also deposits of a slimy nature generally. Its use seems to tend to make the mouth more self-cleansing.

In the latest and most authoritative English work on "The Prevention of Dental Caries and Oral Sepsis," Professor Pickerill* says: "The amount of sulfocyanate in the saliva may be readily increased by internal administration," and that advantage of this may be taken in cases where a continuous antiseptic action is desirable, such as in rapid and acute caries of children. He adds: "The drug is not an active poison, and may be given advantageously in repeated doses of one-fourth to one grain."

It is an old saying that "A prophet is not without honor save in his own city." As a discredited and persecuted prophet I have no fear that I shall be crucified or burned at the stake in Buffalo, however. Attest—the spicy "Buffalo Letter" appearing in the December 1911 *Dental Practice* of Toronto. This epic is written under the *nom de plume* of Habec, which being untangled would be made to read "J. Wright Beach of Buffalo." It bears the euphonious caption of "Wind Pudding *à la Mode.*" After disporting somewhat facetiously at my expense as well as at the expense of the editor of the DENTAL COSMOS, in the language of the poem its author gets down to "brass tacks," and says that "Dr. Low *knows* . . . . while Dr. Kirk merely illusionizes," and then he queries, "Why not show the madness of our method, and hand out something that one can get hold of and turn into good teeth?" Habec then challenges Professor Kirk to—

deliver a package of the real article like this one: A miss of some eighteen happy summers whose ivories have been under the watchful care of Habec for at least eight of the above-mentioned seasons, was but yesterday within the environs of his dental outfit, and a test of the saliva of this young lady was made, and revealed a sufficient quantity of sulfocyanate in it to render the teeth comparatively safe from decay. History: For the first six years of our care it was a nip-and-tuck fight to save the teeth from destruction by caries. In spite of our best efforts cavities seemed to appear over night, as it were. Three years ago the saliva was tested and showed pale lemon in color, together with mucin much in excess. Potassium sulfocyanate was prescribed in the usual way, and after one year results began to be noticeable. At the end of the second year, decay of the teeth appeared to be nearly arrested, and yesterday but two slight repairs were made about defective fillings. For the last eighteen months no sulfocyanate had been taken, yet the saliva test showed the light red color indicative of full normal percentage of this necessary ingredient, and the quantity of mucin was not excessive. The enamel surfaces had changed from a dull, lifeless cast to that of glistening translucence, and were readily freed of the little extraneous matter. A bright, intelligent face enhanced by such teeth is the argument Habec puts up against a large wind pudding. And this case is but one among the many we might record to show the value of this treatment and the persistence of the sulfocyanate in the saliva after nature has been assisted to secrete it. So what care we whether or not Zoöglea is second cousin to Mucin, or Microbe is father to Gelatinous Plaque? It's "mox nix ouse" to us, so long as sulfocyanate of sodium and hydrastis in tablet form given internally does not interfere with physiological processes and puts the kibosh on Micro and his ilk.

Corroborative of Habec's testimony I offer the accompanying compilation—it records the behavior of the teeth in the mouths of two of my patients that I consider in the class of the most extremely susceptible: Marjory and Marion are sisters, who first came under my care in 1908. Marjory is the older by four years. Marjory had just passed the day of longer skirts and the critical experiences which are associated with the recurrence of every new moon, and was in several respects a fit and proper subject for systemic medication according to both Squibb and Merck.

Upon examination there appeared to be no sulfocyanate in her saliva, while it was extremely thick, ropy, and strongly alkaline; consequently I prescribed teaspoonful doses of Schlotterbeck compound (hydrastis and pepsin) after meals, and one-half grain potassium sulfocyanate each night at bedtime. This treatment I ordered continued for twenty days; then, after a rest of ten days, I again examined the saliva, and found, to

* "The Prevention of Dental Caries and Oral Sepsis," by H. P. Pickerill, M.D., Ch.B., M.D.S.Birm., L.D.S.Eng., professor of dentistry and director of the dental school, University of Otago, N. Z.

my very great surprise, that there was no apparent improvement in its condition, and that there was no indication of potassium sulfocyanate. Fearing I knew not what, inasmuch as the usual phenomena following such medication were not obtaining, I discontinued treatment, and went about the filling of her carious teeth. Thirteen cavities were attended to, mostly of recurrent superficial enamel decay occurring about the margins of fillings made by some other dentist.

Observing that these recurrent cavities still continued to develop rapidly, on January 2, 1909, I screwed up my courage and repeated the medication. Again no manifestation indicated that she had taken any medicine, and I gave up the fight, anticipating eventually the necessity of crowning and bridging as the only remedy; and I reported a first case of such idiosyncrasy that sulfocyanate treatment was entirely useless.

Let us here digress a moment to consider conditions that were obtaining in the mouth of the younger sister. Upon first coming under my care she was about nine years of age. No fillings had ever been made in her teeth. Immense crown cavities, involving all but a mere rim of occlusal surfaces, were present in the left upper and both lower first molars, while in her other teeth about a dozen small cavities were detected. Her saliva showed no potassium sulfocyanate and was extremely ropy.

On May 15th I placed her under the same treatment instituted for the older sister. Her system responded promptly to medication, and the condition of her saliva was almost immediately very much improved. During the year I filled the three bad and two other smaller cavities, but this young lady being somewhat headstrong failed repeatedly to keep appointments, though she submitted willingly—as did Miss Marjory—to regular monthly prophylaxis operations. Noting general progress of decay in her teeth, I was gratified to find that it was progressing *very slowly,* while following only her initial sulfocyanate treatment no diminution in its generous proportions seemed to be occurring. On May 21, 1909, I "prophylaxed" her teeth, and made the second of two small fillings. On this occasion she decided to "peach" on her sister, as she termed it, and the fact came out, and was shamefacedly acknowledged by the culprit, that Marjory had cheated herself, and lied to me—that she had never taken any of her medicine. Marjory avowed contrition, and as she promised that if I would prescribe once more she would faithfully take her medicine, I forgave her and consented to prescribe. In consequence, conditions in her saliva and also of her teeth showed marked improvement.

You will note that during the entire year 1910 I had to fill only two small new cavities, and not until the latter part of 1911 did her saliva or her teeth show retrograde conditions. On October 3d, there appearing to be no potassium sulfocyanate in her saliva, which once more was discovered to be extremely thick and ropy, I again prescribed for her, but this time I gave her the combination *sodium* sulfocyanate and hydrastis tablets, for which more agreeably taken substitution I am indebted to the doughty Habec. After the above date recurrent enamel decay necessitated the filling of nine new cavities.

The latest examination of Marjory's teeth and saliva occurred last Monday. I found three cavities in her teeth, two of which were recurrent in badly broken-down first molars that have long been merely "patched up" sufficiently with dwarfed amalgam fillings, so that I might eventually make some gold crowns upon them, and the third a very small cavity consequent upon contamination with the decay of one of these molars. All other teeth are holding fillings well. The appearance of the enamel of her teeth is satisfactory generally, and there is a more than a moderate showing of potassium sulfocyanate in her saliva. [Here the speaker exhibited test tubes of different specimens of saliva.] The sulfocyanate content in each of these tubes, taken in connection with the dates at which the specimens were secured and the coincident conditions at the time the samples were tested, all point conclusively, to my comprehension, to this conclusion: That the presence of potassium sulfocyanate in the saliva does have an inhibitory influence, if not on plaque formation, at least upon conditions of *rapid superficial enamel decay*.

To return once more to consideration of Marion's condition. During 1910 I filled ten cavities; they were all small. These operations were not very painful, and it should be remembered that every one of these had been located and was known about, from her very initial visit to my office (May 1908).

Though salivary conditions remained fairly satisfactory during 1911, I filled four cavities, notwithstanding which the translucence of her enamel remained apparently unimpaired until quite recently. She is now approaching the critical age which her sister passed through four years ago, and on May 3d just past, her saliva again suddenly appeared to be distressingly thick and ropy, and again at the present time she is taking sulfocyanate tablets.

Concerning a case of very remarkable immunity, accompanied by most generous proportions of potassium sulfocyanate in the saliva, I suggest that one of my Buffalo *confrères*, Dr. Murray, be asked to report, and that another, Dr. Meisburger, be induced to relate his experience in making an endeavor to overcome by systemic treatment a distressing condition of hypersensitive dentin and cementum about the cervical margins of the teeth of one of his patients.

Possibly it may be thought by some of you that the lengthy and hypercritical discussion of this subject had better not be taken altogether too seriously. Well, I feel about that as about the little sulfocyanate tablets: It is entirely immaterial whether they be taken seriously or otherwise, so long as they are taken.

Concerning the presence of potassium sulfocyanate in saliva, I have this to say in conclusion—and I would say it most emphatically: *If you don't find it, give it!*—in the meantime continuing to coerce Professor Gies until eventually he finds out the reason why its presence does the work.

Dr. R. Murray, Buffalo. I do not know that I have very much to say. I did not have the privilege of hearing the paper, and only arrived as Dr. Low was mentioning my name, so that I did not have the pleasure of enjoying the paper.

Dr. Low. Dr. Murray can verify what I have said. I simply wanted to prove by him the results in the case that he referred to me.

Dr. Murray. The case to which Dr. Low refers was that of a young lady of twenty-four, connected with the educational department of Buffalo. I found her teeth absolutely immune from decay, so I immediately took a sample of her saliva, and had Dr. Low examine it, with the result as stated—generous proportions of potassium sulfocyanate.

Dr. L. Meisburger, Buffalo. This paper has given me a great deal of pleasure, principally because of the instruction which I have received from it. Sometimes I cannot help but think in listening to such papers as these, which have a tendency to bring the allied professions together, that we are in reality coming closer to the medical profession in the matter of putting our patients gradually to sleep as the latter have been doing, and I wonder if we are not getting into that class possibly by the administration of drugs the systemic effects of which we do not know. I think therefore, that the New York State Dental Society is to be highly commended on bringing this subject to our attention in this way, because we do not want to administer anything that will do harm to our patients.

As to the case referred to by Dr. Low, I had a patient coming to me regularly for prophylactic treatment, a person with a highly sensitive condition of the teeth. I could in no way account for this condition, as the oral secretions were about normal, with the gums and teeth indicating good care except possibly that the patient's index was below par, she having been overworked in her profession as a nurse. I was somewhat nonplused as to what treatment to give in this case. I treated the teeth with formaldehyd of full strength, and recommended the use of bicarbonate of soda on the tooth-brush in direct contact with the tissues of the mouth, and finally the use of Phillips' milk of magnesia; but all of these procedures failed to give the desired relief. Dr. Low suggested the use of potassium sulfocyanate. I followed his suggestion and administered sulfocyanate, and the condition was relieved to a very great extent.

Dr. HOFHEINZ. In how short a time?

Dr. MEISBURGER. In less than three weeks.

Dr. HERMANN PRINZ, St. Louis. It would be folly on my part to discuss this exhaustive lecture we have just listened to. I have been vitally interested in this subject, and have made it a point to look up its literature. Very recently a most excellent summary on this subject has been published under the title, "Vergleichende Uebersicht der hauptsaechlichen Literatur ueber Vorkommen, Nachweis und Bedeutung der Rhodanverbindungen im menschlichen Koerper. Von Dentist Knoche." (*Ergebnisse der gesamten Zahnheilkunde,* vol. ii, No. 6.) I take the liberty of calling Dr. Gies' attention to this paper.

It seems to me that the whole question, when simmered down, resolves itself as follows: Sulfocyanate, as present in the saliva, has to be regarded as a waste product of tissue metabolism; it has no specific significance in regard to antiseptic or prophylactic measures. Dr. Low in his discussion has frequently mentioned the names of Merck and Squibb as references. It must be borne in mind that these names merely represent chemical houses, and that references taken from their price lists and catalogs should not be quoted as authoritative statements. From a pharmacologic point of view, Pauli of Vienna has published some notes on the therapeutic action of potassium sulfocyanate; he employed it principally as a sedative in doses of about one gram. At present, potassium sulfocyanate is rarely employed therapeutically.

Dr. W. B. DUNNING, New York. It is my great regret today that the other members of the committee, Dr. Merritt and Dr. Waugh of Buffalo, are not with us. Dr. Waugh has taken a very active interest in this topic, and I am sure that his discussion on this subject would be of great value. Dr. Merritt, of course, is an active worker in matters of this sort. I feel, however, that I am not taking a liberty with my colleagues in stating that it is the sense of the committee that its successors should be empowered to go on with this really important work. Dr. Gies' statements cover a field of investigation which has consumed an entire winter session. His splendid address has outlined what has been accomplished, yet no one sees more clearly than Dr. Gies that the work is only started—that there is yet much to do; that almost certainly, years will be needed for the attainment of that grand object, the knowledge of causes underlying dental caries. I trust that the Scientific Committee for the coming year will be empowered to continue this work in Professor Gies' hands.

Dr. GIES (closing the discussion). I appreciate the kindly comment by Professor Kirk. We have not yet arrived at the point of making comparative analyses of blood entering and leaving the liver at a given moment. What I have said about the liver as probably the most active organ in the production of sulfocyanate should have been accompanied by the statement that we hope to make such comparative analyses, among others, before we draw final conclusions. I have no data on the subject of sulfocyanate formation from, or in association with the production of, urea, but any positive opinion I might have entertained in that direction has been dispelled by our negative results with thiourea. The appended formulæ for thiourea and urea are interesting in this connection:

$$O{=}C{<}^{NH_2}_{NH_2} \qquad S{=}C{<}^{NH_2}_{NH_2}$$

Urea. Thiourea.

Although the SCN group of atoms is present in the formula of thiourea, our negative results indicate that the SC and NH_2 parts are not convertible into SCN *radicals,* but pass independently into other compounds, or remain wholly as thiourea without change prior to excretion. Since urea is produced by dehydration of ammonia, water, and carbon dioxid, after their collective conversion into ammonium carbonate—

$$2NH_3 + H_2O + CO_2 = OC\left\langle\begin{matrix} ONH_4 \\ ONH_4 \end{matrix}\right. \xrightarrow{-H_2O} OC\left\langle\begin{matrix} ONH_4 \\ NH_2 \end{matrix}\right. \xrightarrow{-H_2O} OC\left\langle\begin{matrix} NH_2 \\ NH_2 \end{matrix}\right.$$

—it is quite likely that sulfocyanate formation occurs along the CN and HS line of transformation, rather than on a modification of the NH_3 and CO_2 conversion.

We always welcome the invention of time-saving devices. Dr. Ferris' procedure is very interesting. It is not his fault that the ferric chlorid reaction is not suitable for accurate quantitative work. For general and convenient estimations it has all the virtues of many excellent "clinical" methods, but what is the use of getting *salivary* data by methods that we know beforehand cannot be reliable. Such data are insidiously misleading, and pseudo-science feeds upon them. We know so little about the significance of the quantitative variations in salivary composition, even when the constituents are very accurately determined, that we cannot rely upon easy and convenient methods that sacrifice precision for speed and comfort. If it is Dr. Ferris' purpose to use his method merely to determine salivary excretory responses to sulfocyanate treatment, it would doubtless be very useful in such observations, since analytic errors would probably be buried in the gross differences due to the medication.

I have listened with great interest to Dr. Low's emotional discussion of this matter, especially his elaborate apology for empiricism. His reference to himself as "the dog" in his tests, and the presence of our Missouri colleague, lead me to assure Dr. Low that I wish I could "quit kickin' his dog around," for I am not hunting trouble—my "hat is *not* in the ring."

Empiricism needs no defense when it is compared with ignorance, but when it is matched against science there is nothing at all to say for it—it stands to reason that the guessing which involves merely utter ignorance, poor logic, and no little complaisance, cannot uniformly yield the information that may be obtained by guessing which depends upon precise knowledge, sound reasoning, and impersonal considerations. Fortunate accidents have often accounted for great discoveries, but reliance upon happy accident *as a method* in dentistry would hardly be suggested by Dr. Low.

If Dr. Low proposes to exalt empiricism as a method, it would be well for him to choose examples of its superiority over the scientific method from the present era, and not from periods when science either did not exist or was in its infancy. We are considering the sulfocyanate question in 1912, not before the battle of Waterloo.

I learn, for the first time, that when Dr. Low came to see me in New York two years ago, he and I were "not viewing the same picture" in the matter of plaque formation in the presence of sulfocyanate. He came to see me *after* all but a few almost useless portions of our materials had been consumed in the detailed examinations on which our 1910 report was based. I informed Dr. Low of that fact. He himself picked out what he regarded as a typical plaque *in one of our least typical* test-tube specimens of the very few that happened to be available. I recall nothing in our conference to warrant Dr. Low's assertion about it today.

It is a great surprise to hear, in such a convention as this, that pharmacological reliance is placed upon the trade books —I almost said the trademarks—that Dr. Low has mentioned. This alone shows how completely empirical Dr. Low's position is on this subject. It is a new method—or rather, it is no method at all—to ignore original records of investigation, but instead to rely on trade prospectuses for scientific information. The *Journal of the American Medical Asso-*

ciation has recently shown that Squibbs misrepresented one of the remedies in which the firm is commercially interested.

I fail to see that Professor Hill's personal courage has anything to do with the question before us. Thousands of men are not afraid to get drunk as often as "free beer" is available, but no one considers that fact an indication that beer is a harmless beverage. The courage, or rather the foolhardiness, of such men is not even an *empirical* suggestion to that effect.

I am at a loss to comprehend Dr. Low's statement that in a former communication I reported that "among immunes there was, on an average, just twice as much potassium sulfocyanate as among susceptibles." The averages were 1 part of sulfocyanate in 40,000 parts of saliva for the "immunes," and 1 part of sulfocyanate in 48,000 parts of saliva for those showing caries,* in one group; in another group the averages were 1 part of sulfocyanate in 33,000 parts of saliva for the "immunes," and 1 part of sulfocyanate in 23,000 parts of saliva for those showing decay. Dr. Low did not tell you what was indicated by the *individual data* from which the averages were calculated. They further flatly contradict his assertion. If you are interested in the details in this connection, I suggest that you examine the data for yourselves in the reports referred to. You will find that Dr. Low has overlooked some essential points. Drs. J. Morgan Howe, G. S. Allan, and J. K. Burgess of the New York Stomatological Institute carefully studied and selected the forty cases from seventy medical students in the second group, which Dr. Low feels gave us inadmissible evidence. I am sure these gentlemen knew well what they were doing.

It was very amusing, as I listened to what Dr. Low said of the growth and spread of his "pet sulfocyanate theory" —"as upon sowing a tiny mustard seed" —to recall that Michel, the apparent originator of the theory ten years ago, lately complained of the fact that his European colleagues have refused to take seriously his sulfocyanate theory. In Europe the "mustard seed" is just as "tiny" now as it was when Michel planted it. I am very glad that I happen to have brought Pickerill's book with me—I feasted on it all the way from New York to Albany this morning.

I think, after what you have heard Dr. Low quote, that you will be quite as surprised as I am that he presented only such parts of Pickerill's comment as suited his present purpose. In this, also, I refuse to stand for the empirical and prejudiced as against the reasonable and impersonal way of doing things, and I now read from Pickerill's book certain significant parts that Dr. Low has suppressed:* "Reference has been made to the associations between percentage of sulfocyanate and immunity to caries. I have not made many observations in this direction, but such as they are, they do not entirely accord with the findings of Michel, Low, and Beach; but the numbers are too small to make any definite deductions. . . . Waugh has recently claimed that sulfocyanate has the property of preventing organisms from forming adhesive plaques. His experiments are, however, somewhat inconclusive, since ten tubes of broth to which sulfocyanate had been added, infected with mouth organisms, showed no plaque formation, but of ten control tubes only one showed plaque formation. . . . Whilst undoubtedly sulfocyanate of potassium is a beneficial element in saliva, and one making for freedom from disease, yet it cannot be regarded as the most important or only factor in producing a natural immunity to dental caries or oral sepsis, ... *All the normal constituents* of saliva are, if present in sufficient amount, of value and importance in protecting the teeth against the occurrence of dental caries, and in maintaining the health of the oral mucous membrane."

In short, Pickerill is not a convert to the "pet theory" and does not present

* Lothrop and Gies, *Journal of the Allied Dental Societies*, 1910, v, p. 267; 1911, vi, p. 88.

* Pickerill. "Prevention of Dental Caries and Oral Sepsis," 1912, pp. 176, 177, and 195.

any findings in favor of it. Pickerill would not have been quoted in support of this theory, if Dr. Low had been making a judicial presentation of the matter. I regret Dr. Low's choice of quotations, because it is not very agreeable to call attention to such striking evidence of extreme prejudice.

I suggest that instead of reporting a few favorable results after sulfocyanate medication, and ignoring all else, Dr. Low would do well to adopt the scientific method. If he would select, tomorrow, a number of cases for continuous treatment, and present here next year a full and accurate history of the outcome in each case, good or bad, we might all agree with him that sulfocyanate is the brilliant remedy he thinks it is. From that standpoint I wish him abundant success. I cannot say that Dr. Low is not right in his contentions—I have no knowledge on the subject—but what he states cannot be regarded as evidence, especially when we recall how he quoted Pickerill. I do not see that he has ruled out simple coincidence as an explanation of the results he has presented.

I have taken altogether too much of your time today. I thank you for your patience in listening so attentively to all that I have been privileged to say.

FRIDAY—*Evening Session.*

The meeting was called to order on Friday night, May 10th, by the president, Dr. Hillyer, at 8.30 o'clock.

DR. HILLYER. Ladies and gentlemen, it was said this afternoon that this particular occasion was to be the most unique in the history of this organization. I have never known of one of a similar character, and let us hope that for many years to come we may not have cause to repeat it. It is not intended, however, that this shall be in the least a sad occasion. We have had our sad moments regarding the particular ones we are honoring this evening, but these are feelings that we will attempt to set aside tonight. We will now hear from the Committee on Necrology, through the chairman, Dr. W. S. ROSE.

REPORT OF THE COMMITTEE ON NECROLOGY.

The report was as follows:

It is the sad duty of your committee to report the deaths of the following members:

Dr. Charles J. Holt.

DIED, at his home in Westport, N. Y., Feb. 18, 1911, Dr. CHAS. J. HOLT.

Dr. Holt was a graduate of the University of Maryland, Baltimore, in 1888. He joined the Fourth District Dental Society in 1898, and was a much respected and most faithful and useful member of this organization. He was elected unanimously to its presidency in 1909. He was elected to membership of the Dental Society of the State of New York in 1903. As a dentist Dr. Holt was exceedingly conscientious, had high ideals, and always commanded the esteem and co-operation of his *confrères,* among whom his early demise caused the most profound regret.

Dr. Chas. J. Barber.

DIED, in Auburn, N. Y., February 11, 1912, at the age of fifty-three, Dr. CHAS. J. BARBER.

Dr. Barber was born in Geneva, N. Y., and was graduated from the Baltimore Dental College, immediately after which he entered upon the practice of his profession at Auburn, where he enjoyed an excellent practice until his death. He was a member of the Rochester Dental Society, of the Seventh District Society, and of the New York State Society. His death resulted from an attack of pneumonia, subsequent to a surgical operation. Dr. Barber served during the Spanish war as captain of the Second Separate Company of New York, and as is often the case, the strenuous work of the campaign made too great a demand upon his physical resources. His courtesy, geniality, helpfulness, and efficiency will long live in the minds of his friends and professional brethren.

Dr. Thos. Clarence Phillips.

DIED, in Buffalo, N. Y., March 31, 1912, of endocarditis, THOS. CLARENCE PHILLIPS, D.D.S., at the age of thirty-seven.

Dr. Philips was a member of the class of '95 of the dental department of the University of Buffalo, and the ensuing year he acquired the M.D.S. degree from the University of the State of New York. After several years of practice he combined forces with his father, Dr. T. S. Phillips, continuing in this connection until his death.

Dr. Phillips was an ardent supporter of every movement for the welfare and advancement of his profession. He was devoted to society work, and in 1910 was president of the Eighth District Dental Society. As a dentist he displayed unusual judgment and ability, and enjoyed the confidence of a large *clientèle*. He did much of late in the investigation and treatment of pyorrhea.

Dr. Phillips exerted a strong influence locally upon the upbuilding of his profession. His sterling qualities were worthy of commendation and his professional ethics of emulation. His personal character was such as to endear him to all with whom he came in contact and attract to him a host of loyal friends, far greater than the average man might claim. It seems sad that one so promising should be called away so soon; yet will we cherish his memory, and his life will do us good.

Dr. Samuel Arthur Freeman.

Died, at Buffalo, N. Y., December 11, 1911, in his eighty-second year, Samuel Arthur Freeman, M.D.

Nearly sixty years ago a medical practitioner, for nearly fifty years a practitioner of dentistry, forty years identified with our State Society, and nearly thirty years an official exponent of the Presbyterian church, always modest, trusted, and esteemed, Dr. Freeman leaves us a heritage best prized by those who knew him best.

He was born in South Orange, N. J., in 1830, of New England ancestry, attended the public school of Hoboken, and was graduated an M.D. from the New York Medical College in 1855. He practiced medicine at Fort Wayne, Ind., and served as an army surgeon during the early years of the civil war. In 1864 he located as a dentist in Buffalo, where he practiced until his death.

As a pioneer in the organization and development of official dentistry Dr. Freeman was most active and influential. He was the first secretary of the Eighth District Dental Society, was its president in 1882 and 1883, and its librarian since 1895. In the last-named capacity he has secured for the society an invaluable dental library. He was made corresponding secretary of our State Society at its third meeting in 1871, served from 1875 for seven years as our recording secretary, made a record as its treasurer *pro tem.* in 1907, and was a member of its Fellowship Committee from 1907 until his death.

Dr. Safford Goodwin Perry.

Died, in New York, N. Y., December 22, 1911, of uremic poisoning, Safford Goodwin Perry, D.D.S.

Dr. Perry was born at Wilton, Saratoga county, N. Y., in 1844. He began the study of dentistry in Yonkers, N. Y., and was graduated from the Pennsylvania College of Dental Surgery in 1865, after which he entered into practice with his cousin and preceptor, Dr. Geo. Perry, at Yonkers. Soon an additional office was secured in New York city, which finally was assumed by Dr. S. G. Perry, and in this city he practiced until his death.

As a dentist Dr. Perry attained the highest rank. His ideals were abreast of those of the foremost exponents of the dental art, and these ideals he was indefatigable in striving to attain. He was lecturer on operative dentistry in the University of Pennsylvania, member of the Odontological Society of New York, member of the New York State Dental Society, of which society at his death he was Fellow-elect. He was also a member of the National Dental Association.

We have many devices in technique which we owe to his industry and ingenuity. Dr. Perry is entitled to a prominent place upon the world's roll of dental honor. His greatest contribution to dentistry was his own self. An article from his pen would cause the reader to desire to know him personally, while personal contact with him added dignity to dentistry, gave importance to its humblest task, impressed one with his culture, his magnanimity, and most of all his great and loving heart. He knew the "luxury of doing good." He was born well, lived nobly, and died beloved.

Respectfully submitted,

W. S. Rose,
C. S. Butler,
Committee.

Dr. Hillyer. We will next hear from the Fellowship Committee, through its chairman, Dr. R. H. Hofheinz.

The report was as follows:

Report of the Fellowship Committee.

Mr. President and Members of the Dental Society of the State of New York:

It is with much grief that your committee presents this report. At our last gathering in Albany, Dr. S. A. Freeman became chairman of the Fellowship Committee, and it was unanimously agreed to confer the medal on Dr. Safford G. Perry of New York city. Both of these gentlemen during the year have been called away from their earthly abode. As long as Dr. S. A. Freeman served on this committee he did it with the same integrity and justice that characterized him at all times.

Owing to his long acquaintance with Dr. Safford G. Perry, he would have added a personal loftiness to this report which no present member of this committee can hope to attain.

After the sudden departure of Dr. Perry the question arose as to what we were to do under the circumstances. On consultation, your committee was of one opinion. The medal and the honor that goes with it was not bestowed upon the perishable part of Dr. Safford G. Perry; it was given in recognition of his superior skill as a dentist, in recognition of his fine character and grand personality. These qualities have not died with him; "Beyond the poet's sweet dream, lives the eternal epic of the man." Every one of his fine qualities influences this very meeting, and permeates the entire profession. A man of such strength can never die. It is for that reason that your committee desires to honor the society by placing his name in the Fellowship class, and we beg the family of Dr. Safford G. Perry to accept the medal. It will show the profession and the family that this society appreciates the fact that human value and good professional qualities survive the body.

We therefore recommend the Fellowship medal to be given to the family of Dr. Safford G. Perry, of whom we may well say: "Describe him who can! He was an abridgment of all that is noble in man."

Respectfully submitted,
RUDOLPH H. HOFHEINZ, *Chairman*,
WILLIAM J. TURNER,
A. R. COOKE,
A. L. SWIFT, *Committee*.

Dr. HILLYER. The Fellowship fund was established about eight years ago by a member of this society, Dr. William Jarvie, who I regret to say has been detained at home by illness—the only thing that could have prevented his being with us at this time. It provides for the presentation of a medal once a year to some member of the profession in the United States or Canada who has shown by his achievements his particular fitness for the honor. It is given but once a year, and it is the highest honor that our society can bestow. According to the expressed wish of the chairman and the other members of the committee the medal is to be presented this year, as our particular token of affection for Dr. Perry, to his family, and I think it is particularly fitting that Dr. Darby has consented to receive the medal in behalf of Dr. Perry's family.

[Addresses in eulogy of Dr. Perry were then made by several members and visitors, and a number of communications in sympathy with the occasion, from prominent members of the profession, were read.]

The next order of business was the report of the Executive Council by Dr. G. B. BEACH.

Motion was made and carried that the report be adopted.

The next order of business was the installation of the newly-elected president, Dr. Baylis.

Dr. BURKHART. I move you, sir, that, when we adjourn, we adjourn until the second Thursday in May 1913. [Motion carried.]

Dr. HOFHEINZ. I move that we extend a vote of thanks and appreciation to our retiring president for his most efficient work during the meeting. [Motion carried.]

Dr. Baylis then declared the meeting adjourned until the second Thursday in May 1913.

The Clinics.

Dr. W. S. WATSON, Brooklyn. "Orthodontia."

The clinician demonstrated a method of taking plaster impressions of the mouth for obtaining models for orthodontic work or for prosthetic work (partial plates), consisting in the making of cores for spaces, allowing the plaster to set, removal of the tray without the plaster, and cutting of grooves over the canines.

Dr. G. A. Fletcher, Albany. "Orthodontia."

This clinic consisted in the demonstration of the application of grass line and rubber ligatures for the rotation and lingual movement of the incisors without the use of the expansion arch. The clinician also showed the use of the lingual bar to avoid ligating bicuspids and canines in expansion.

Dr. Bernard Fischler, Brooklyn. (1) "A Hollow Gold Shell Saddle with Cast Base Over Gold or Platinum Leaf."

Gold or platinum leaf is burnished over that part of the model which is to carry the saddle. This is covered with a thin layer of inlay wax and the hollow gold shell is added, following the same method of procedure as with the pivot.

(2) "A Moldine Flask Made of Thick Air-chamber Metal." (For making gold shell pivots and saddle.)

The advantage of this flask over the rubber ring usually furnished with the moldine outfit is that it can be separated into halves, and the model removed without distorting the impression; at the same time the air-chamber metal is pliable and will give, and can be pressed in the same manner as the rubber ring is used.

(3) "An Adjustable Soldering Tool."

This consists of a combination of two pairs of tweezers in one, and means for adjusting two pieces of metal, end to end, for soldering. This is especially useful for adding pieces of gold to shell crowns that have accidentally been cut too short.

Dr. R. E. Luther, Batavia. "Convenient Devices."

As a means of anchoring a large amalgam filling in a badly broken-down molar or bicuspid, a one-quarter inch platinoid wood screw is used. The screw is covered with soft cement and screwed into a root-canal, leaving the flat head projecting well up in the cavity. The amalgam is packed around the screw. In this way many teeth, which would otherwise have to be crowned, may be saved.

Dr. J. O. McCall, Buffalo. "Polishing Roughened Enamel."

The method advocated consists in grinding where necessary to secure a true enamel surface, then polishing with disks, etc., lubricated with a paste made of Arkansas oil-stone powder mixed with perfumed vaselin. The powder comes in different grits, numbered 0, 1, and 2, and is obtained from the Pike Mfg. Co. A fine garnet disk is used with paste No. 1, then a medium cuttle disk with paste No. 2, then a medium cuttle disk with paste No. 0, finishing with a crocus disk used dry. Paste No. 0 may have a little rouge or crocus powder mixed with it, to give distinguishing color and fine polish. Pastes are also used on stones, wood points, buff polishers, for polishing rough enamel, and for other polishing operations.

Dr. J. W. Canaday, Jr., Albany. "A Method of Restoring Lost Buccal or Lingual Cusps of Bicuspids with Porcelain."

This method is designed to do away with the necessity of placing gold crowns on bicuspids that have lost either cusp through accident or caries.

A porcelain flat-back tooth, or facing, is selected of the same shade as the broken tooth, and the pins are threaded. The root being filled, the cavity is shaped retentively, and a square butt joint is made between the facing and the root at the gingival border, or a little beneath. A threaded pin may be inserted in the canal and the pins bent around it and soldered. This gives considerable strength, and it is advisable to use the post whenever possible. The pin is cemented into the root and the cavity lined with oxyphosphate cement, and an alloy filling is inserted while the cement is plastic. The alloy may be best inserted if a matrix is placed about the tooth. If the pulp has not been exposed, the facing is ground as before, the pins threaded and bent to conform to conditions, and as much retention as possible is obtained in the cavity by burs and hand instruments. The cavity is now lined with cement, as before, and the facing anchored in place with alloy, care being taken to work it thoroughly around the pins. By using care in shade-selection and finishing, a very beautiful and useful result may be obtained.

Dr. H. G. Kittell, Troy. "Porcelain Faced Dummy with Gold Tips."

The facing is ground in the usual way, having the cutting edge beveled and shortened sufficiently to allow for a gold tip as heavy as desired. The facing is backed with pure gold, No. 34 or 36 gage, punching the holes with a sharp instrument rather than with the plate punch, and making them large enough to allow the backing to be easily removed. The backing is trimmed flush with the facing except at the cutting-edge, where it is allowed to extend over about one thirty-second of an inch. The backing is then removed, and on the portion covering the beveled edge of the facing 22-karat solder is flowed as thick as the tip is desired to be. The backing is then replaced on the facing and burnished thoroughly about the pins to exclude borax. A cusp is now stamped of pure gold, No. 34 or 36 gage, the parts are assembled on the articulator, and before the wax has thoroughly hardened, the articulator is closed firmly, whereupon the cusps of the opposing teeth will accommodate themselves in the soft pure gold to a perfect occlusion.

The joints are all burnished tightly, and any open spaces filled with wax; the whole is invested and soldered in the usual manner, after which the gold extending beyond the cutting-edge of the facing may be dressed down with files or stones.

Dr. J. H. Carter, Cohoes. "Cast Porcelain."

The success and universal use of the gold casting by means of the disappearing wax pattern no doubt prompted the pioneer workers in this field to adapt porcelain to the same method. Just what success has been attained, and how far toward taking the place of the baked porcelain this method has advanced, we have yet to determine.

My personal experience with the cast porcelain began last May at the state meeting, where I procured a small quantity of the Weldon casting porcelain. I followed directions, but my results were far from being successful. I found that with a Melotte's blowpipe and a foot bellows I could not get my material sufficiently molten to draw down, but by the use of a Brophy blue blast and a Vernon rotary motor, I was able to duplicate my wax patterns in the so-called cast porcelain. It, however, failed in the color, producing a variety of shades with a continued grayish tendency, apparently the result of oxidation. This grayish tendency continued even after insertion in the mouth, and in one particular instance the color, though having been true at the time of casting, assumed this grayish tinge after being in the mouth for a short time. With a later product I obtained results that were much more satisfactory. It cast at a much lower heat and was more positive as to color, with better adaptation, and apparently not affected by the oral secretions. The shades in which it can be cast are twenty in number, sufficient to cover the field of our work. The best results are obtained by the use of the Elgin machine, as the material will not stand pressure from without.

This product recommends itself to our further consideration.

Dr. H. E. Tompkins, New York. "Analgesia and Anesthesia by Nitrous Oxid and Oxygen."

The clinician demonstrated the use of several apparatus for the administration of nitrous oxid and oxygen, including the S. S. White, Teter, and Tompkins outfits, and the use of a regular yoke for the gas-bottle and four feet of hose. He also introduced a new nasal inhaler of his own design. He displayed a new pearl of aromatic ammonia wrapped in cotton and wound with China silk, used for the resuscitation of patients who show a disposition to faint. These pearls are known as Vaporole Ammonia.

His success with all of the apparatus was notable, but that obtained by the use of his own inhaler was especially good.

This inhaler consists of a spring clamp which fits over the head, and to which is fastened the nosepiece, adjustment for the air inlet, and the exhaust valve. The use of the yoke and hose attachment to the gas-bottle demonstrated that no especial apparatus for the administration of gas and oxygen was necessary as long as care was taken to admit gas at inspiration and to cut off the supply at expiration. The hose end was placed in the patient's mouth and the respiration watched; when the characteristic numbness was felt, a few breaths of air were allowed, and analgesia was then kept up by admitting alternate inhalations of gas and air.

Dr. Frank Wright, Ticonderoga. "Pressure Anesthesia."

Regarding the principles of pressure anesthesia, it should be remembered that we cannot force a liquid through healthy dentin by a mechanical device without injury to the tooth itself. If a cocain solution is held in close contact with the protoplasmic fibers of the dentin, the absorption of the cocain takes place in accordance with the law of osmosis. The imbibition of the anesthetic is enhanced by employing a physiological salt solution as a vehicle. On the other hand, living protoplasm reacts unfavorably against ready absorption of substances, for two reasons: First, its albumin molecules are relatively large and not easily diffusible; second, as an integral part of its life it possesses vital resistance toward foreign bodies. These attributes are sufficiently demonstrated by the fact that it is almost impossible to stain living tissue. Dehydration of protoplasm increases the endosmosis of the anesthetic solution markedly.

When we supply the same "pressure" anesthesia upon carious dentin, the above statement does not hold good. We are able to press fluid quite readily through carious dentin. We must bear in mind that such dentin has been largely deprived of its inorganic salts, leaving an elastic, spongy mass in position. By drying out this dentin, and then confining the anesthetic solution under a suitable watertight cover, the pressure applied by the finger is quite sufficient to obtain the desired results.

In teeth not fully calcified and in so-called "soft" teeth, pressure anesthesia is most readily obtained, while the process fails in teeth of old persons, abraded and eroded teeth with extensive secondary calcific deposits, teeth with metallic oxids in the tubules, or badly calcified teeth—all mainly for one and the same cause, namely, clogged tubuli.

In most cases no amount of pressure will prove successful. The successful anesthetization of the pulp depends largely upon this most important factor—allowing sufficient time for the proper migration and action of the drug. After the cavity of exposure has been cleansed of débris, isolated, and dehydrated, it is ready for the application of the anesthetic. As an anesthetic agent I use the cocain-adrenalin tablet or pellets put up by Parke, Davis & Co., about one-sixth of a grain in each tablet.

By moistening a small pellet of cotton held in the pliers and touching it to one-half of a pellet of cocain-adrenalin, the agent is easily conveyed to the cavity and point of exposure, if there be one, in the form of a thick paste. A pellet of soft yellow wax is then placed in the cavity in such a way as to confine the semi-fluid cocain directly against the pulp, and at the same time to exclude air-bubbles that might displace the anesthetic. Then by slight pressure on the wax, either with the finger or a pellet of cotton held in the pliers, the pulp is almost instantly anesthetized. If the cocain is allowed to remain in contact with the pulp for a few minutes before it is subjected to pressure, the anesthesia is usually accomplished without pain. After the pulp has been anesthetized, the cavity is enlarged and the pulp-chamber is drilled out and enlarged, so that free entrance may be had to the root-canals. For removing the pulp from the roots, I first use a smooth broach, by passing it between the walls of the canal and the pulp to the end of the root-canal; then a barbed broach deftly worked to the apex, which can usually be determined through a delicate sense of touch by a suddenly increased resistance; next, the broach is slightly rotated to break loose the pulp at the apex, and then the whole mass can be removed.

We find teeth, of course, with such constricted canals that it is practically impossible to remove from them all of the contents. But the difficulty in this case would not be obviated by the use of devitalizing agents, and in my opinion it is safer to leave these filaments in a sterile condition and risk their gradual degeneration than to leave them in what we know to be a septic condition. Nature is wonderfully resourceful in taking care of impaired tissue that has not been subjected to outward septic influences.

"F. D. I."

INTERNATIONAL DENTAL FEDERATION.

Summary of the Proceedings at the Annual Meeting held at Stockholm, August 28 and 29, 1912.

[Report furnished to the DENTAL COSMOS per courtesy of the *British Dental Journal.*]

THE International Dental Federation met at Stockholm on August 28 and 29, 1912. On the evening of August 27th, a reception of foreign visitors was held at the Opera Café.

Opening Session.

The opening session took place on Wednesday morning, August 28th, in the Aula of the University of Stockholm. On the invitation of Mr. W. B. Paterson (President of the Federation), Prof. Wilhelm Leche (Professor of Biology and Comparative Anatomy in the University) took the chair as Hon. President, being supported on his right by Mr. W. B. Paterson, and on his left by Stadsrodt Stäneström, the Minister of Education, Dr. Schaeffer-Stuckert (Frankfort, General Secretary of the F. D. I.); Dr. E. Rosenthal (Brussels, Hon. Treasurer); Dr. T. W. Brophy (Chicago), Dr. Florestan Aguilar (Madrid), and Hofrat Professor O. Walkhoff (Munich), Vice-presidents; Dr. W. Guy (Edinburgh), and M. Roy (Paris), Adjoint Secretaries.

Those present included: Dr. E. Förberg, Mr. Albin Lenhardtson, Mr. A. Hultgren, and Mr. H. Boström (Stockholm); Professor Jessen (Strasburg); Professor Christensen (Copenhagen); Professor Dieck (Berlin); Dr. Gabriel Wolf (Vienna); Mr. Horace Fletcher (New York); Mr. Walter Harrison (Brighton); Mr. H. R. F. Brooks (Banbury); Mr. G. Cunningham (Cambridge); Mr. G. Thomson, Mr. W. Penfold, Mr. H. Atkins (London); Mr. W. Dall (Glasgow); Mr. T. E. Johnston (St. Andrews); Mr. F. J. Turnbull (Edinburgh); Dr. C. Van der Hoeven (The Hague); Professor M. Ayrapaa, Dr. A. Aspelund and Dr. Th. Weber (Helsingfors); Dr. Ottesen (Christiania); Dr. Piperno (Rome); Dr. Guerini (Naples); M. R. Lemière (Paris); Mr. E. Huet (Brussels); Dr. J. Valenzuela (Chile); Dr. T. Shmamine (Tokyo); Dr. A. Scheele (Cassel); Dr. V. Bensow (Gothenburg); Dr. Punske (Berlin); Dr. A. Van Geldere (Zaandam), and a number of Swedish dentists, including Messrs. C. S. Bensow, Kior, Th. Sundvall, Carl Firm, Jessel, Nordströn, Häyer, M. Schmidt, Emil Lindblad, Carl Hultbom, J. Wessler, Svetlan, Charles Nilsson, S. de Verlier, N. Stene, Stangenberg, Amell, Thomsen, H. Strang, V. Renstrom, H. Romberg, G. Swen, W. Dumky, and others.

Professor Leche, on behalf of the Rector of the University, delivered an address of welcome and expressed gratification that the F. D. I. had again chosen Stockholm for its meeting-place.

Mr. Paterson, in the name of the F. D. I., thanked Professor Leche and the authorities of the University for their hospitable welcome, and for the use of the University buildings. Professor Leche had dwelt upon the scientific aspects of the Federation's work, and members would learn with pleasure that Professor Leche was not only a great advocate of Darwin's views on "Evolution" and the "Descent of Man," but was himself making researches in connection with the development of the teeth of man. Mr. Paterson introduced the Minister of Education, and then called upon Dr. Förberg.

Dr. Förberg said it was with feelings of pleasure that the Swedish dental profession heard that the F. D. I. had decided to hold its annual meeting in Stockholm. They considered it a great honor for their capital, as it was the second time the Federation had met there. At the 1902 meeting, resolutions were adopted which proved to be of fundamental importance in the organization of dental education in many countries. At the Cambridge meeting in 1901, a Commission on Dental Hygiene had been appointed, and at Stockholm a detailed report was presented, which concluded by stating that the public dental service was in a state of neglect, though here and there some signs of activity were manifest. Since then the appreciation of public dental hygiene had spread in all classes of society and the number of school clinics was continually increasing. They saw realized the prophetic words of the first president that the F. D. I. existed not only for the benefit of the dental profession, but for that of humanity at large. In the name of the Swedish Dental Society and Federation, he extended to the F. D. I. a most cordial welcome to Stockholm.

Letters of regret for absence were read from the Minister of the Civil Department, who expressed his best wishes for a successful meeting and his warm sympathy with the aims of the F. D. I.; the Lord Mayor of Stockholm; the General Director of the Royal Board of Health; and from members of the Federation.

Address of the President.

Mr. W. B. Paterson then delivered the following address:

Honored Colleagues,—The International Dental Federation has, at the end of a decade, returned to Stockholm, the scene of its early labors and pioneer work in dental education and public dental hygiene.

In accepting the cordial invitation of our Swedish *confrères* we were influenced by two chief reasons: The first was the remembrance of our former meeting in this fair city in 1902—a meeting of happy and pleasant memories, and one which laid the foundations of much good and useful work. The second reason was more closely connected with Sweden and its people. It was the universal feeling and unanimous desire of our members to offer their tribute of thanks in the capital of his kingdom to the monarch who, first among the rulers of the world, has permitted his name to be associated with a movement for the improvement of the dental health of the people.

To his most gracious Majesty, King Gustaf, our grateful thanks are due for his august patronage of the Hygiene Commission of the International Dental Federation. The association of his Majesty's name with the dental profession is no mere nominal act, for we know that his kingly interest is deeply stirred by all movements which are for the improvement of the health of his people. His interest in public dental hygiene is real. [Applause.] Knowing this, we are met here today, representatives of national dental associations from different parts of the world, to testify to the steady growth of ideas and measures for the relief of suffering humanity by means of properly devised systems of public dental hygiene.

If further illustration of the association of the ideas of the F. D. I. with those of Sweden is required, I would point to the fact that the Swedish government was among the first to recognize the importance of the care of the teeth of the school children, and in response to dental opinion to inaugurate a scheme of inspection and treatment of school children's teeth in this city and throughout the country. Whilst Sweden was active and awake in these matters, most of the world remained dormant until a few years ago, although the need for action was, and still is, equally great in all civilized communities throughout Europe and America, as we of the Federation were able to demonstrate in Stockholm in 1902 by means of the very full and extremely valuable report presented to us by our colleagues, Frank, Cunningham, and Förberg. With these strong reasons for revisiting Stockholm it is unnecessary for me to dwell for more than a moment upon a minor one—such as a natural desire to visit the scene of the recent struggles in the Olympic games. For while dentists are hard workers in their profession, they are, many of them, keen sportsmen out of it, and, as sportsmen and internationalists, they heartily congratulate Sweden on her success in the Olympic games. [Applause.]

But there is one other reason I must not forget, and it is the welcome of the Swedish Dental Society and the Swedish Dental Federation, which you, Dr. Förberg, have in such friendly and eloquent terms extended to us. To the members of those societies and to you, sir, we are indebted for the success of our meeting. On behalf of my colleagues of the F. D. I., I offer to those gentlemen our cordial thanks for their kind and highly valued services.

Coming to the work immediately before the Federation, I wish to say that, apart from the important subjects which will occupy the attention of the commissions, we have a duty to perform in making an award, for the second time, of the Miller Memorial prize to the person or persons who, in the opinion of the Executive Council of the International Dental Federation, have rendered the most eminent services to dentistry. The national committees have doubtless already weighed the claims of those who are qualified to receive this honor, and this afternoon the Executive Council, consisting of the national representatives, will sit as a jury to decide upon their merits. You will remember that upon the last occasion of the award of the Miller prize, our choice fell upon Dr. G. V. Black, of Chicago, U. S. A., and it proved to be a happy one, judging by the chorus of approval in the world's dental press which greeted our selection. A facsimile of the diploma presented to Dr. Black was printed on a reduced scale as a frontispiece in the Transactions of the F. D. I. for 1911. The medal ordered to be struck in memory of Professor Miller is now finished, and before sending it to Dr. Black I purpose presenting it for your inspection during this meeting.

Amongst other business of the Executive Council, two subjects stand prominently out. One relates to our duties as an international bureau of dental congresses in connection with the work of the national committee of the inviting country in the organizing of the next congress, to be held in London, in August 1914.

The other refers to the proposed establishment of an official journal of the F. D. I.

On the first subject, Hofrat Prof. Walkhoff has a useful suggestion, which is set down in the program for our consideration, viz, the formation of an International Directory of Dental Societies and Dentists. Dr. Schaeffer-Stuckert, from his profound experience of the organization of an international dental congress, may have advice to offer us on the means to be taken to check the introduction of papers on matters of national rather than of international importance in the various sections of the congress—a practice, unfortunately, only too commonly seen in medical and dental international congresses. I would suggest that we might, through the F. D. I., assist the Organizing Committee of the congress by requesting our delegates from the different national dental associations to invite the leaders and exponents in dental thought and practice in their own countries to read papers, or give demonstrations, on selected subjects of international interest.

The second subject to which I referred is the proposal to use as the official journal of the F. D. I., the *Internationalen Archiv für Mund-Hygiene.* The idea of an official journal of the F. D. I. is an old one. Dr. Förberg, in 1902, gave us his views on the establishment of an Analytical Review, which, in addition to the Transactions of the F. D. I., should embrace the latest items of dental science from all parts of the world. Later, when Dr. Förberg was succeeded by Dr. Harlan as president of the Committee on International Dental Press, the question was fully considered in its financial aspects, and owing to lack of sufficient support the idea fell through. The proposal on the present occasion, however, differs somewhat from the last one, and an offer of support, whether sufficient or not I cannot say, appears to be forthcoming. We have in the past depended largely upon the courtesy of the proprietors and editors of various dental journals, *e.g.* the DENTAL COSMOS, *L'Odontologie, Archiv für Mund-Hygiene,* and the *British Dental Journal* (the organ of the British Dental Association), as well as upon the individual efforts of certain of our members, for a printed record of our Transactions.

There can be no doubt as to the value of an official record and publication of the Transactions of the F. D. I. and its commissions, if printed in French, German, Spanish, and English, and more especially if the accuracy of the translations could be guaranteed; but the financial considerations involved are the whole crux of the matter, and with regard to them we must perforce be largely guided by the report of our hon. treasurer (Dr. Rosenthal). The financial constitution of our Federation is at present such that it might be seriously imperiled by any hasty attempt to reach an ideal publication.

Individual effort, loyalty and *esprit de corps* amongst the members of the F. D. I. have done much in the past and are doing good and great work still—work which enhances the reputation of the Federation, and it is upon this happy combination of forces that I rely in the future for the continuance of our success. Whether the results of our labors are duly and accurately recorded in official journals or not, I earnestly hope that we shall not relax our efforts in the slightest degree in the cause of dental science on behalf of the Federation.

In conclusion, I would draw your attention to a revival of a practice of the Federation in having a paper read or a demonstration given on some subject of scientific interest during the meeting.

At this session we are promised four short papers on subjects of public dental hygiene in the Commission of Dental Hygiene, and one demonstration, which is the first of its kind yet given before a scientific gathering. The subject of it is: "How to Save a Nation's Teeth," and Mr. George Cunningham submits it for our inspection and judgment as a cinematographic film, which he has had prepared by Messrs. Pathé Frères of Paris. I believe you will find the demonstration interesting. With the help and advice of our members, the cinematograph may become an important factor in the movement for the education of the public on the care of the teeth.

With these observations upon the work before us, I conclude by expressing the hope that our business may be transacted with precision and in a spirit of harmony and *camaraderie.*

Brief Addresses by Delegates of National Dental Societies.

Hofrat Prof. O. WALKHOFF (Germany) said the splendid city and the far-famed hospitality and kindness of their Swedish colleagues would insure a happy and successful meeting, which he trusted would be of great value to their profession. It was high time that dentists of all countries became more closely united for defense against unjust attacks which were made from various quarters. For example, dentists who had created modern scientific and practical dentistry had been excluded from the International Medical Congresses. Let them, therefore, do their utmost to insure that the next International Dental Congress in London should be a brilliant success. Let them also work for definite proof of the fact that civilized nations absolutely need an abundant and sufficient number of practical dentists from the standpoint of national health. They should strive to enlighten governments on this question, and also urge upon them the necessity of certain stipulations for the practice of their profession. For these purposes the F. D. I. was the most efficient means, and only the united, earnest efforts of dentists in all countries could render it possible for the dental profession to be conceded "a place in the sun," which was its due. He hoped the Stockholm meeting would lead them a step nearer this goal. For the kindly reference made by Professor Leche to the scientific achievements of dentists and the mention of himself (Professor Walkhoff) he desired to express his best thanks.

Dr. Brophy (America) said that as the representative of the National Dental Association of the United States he brought cordial greetings. Might he say that the association which he represented was the highest exponent of the art and science of dentistry in a country of 92 millions of people, with a profession numbering 40,000 practitioners? Yet he ventured to remark that the profession in America was not numerous enough to supply more than 30 per cent. of the people with their requirements in dentistry, and to care for them in a professional way. He was glad to say that America was also represented by Mr. Horace Fletcher, the distinguished advocate of proper living, who had perhaps contributed as much to building up the health of the people as a large part of the medical and dental professions combined. Mr. Fletcher had taught the medical profession how to avoid the use of drugs, and he had taught the dental profession the importance of their vocation. Though he was referring to America's foremost citizen in oral hygiene, he knew that he spoke also in the presence of Dr. Jessen, the great exponent of oral hygiene and oral prophylaxis, whose early days were spent in discouragement, but who now saw his reward in the great wave of oral prophylaxis that had swept over the world. Meeting again in Stockholm brought many pleasant recollections of 1902, yet there was a feeling of sadness as they remembered the lives of Frank, Miller, and Harlan, who had passed away since. They bowed in reverence on recalling the names of men who gave of their best for the uplifting of the profession, and whose rich inheritance was theirs. The American Dental Association recognized in the F. D. I. the foremost power for the advancement of the science and art of dentistry. America was loyal to the F. D. I., and wished to show this in a substantial manner when the Federation would visit them. America would contribute its best in carrying on the work of the F. D. I. to an even higher plane.

Dr. W. Guy (Great Britain) said it was a matter for regret that only a few representatives from the little island on the other side of the North Sea could be present, but it took a stout heart and a stouter stomach to brave the terrors of the sea passage. Those attending had an ample recompense in the hospitable and cordial reception accorded them, and in the interesting program. He knew of no country in which a Briton found himself more at home than in Sweden, with which England had an unbroken record of friendship. To his mind, Sweden afforded at the present day a very close parallel to ancient Greece in its palmy days, for in no other country had the cult of physical beauty—because health was physical beauty—been carried to such a high point. In that respect their country offered an example to the whole civilized world. While he believed that the trend of modern legislation would be in the direction of improving the public health, he held further that it was to the achievements of Sweden in this field that other nations in the world would be chiefly indebted, and to Sweden they would look for guidance in their legislative proposals. On behalf of the British dental representation he expressed their feelings of joy and satisfaction at being once more in Stockholm. Such meetings strengthened the bonds of friendship already existing between nations, and also strengthened the hands of statesmen in the most important of all tasks—the maintenance of international amity.

Dr. Gabriel Wolf (Austria) offered greetings on behalf of the Hygiene Committee of Austria and the Austrian School Dental Hygiene Society, the establishment of which was due to the F. D. I. He would have the honor of reporting at the Hygiene Commission on progress made in school dental treatment in Austria.

Dr. E. Rosenthal (Belgium) said that thanks to the energy and perseverance of dentists belonging to the National Belgian Federation, the first Belgian dental school would shortly be opened. This result was certainly due in part to the influence and moral support of the F. D. I. Left to themselves the dentists of Belgium would have been unable to shake off the torpor in which they slumbered, but the F. D. I. evoked their *amour propre* and encouraged them in the course now adopted. The example of unity for the common good set by the F. D. I. had also silenced all internal dissensions. The great movement of altruism which had characterized the labors of the F. D. I., and the study devoted by it to programs of professional training, had inspired the evolution of this scheme, and the F. D. I. had supplied the guidance for laying its foundations. Their ambition was to achieve as perfect a result as possible. From both a scientific and a practical standpoint they intended to maintain the level of instruction reached abroad, and he hoped next year to report on the results accomplished. The F. D. I. could certainly be congratulated upon having gained such an important position in the world, and especially upon the ambition to advance in dental progress that it aroused in civilized nations.

Dr. Valenzuela (Chile) said he had the honor to be commissioned by the government of his country to represent it at the annual meeting of the F. D. I. Chile had today a modern dental school in a building specially erected and completely equipped, in which instruction was given to 100 students. He was happy to have the opportunity of meeting the *savants* and masters of odontological science, and to be able to communicate to Chile the latest information as to their specialty, which was becoming more important every day.

Dr. Christensen (Denmark) offered salutations on behalf of the dental profession in Denmark.

Dr. Aguilar said Spain appreciated the work of the F. D. I., from which they were deriving so much good. Last year he reported that they had recognized their system of teaching dentistry on lines recommended by the F. D. I. He was glad to report that they were now organizing a dental hygiene movement, and at Barcelona a few months ago 3000 children assembled to receive prizes for the care of the teeth. He wished to congratulate the dentists of Sweden, who had, he believed, the oldest dental society in Europe. Further, he was authorized to invite the F. D. I. to visit Spain and meet in Madrid or Barcelona, if they did not go to America, in 1913.

M. Roy (France) said that there was current in France a proverb, "On revient toujours à ses premiers amours," and in coming again to Stockholm it seemed that the F. D. I. acted upon it. Two years ago the Federation returned to Paris, its birthplace, to celebrate the tenth anniversary of its foundation. Last year they were in London, ten years after the London-Cambridge meeting, which they all remembered. This year they returned to Stockholm, ten years after the 1902 meeting which took place with such *éclat*. In the name of France he brought cordial salutations to the F. D. I. and to the Swedish *confrères,* who offered such charming hospitality. He must express the sincere regrets of the honorary president, Dr. Godon, who for the first time was prevented from attending an F. D. I. meeting, owing to domestic affliction, and also owing to the obligations involved by his appointment as maire-adjoint of the eighth arrondissement of Paris. He knew that Dr. Godon had their deep sympathy in his grief. During the past year France had completed the organization of the curriculum for dental mechanics (*prothèse*), prescribed by the new regulations for dental studies, and the first examinations were held in July. In France they had realized the program of studies elaborated by the F. D. I.—not the minimum program but the ideal program—and they were glad to rely upon the resolutions of the F. D. I. in securing this result. In hygiene they had endeavored to develop the various fields of school and military dental hygiene. Special attention had been given to dental inspection of schools. A bill was being prepared to reorganize medical inspection of schools; they had endeavored to get dental inspection included, and hoped to obtain a satisfactory result; there, again, the work of the F. D. I. had been of powerful assistance. It was with pleasure they came again to Stockholm, feeling sure that they would accomplish more sound and good work for the greatest benefit of odontology and of humanity.

Dr. V. Guerini (Italy) said: After ten years' absence I am very happy to be once more in the beautiful Swedish capital, and to offer my cordial greetings to our valued and esteemed Swedish colleagues.

It is my duty to call the attention of the International Dental Federation to an important event that has lately taken place in Italy. The Italian Parliament has now definitely passed a law obliging all those intending to exercise the dental profession to be duly provided with the degree of Doctor of Medicine. It is, of course, understood that the present surgeon-dentists will preserve intact all their existing rights. The law provides that all persons who have practiced dental surgery for eight years without a diploma shall be admitted within the space of one year from the promulgation of the law to a practical examination, on passing which they shall be qualified to continue in the practice of the dental art. The law also establishes that those dentists who have exercised the profession without any diploma during a period of fifteen years, may obtain authorization to continue practice, provided they can produce documents or other attestations of their capability, to be submitted to the judgment of a special commission and ratified by the sanitary board of their respective provinces.

I should also mention that by disposition of the new law, Art. 2, courses of odontology and dental prosthesis will be gradually instituted in all the medical faculties of the kingdom.

I now wish to say a few words on the subject of the International Exhibition of Social Hygiene and of the Congress for Combating Tuberculosis, both recently held in Rome. At the International Exhibition of Social Hygiene there was one section of especial interest, devoted to dental art and its history. This section was the object of great attention and much admiration on the part of the public and of their Majesties the King and Queen of Italy. Amongst other things I exhibited a collection of documents by which I have been enabled to demonstrate that the invention of mineral teeth with platina pins was due to an Italian dentist named Guiseppe Angelo F. Fonzi.

With reference to the Congress on Tuberculosis, it is my duty to tell you that I was charged by Professor Jessen to make a communication on the importance of buccal hygiene in combating tuberculosis. I endeavored to put in strong relief all the various aspects of this very important question, and I am pleased to know that many Italian newspapers have published my paper.

I was also charged by Professor Jessen to take steps to obtain the patronage of her Majesty the Queen of Italy for the Hygiene Commission of the International Dental Federation, and I have taken the initiatory steps in this business in conjunction with my colleague Dr. Piperno. I have reason to hope that the end desired will be reached.

Dr. C. Van der Hoeven (Holland): As delegate of the two national societies of Holland (Het Nederlandsch Tandheelkundeg Genootschap and the Nederlandsche Tandartsen Vereenigung), my first and most pleasant duty is to bring you the hearty greetings of my Dutch *confrères* and to thank the Swedish dental societies for their cordial reception in their splendid city of Stockholm—the Venice of the North. The teaching of dentistry in Holland has made progress by the appointment of another lecturer, so that there are now in the Dental Institute of Utrecht University five lecturers and several assistants under the directorship of our esteemed friend, Dr. Grevers. The only thing we still want is a more thorough theoretical instruction in the auxiliary branches of the science of dentistry. I hope to be able to announce next year that the bill will be passed, regulating also this part of the dental curriculum according to the views of the F. D. I. The hygiene movement makes but slow progress in Holland. We have not yet succeeded in getting a school dental clinic, but as we are convinced that dental aid to the poor is the most difficult and also the noblest problem for us to solve, the dental profession in Holland will continue to devote all its energy until success is achieved.

Dr. Ottesen (Norway) said: As representative of Norway, I desire to offer hearty greetings to the F. D. I. from the Norwegian Dental Association. We are deeply indebted to the F. D. I. for the impulse it has given to the work of developing our dental education and for forming the Norwegian Dental Hygiene Association. I am glad to say that this association is progressing well; it is a good sign of its popularity that it has received a yearly grant from the Norwegian Parliament. There is no doubt about the good influence of the F. D. I. in inspiring and spreading progressive ideas among the different national dental associations, and I wish the Federation a prosperous future.

Dr. Shmamine (Japan) said: This is the first time that a representative of my native land has spoken at an F. D. I. meeting, and I rejoice to have the honor of being that representative. As in all departments of industry, art, and science, dentistry has now its share in the modernizing of life in Japan. Strictly speaking, I cannot speak of modernizing in reference to dentistry in Japan, because forty years ago, the period of our great revolution, we did not possess, in the literal meaning of the term, a science of dentistry at all. Of course, bare necessity compelled some treatment of painful conditions of the teeth in earlier times, yet means and ways were far from complying with the most modest requirements of a scientific nature. Cataplasms and blistering were employed from time immemorial as remedies for dental trouble. In the lower strata of the people a kind of magic-suggestion was practiced. If nothing can be said of our ancient dentistry in the modern sense, nevertheless, hygiene of the mouth and the teeth is perhaps older in Japan than in any other civilized country. This has its foundation less in the recognition of the importance of mouth hygiene for the body than in old-standing religious ideas and obligations which have gained such a firm hold of the sentiment of the whole people that no one needs to be compelled by special admonition to practice a certain amount of mouth hygiene. Every family without exception has its home-altar, usually two, one Shinto and one Buddhist. When the Japanese rises in the morning his first act is to rinse his mouth and clean his teeth automatically with his forefinger and salt. His second act is then to go before the altar and say his prayers, for he may not utter a prayer to his god without a clean mouth. That is the religious obligation. Among the well-to-do and better educated classes a primitive tooth-brush in the form of a short stick with a frayed end was used for many centuries, but its place is taken today by the modern tooth-brush. In popular use are now tooth-brushes, costing less than a farthing, which are replaced by new ones after a few weeks' use. The poorest working-man's family possesses such tooth-brushes, and each member of the family has his own. An old Japanese proverb says:

Otoko kro kare
Ha shro kare.
(Let the man be brown, but his teeth must be white.)

People were surprised that in the Russian-Japanese war every Japanese soldier possessed a tooth-brush and tooth powder. But with us that is a matter of course, and no military regulation exists for it. The beginning of modern dentistry in Japan proceeded from America, after our great revolution, when American dentists came across to us. By degrees, however, we have established our own dental schools, and we intend constantly to improve their equipment in a modern sense. Thus Japan may now be entitled to join the circle of civilized nations in the province of dentistry, and for me it is a great honor to be the first Japanese representative at the annual meeting of the F. D. I.

Professor JESSEN, president of the Hygiene Commission, said: The care of the teeth in the schools constitutes the foundation of health. You may think these words are exaggerated and pretentious. But if you consider the oral cavity as the gateway of the body you will be convinced of the probability, the truth, and the accuracy of the statement. The air which we breathe must be pure, the nourishment we take must be free from harmful germs, and the mouth through which both are introduced must be clean. For the air and the food become contaminated during their passage through a diseased oral cavity, and infect subsequently the lungs, stomach, intestines, and the whole body to a degree more or less serious in proportion to the body's capacity for resistance.

The greatest danger is in childhood. Almost all children have diseased teeth; in the mouth they have the germs of illnesses which may infect the whole organism, prevent normal development, and condemn them to a condition of debilitated health or a premature death. Happily, the prognosis is not always so serious, or else most children would fall ill and die too soon. Nevertheless, we shall have a healthier race if we improve all the vital conditions, and take care that children have sound teeth. We cannot change everything, but this precaution is within our power.

In view of the fact that many countries have established school clinics, and that governments have recognized the necessity of dental treatment in schools, we are filled with hope, and we have the courage to proclaim anew that such methods are essential to combat infectious diseases, especially tuberculosis, and constitute the most economical prophylactic against this formidable enemy.

Professor Kirchner of Berlin says: "Bad dentition involves serious troubles in nutrition, favors the development of arterio-sclerosis, and lessens the resistance against infectious diseases, particularly tuberculosis, and thus tends to shorten life."

Youth is the greatest capital of a nation. Juvenile health represents wealth, but this is dissipated by illness and early death. Germany has 65 millions of inhabitants, but only 20 millions care for their teeth. This lack of dental care by 45 millions costs the German nation hundreds of millions of marks, which are paid by institutions, workmen, and employers. Dr. Volz has shown by statistics that 210 millions of marks at least could be saved annually if care of the teeth was in operation throughout Germany. The National Committee of Hygiene has a gigantic task in converting 45 millions of people to its ideas. In other countries the situation is no better, and thus one can understand that the International

Hygiene Commission sees itself overwhelmed by an immense undertaking, in which success can only be obtained by the united assistance of all the national committees. It is for them to employ all their energy, and to go forward boldly and tenaciously toward the splendid goal before us.

Mr. Huet, president of the Commission on Bibliography, gave a brief address.

The President, in conclusion, thanked Professor Leche for presiding.

The meeting then adjourned.

Executive Council.

The Executive Council met on Wednesday morning, August 28th, Mr. W. B. Paterson, president, in the chair.

There were present: F. Schaeffer-Stuckert, secretary-general; W. Guy and M. Roy, adjoint secretaries; E. Rosenthal, treasurer; F. Aguilar, M. Ayrapaa, T. W. Brophy, C. Christensen, W. Dieck, E. Förberg, V. Guerini, W. Harrison, Van der Hoeven, E. Huet, J. Shmamine, Valenzuela, O. Walkhoff.

The President regretted that Dr. Godon could not be present, owing to a family bereavement.

Dr. Aguilar said it was the first time that Dr. Godon had been absent, and they missed him very much. He proposed that a telegram of sympathy be sent.

This was agreed to.

Dentists with Commissioned Rank Appointed in U. S. Navy.

The President read a letter of congratulation from Dr. Williams Donnally, announcing the appointment in the United States of America of sixty commissioned naval dental officers.

Professor Brophy expressed his conviction that the influence of the International Dental Federation had been a potent factor in producing this result.

The President also announced that Sir Henry T. Butlin, who presided at the F. D. I. meeting in London, has since died. On behalf of the F. D. I. he attended the funeral and presented a wreath. He also wrote a letter of condolence to Lady Butlin, who replied very graciously, and said that the recollection of the meeting at the Royal College of Surgeons had been one of the greatest sources of comfort to her husband in his illness.

A Question of Ethics.

The President said he had received a letter from Mr. J. Howard Mummery, one of their vice-presidents, who was unable to be present, stating that he had been asked to contribute a paper to the International Medical Congress in London, in August 1913. Mr. Mummery wished to know whether the F. D. I. would give him permission to read a paper in the Stomatological Section of that congress. The President thought Mr. Mummery, who was medically qualified, was entitled to attend the Medical Congress, but though both Mr. Mummery and himself had been offered the position of president of the Stomatological Section, they had both refused to accept it, because they felt that the International Medical Congress had not treated the F. D. I. and the dental profession as their members would have desired. However, he hoped there would be no objection to Mr. Mummery's reading a scientific paper before the congress.

Dr. Schaeffer-Stuckert said he was very glad that Mr. Paterson and Mr. Mummery had not accepted a position in the Stomatological Section, after the refusal of the International Medical Congress to recognize dentists. In the time of Miller it was agreed that they should not attend the congress at all, and this was enforced upon German doctors who were also dentists. He thought the situation was not different now.

Dr. Aguilar said that, as the president said last year, he regarded it not as a divorce, but only a temporary separation of medicine from dentistry. It had originated with one man, and the Medical Congress had been influenced by the conflict in France between stomatologists and dentists, which reflected itself in the congress at Lisbon. He thought they should attend and show that they wanted nothing for themselves, but went solely in the cause of science. He was sorry that Mr. Paterson and Mr. Mummery did not accept the positions offered, as he knew they would be loyal to their ideas. They must reconquer the position occupied before by dentists.

Dr. Brophy was in favor of Mr. Mummery's presenting a paper, as he felt it would enlighten members of the medical profession on a subject not thoroughly taught in schools of medicine. A paper by a master in this field of knowledge would benefit the whole scientific world.

Professor Walkhoff said he had always refused to read a paper in the International Medical Congress, owing to the resolution of the F. D. I. on that point. He thought that if permission was given, it must be universal, but they would be very much surprised in Germany, because the Central Verein had decided that its members should not go to the congress.

Dr. Guy said they had taken a very strong stand in view of the fact that dentists, as such, were excluded from the Stomatological Section. Consequently, Mr. Paterson and Mr. Mummery had declined official honorary positions in the Stomatological Section. He made up his mind to abstain from any participation in their proceedings, because, if they attended in their capacity as medical men in this section, he thought they weakened seriously the position of the F. D. I. However, he did not consider it would be contrary to the interests of the F. D. I. if a member read a paper in the sections of Physiology, General Surgery, or Medicine. But he held that they should maintain their position and abstain from taking part in the proceedings of the Stomatological Section until such time as the International Medical Congress decided to admit dentists, as such, to that section.

Professor Walkhoff explained that they had no feeling of opposition to members of the Stomatological Section.

Dr. Roy said it was a delicate question, and he supported Dr. Guy's suggestion.

Dr. Christensen thought it was a personal question affecting Mr. Mummery.

The President: If you give permission to Mr. Mummery, you must give permission to all.

On the motion of Professor Walkhoff, seconded by Dr. Rosenthal, it was resolved:

"That, inasmuch as the International Medical Congress has refused the admission of dentists to the congress, the F. D. I. does not approve of its members contributing to the Section of Stomatology; but the F. D. I. has no objection to its members contributing papers or communications to other sections of the International Medical Congress."

The President said he would inform Mr. Mummery of this resolution.

Wednesday Afternoon.

At the meeting at 4 p.m., August 28th, Mr. Paterson again presided.

The following members were proposed and duly elected:

Dr. L. Frank, Stationsweg 35, Rotterdam; Dr. Harold Ramberg, 83 Arsenalsgatan, Stockholm; Dr. Sigurd Hendricksen, Lillehammer, Norway; Dr. R. H. Riethmueller, Lock Box 1615, Philadelphia, U. S. A.; Dr. M. Walling, Mathias, Maine, U. S. A.; Dr. A. Joachim, 17 rue de Dublin, Brussels.

The Secretary-general presented his report.

The Hon. Treasurer next submitted the accounts.

Messrs. Aguilar, Harrison, and Roy were appointed auditors.

Dr. Schaeffer-Stuckert, referring to the list of members, pointed out that there were members of the Hygiene Commission who were not members of the F. D. I. He thought that all such should be first members of the F. D. I., and pay their dues.

The Council agreed with this opinion.

Dr. ROSENTHAL brought forward the proposal to establish an International Code of Ethics, which, he said, was suggested by Messrs. Aguilar and Cunningham.

It was agreed to appoint a special committee (consisting of Messrs. Aguilar, Harrison, Rosenthal, and Schaeffer-Stuckert) to consider and report on the proposal. Dr. Rosenthal was appointed chairman of the committee.

The Council then considered the following proposals by Professor Walkhoff:

To form an International Directory of all dental societies and of all qualified dentists, to be published annually. The F. D. I. should state officially the number of qualified dentists of all countries, also the curriculum and the time necessary for the study of dentistry, and the conditions of the examination for a graduate dentist. The F. D. I. should state officially the number of persons practicing dentistry without qualifications, viz:

(*a*) Physicians practicing dentistry without having passed any dental examination.

(*b*) Persons practicing dentistry without any preliminary education, and without having passed any dental examination.

The PRESIDENT thought such an International Directory ideal, but described the carrying out of the three proposals as difficult. There were official registers of qualified dentists in Great Britain and Ireland, some States of America, Germany, and Belgium, which could be utilized, but he knew no means of ascertaining the number of physicians practicing dentistry, or the number of unregistered dental practitioners.

Dr. GUY moved that the proposals be referred to the Commission on Bibliography, with instructions to form a collection of all published directories and registers of qualified dentists, and also to communicate with the secretaries of all national dental societies, requesting information as to the membership and constitution of all dental societies in their respective countries. He thought they could not afford an annual publication.

Dr. SCHAEFFER-STUCKERT explained that Professor Walkhoff did not ask for a directory to be published.

Dr. BROPHY (Chicago) said it was impossible to state the number of irregular dental practitioners, or of physicians practicing dentistry in America.

Dr. ROSENTHAL pointed out the risk of legal proceedings.

Professor WALKHOFF (Munich) said that, when questions of dental laws and education came before parliaments, information might be asked for on these points. He wanted, if possible, authentic material and data in the F. D. I. archives to be supplied to governments who inquired, "How is it in other countries?"

Dr. ROSENTHAL observed that the exercise of the professions was free in Germany, but different conditions prevailed all over Europe.

M. ROY thought information concerning all dental societies would be more important and valuable to the F. D. I. than the compilation of statistics, which could hardly be accurate.

Dr. BROPHY seconded Dr. Guy's motion, which was carried.

The Council then considered a proposal to establish a complete bibliography of existing dental books and publications, and to assure the continuance of the information in the future through the agency of the Institute of Bibliography in Brussels.

M. HUET stated that the proposal to publish a complete dental bibliography was justified as much by the constant accumulation of material as by the impossibility of finding one's way among the mass of information given in books, treatises, medical journals with a dental section, and the 145 periodicals concerned solely with Odontology. But they must not lose sight of the fact that the *Concilium Bibliographicum,* of Zurich, made an abstract or list of articles on General and Dental Anatomy and Physiology, Dentition in Animal Species, etc. He must remind them that such an undertaking would involve a considerable amount of labor and expense for the F. D. I. For dental periodicals only, the yearly average of notices concerning original articles would be about 3500, equal to 1000 octavo pages printed on one side only. Moreover, their library was not yet supplied regularly enough with the materials to justify any useful examination of the question. He moved that it be adjourned.

Dr. ROSENTHAL said it was desirable to establish such a Bibliography, but it was impossible for the Institute of Bibliography in Brussels to make an index of dental books and publications every month, as ought to be done. He suggested that each national dental journal should have its index of bibliography published monthly.

The PRESIDENT said the proposal appeared to him to be "a counsel of perfection." For example: In England, the medical and dental journals were accustomed to publish an index at the end of the year, and although a monthly index might be made, it might be inconvenient to publish it. He imagined similar conditions prevailed in other countries.

No action was taken in the matter.

Invitation to America.

Dr. BROPHY, being obliged to leave for America that evening, asked for permission to submit a cordial invitation from the National Dental Association of the United States to the F. D. I. to hold its next meeting in America. He added that Dr. Kirk, himself, and others quite understood that the feeling of the London meeting was in favor of holding the F. D. I. meeting of 1913 in America.

The PRESIDENT thanked Dr. Brophy, and promised the question should receive careful consideration when it came up for discussion the next day.

(To be continued.)

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

Subscriptions and communications relating to advertisements should be addressed to the BUSINESS MANAGER of the DENTAL COSMOS, Lock Box 1615, Philadelphia, Pa.

PHILADELPHIA, JANUARY 1913.

EDITORIAL DEPARTMENT.

"THE COURAGE OF IGNORANCE."

MUCH of the scientific work of dentistry has been done by workers who, though appreciating the value of the results everywhere attained by the scientific method of investigation, have nevertheless, in many instances, themselves lacked the discipline of a scientific training, and who have been handicapped by imperfect conceptions of the broader underlying generalizations of scientific thought which are the directive and often controlling agencies of successful scientific work in new fields. A lack of training in the fundamental principles of science is made painfully evident in the results from time to time reported of research work or investigation as pursued by observers and students thus disqualified for the task which they have undertaken. Erroneous conclusions and defective observations seem to bear a definite ratio to the elementary scientific educational lack. On the other hand, where the exact methods of science have been correctly applied to the solution of any of the important problems that concern us as dentists, the results have always been fruitful of precise knowledge in related degree.

The eternal warfare between truth and error is a record of the conflicts between knowledge and ignorance—conflicts that are oftentimes intensified by the inclusion of the personal element, leading to recriminations and emotionalism that further complicate the problem and overshadow the main issue until all recognition of its importance is lost. It is under these circumstances that questions of personal honesty, prejudice, or fairness are raised when any of the parties to a given controversy express their convictions and are apparently unwilling to change their point of view or modify their contention even in the face of what appears to be overwhelming evidence as to its erroneous character. Such situations are clearly the outgrowth of misunderstanding—*i.e.* not understanding, *i.e.* failure or inability to understand, *i.e.* ignorance of the nature and meaning of the data that are for the time being under consideration. It is not a question of honesty at all, but a plain case of "don't know," the pathetic thing about it all being that the party in the wrong either doesn't know that he is wrong, or, worse still, doesn't want to admit that he is wrong. But there is what might be called an important mitigating factor affecting the case of the man who doesn't know and who doesn't know that he doesn't know—the man who with the courage of his ignorance vehemently asserts that he does know; and that factor is the honesty of his belief in the evidence of what he calls his own experience, and his faith that what he has himself experienced cannot be wrong. It is, however, just that kind of faith that is earliest destroyed by systematic training in precise methods of scientific observation and reasoning, and which must be eliminated before observation and reasoning can be called scientific at all or have any real value as expressions of the truth. The well-known example of the apparent difference in temperature between a wooden surface such as a table-top and a metallic or mineral body in the same room, when tested by the sense of touch, and the contrary indication of the thermometer, is a familiar instance of the unreliability of untrained experience as a standard of scientific truth. The ignorant empiric would contend that the metallic body was colder than the wooden surface; the trained observer would abide by the decision of the thermometer, which shows, in spite of the evidence afforded by the experience of touch, that the temperature of both bodies under the same conditions is equal.

It is the most encouraging sign of the approach of a period of larger interest in the application of the scientific method to the solution of our professional problems that more and more students of these same problems are realizing the great practical difference that exists between empiricism and the empirical method on the one hand, and science and the scientific method on the other. The present issue of the Dental Cosmos furnishes a number of instances of the relative value of these two types of mental activity, besides, in at least one instance, a direct statement of the essential difference and respective utility of the two methods, by one who is himself an able exponent of the scientific method, which leaves little to be desired as to clearness and effectiveness.

We commend to our readers the careful and thoughtful consideration of the presentation which this issue contains of the subject of pyorrhea alveolaris and of the sulfocyanate question as related to dental caries, both of which furnish illuminating examples of the soundness and sanity as well as of the fruitfulness of the scientific as compared with the empirical method.

Bibliographical.

Surgery and Diseases of the Mouth and Jaws. By Vilray Papin Blair, A.M., M.D., Professor of Oral Surgery in the Washington University Dental School, and Associate in Surgery in the Washington University Medical School, St. Louis. Pp. 638, with 384 illustrations. St. Louis: C. V. Mosby Company, 1912.

In presenting this work the author has given us an excellent treatise on the regional surgery of the mouth and jaws, containing in great detail the knowledge required by the general surgeon in meeting conditions affecting these parts.

The tendency on the part of general surgeons to treat fractures of the lower jaw by wiring the bone is upheld, in spite of the certainty of converting a possibly simple fracture into an infected compound one, and in face of all evidence in favor of the metal mandibular or mandibulo-maxillary splint. The advantages of early operations for congenital cleft palate are well brought out, and the most suitable operation for each class of deformity is described very carefully.

In extracting teeth, the author shows a preference for the English type of forceps, of which he describes and illustrates several examples. Impacted teeth are not given as full discussion as their importance and frequency entitles them to, particularly in regard to causes, diagnosis, and local and remote effects.

In speaking of epulis, the author probably takes a too serious view of the prognosis of the majority of these growths, and urges too drastic operations in their treatment. Most of them, even the so-called giant-cell sarcomas, do not demand extensive removal of the surrounding tissues.

A large portion of the book is taken up with a consideration of tumors and other affections of the salivary glands, tongue, and pharynx, with detailed descriptions of the extensive operations required for their treatment. This matter is more within the scope of the general surgeon than of the dentist.

There is a good chapter on Tic Douloureux, with special reference to the diagnosis from neuralgia due to local causes. Treatment by alcohol injection of the divisions of the fifth nerve is clearly described, as well as the Gasserian ganglion operation.

Local Anesthesia is discussed at considerable length, with emphasis on the dangers of injections into inflamed tissues.

Only two pages are given to General Anesthesia, which in a text-book intended for students is not sufficient.

The book is well equipped with illustrations, chiefly original ones, though there are several from other sources, and is completed by a bibliography.

From the standpoint of a text-book for dental students, a large amount of material is presented that it is not necessary for them to know except in a very general way. The dentist is chiefly concerned in the recognition of such affections as carcinoma of the tongue, lips, and jaws, rather than in the details of major oper ations required for treatment of these conditions. For his benefit, however, the dental student will find several chapters devoted to elementary surgical principles and pathology.

As a treatise on the purely surgical affections of the mouth, jaws, and surrounding parts, the general surgeon will find in it a very valuable work of reference. R. H. I.

Review of Current Dental Literature.

[*Anatomischer Anzeiger*, Suppl. to Vol. 41, Berlin, 1912.]

THE STRUCTURE OF THE REPTILIAN DENTITION, AND ITS RELATIONSHIP TO THE MAMMALIAN DENTITION. By Dr. Bolk.

In the dentition of the two vertebrate classes, mammalia and reptilia, two fundamental distinctions are presented: (1) The dentition of the former is diphyodont, of the latter, polyphyodont. (2) In the former there has occurred a complication of the crowns.

The theories of differentiation (Cope-Osborn) and of concrescence (Röse) are practically agreed as to the significance, or rather, perhaps, lack of significance of the first item.

Bolk asks, Is there a genetic relationship between the diminution of mammalian tooth generations and the complication of their crown surfaces? And he answers in the affirmative at the conclusion of his paper.

Although the point of conflict of the two theories is over the manner in which the complication of crowns arose, this question of Bolk is *ipso facto* outside of consideration for any other than the disciples of the concrescence theory.

The author disregards the palatal and vomer dentition of the reptilia. He mentions the general characteristics of the reptilian dentition, such as can be found in any dependable systemic or odontographical work.

Bolk introduces a new terminology to facilitate the systematic discussion of certain anatomical relations of the vertebrate dentition, as follows: A monostichic dentition is one in which the teeth are set in the alveolar arch in a single row, *i.e.* the reptilian dentition apparently. In reality this dentition is distichic—two rows—an outer, exostichos, and an inner, endostichos. (Only secondarily does the reptilian dentition become monostichic.) He gives an account of his ontogenetic investigations in support of this. Even a third row of teeth, parastichos, is suggested, but is rudimentary and resorbed before eruption. Reptilian distichism is best shown in the premaxillary region. The exo- and endo-stichos are contemporaneous tooth "generations"—both functioning contemporaneously.

To quote Bolk: "We have recognized in the reptilia a dentition of three rows of teeth. The parastichos consists of only rudimentary elements, which never function, and disappear without successors. Two of the rows succeed in functioning, an 'outer' (labial), the *exostichos*, and an 'inner' (lingual), the *endostichos*. The elements, *i.e.* the individual teeth, of both rows are in the majority of reptiles replaced by succeeding generations." This tristichism has been inherited from the reptilian parent form of the mammalia. The two tooth "generations" of the mammalia do not deserve the dignity of that designation, but they are identical with the two rows of the reptilian dentition—*i.e.* the deciduous dentition with the exostichos and the permanent dentition with the endostichos; the prelacteal dentition of the mammalia answers to the parastichos of the reptilia.

In man there is a succession of the inner tooth row, the endostichos, into the place of the outer, the exostichos. In the reptilia the two rows continue to functionate throughout life, and the individual elements are replaced—*i.e.* there is a change or succession of the elements or units of the dentition. Therefore the diphyodontism of the mammalia is something of an essentially different character from the polyphyodontism of the reptilia.

What has become of the tooth generations of the reptilia? Each tooth in the primates has arisen from the concrescence of two tooth generations. It is to be remembered that "generation" is here used in its true phylogenetic sense, not in the local sense as usually applied to the mammalia. Each tooth has an external (buccal or labial) and an internal (lingual) division. Each division represents a generation of the reptilian dentition.

Bolk would derive the mammalia, on the grounds of skull and structure and tooth topography, from the reptilian Cynodontia. The complication of the teeth in longitudinal —mesio-distal—direction was initiated among the reptilia, and inherited by the mammalia. The complication of the crown in a transverse—bucco-lingual—direction is the result of the concrescence of two tooth generations, whereby the origin of the mammalian tooth from the reptilia was completed. By this concrescence, the multiplicity of the tooth generations was suppressed, *i.e.* polyphyodontism of the reptilia succumbed in the complication in a transverse direction of the tooth crown of mammals.

TEETH AND MUSICAL INSTRUMENTALISTS. By Zahnarzt Th. Froelich, Baden.

When compared with the great publicity which has been given oral hygiene at home, in school, in the army and navy, and in all kinds of public institutions, little or nothing has been said about the importance of the teeth in the life of professional musicians, especially those playing a wind-instrument. The instruments in the playing of which the teeth play such an important rôle may be divided into four classes: (1) Instruments without mouthpieces, viz, various kinds of flutes. The sound is produced outside of the mouth, which is pointed and simply serves as outlet for the current of air, which is broken at the edge of the blow-hole. (2) Single-beating reed instruments, such as clarinets, etc., in which the lower lip is drawn over the lower teeth and the reed is held with the upper teeth. (3) Double-reed instruments, such as hautboys, bassoons, etc., in which the lower lip is retracted, and the reed is gently held with the upper lip. (4) Brass instruments, in which both lips are retracted, and the mouthpiece is pressed against them. The vibrating membrane is supplied by tension of the lips. In playing the French or hunting horn, the lower lip is retracted, and the mouthpiece is held so that the upper lip covers one half, the lower lip the other half, pressure being exerted especially on the lower teeth.

From this classification, the importance of good teeth becomes very apparent. Especially the anterior teeth serve partly as supports for the instrument, partly as resistance against the pressure of the cheek and lip muscles. In players of certain instruments, therefore, typical changes in the soft and hard tissues of the mouth are to be noted. Players of the clarinet, for instance, exhibit a thickening of the lower lip, horn players at times a retrusion of the lower teeth. In trumpet players, the central incisors play the chief rôle, while in players of larger brass instruments the laterals also play a part.

The lack of loss of individual molars, as a rule, are of no great consequence for the player, but the loss of several approximating molars may become serious for him. In playing the horn especially, the molars are of importance; in double-reed instruments, the canines, resisting the pressure of the cheek muscles. The lack of these teeth weakens the force of the tone, which becomes hollow and thin.

The question of prosthetic appliances is sometimes very difficult to solve. Fixed bridges are indicated, yet no open spaces must be allowed, as, in playing, the mucous membrane of the cheeks is pressed into them, thereby sometimes impairing the quality of the tone produced.

Partial vulcanite pieces are generally well tolerated, and do not affect the quality of the tone. The plate is held firmly by the tip of the tongue, which presses against the gum, especially in staccato play. Full upper dentures may become rather embarrassing, since the increased air-pressure renders even air-chambers ineffective.

The replacement of lower anterior teeth offers great difficulties, since the displacement of a lower plate, especially if the alveolar ridge has become greatly absorbed, is inevitable. The employment of springs is not only very inconvenient but also of little value, so that the preservation of the lower teeth is imperative. The dentist's great responsibility, therefore, in the treatment of musical instrumentalists is self-evident.

SPIROCHETES IN THE MOUTH. By A. A. Thibaudeau, M.B., Buffalo, N. Y.

The author reports that in the routine examination of smears from the mouth, as carried out by students in the classroom, a considerable number were found, which when stained by the Giemsa method showed spirochetes morphologically resembling spirochaeta pallida. As some observers have considered it possible to make a diagnosis of syphilis by the finding of spirochaeta pallida in smears from suspicious sores in the mouth and pharynx, it was thought desirable to examine the smears from a number of normal mouths. Smears were accordingly made from apparently healthy mouths, using the deposit at the junction of the gums with the teeth, and from the root of the tongue. After fixation in absolute alcohol they were stained by Giemsa's rapid method. Smears from each case were also stained by Loeffler's methylene blue or an aqueous solution of gentian violet. Three main types of spirochetes were found:

(1) The large *spirochaeta buccalis* with long flat curves, which is much thicker and wider than the other spiral forms found in the mouth, and which has fewer turns.

(2) A moderate-sized spirochete, probably the "medium" form of *spirochaeta dentium* described by Hoffmann and Prowazek. This organism stains a very faint purple by Giemsa. The coils of this spirochete, as found in mouth smears, are not so sharp or so regular as those of spirochaeta pallida, and the organism is thicker.

(3) A small, very delicate spirochete, with sharp coils fairly closely applied, was the form that most resembled spirochaeta pallida—probably the *spirochaeta microdentium* of Noguchi.

This organism very frequently exhibited irregularities in the arrangement of the coils, as seldom seen in the spirochaeta pallida, but specimens were found in which the coils were regular throughout the organism. The spirochaeta stained by Giemsa's rapid method showed a coloration from a rose-red to a light purple, depending apparently on the degree of heat used and the length of time that it was exposed to the stain. Typical organisms of this type showed pointed ends. It stained but poorly with Loeffler's methylene blue, and in about 30 per cent. of the cases, where present, could not be found in the control smears stained by this method. It is to be noted that while these organisms may not present all the characteristics of a typical spirochaeta pallida, there are usually in stained smears from definite syphilitic lesions, and in which typical spirochaeta pallida may be present, numbers of spirochetes, undoubtedly spirochaeta pallida, which are not typical in every respect, and which could not be distinguished in stained smears from this type of mouth spirochete.

The author has examined smears from 149 mouths; in sixty-one or 40.9 per cent. of these, spirochetes of the last type, which might be taken for spirochaeta pallida, have been found. In none of these cases did inquiry bring out a history of syphilitic infection. The possibility of these organisms causing a mistake in diagnosis in a non-syphilitic ulceration or other non-syphilitic lesion of the mouth seems self-evident.

INTERSTITIAL DENTAL CARIES. By R. Charlet, Rouen.

Interstitial caries—viz, caries of the approximal surfaces of the teeth—can be classed into two groups, according to its starting-point above or below the contact point. The second class—viz, cervical caries—pass often unnoticed until discoloration of the dental tissue occurs, while caries seated between the contact point and the crown surface of the tooth are readily noticeable. If the cervical portions of the mesial and distal surfaces of teeth are closely examined, a small spot of bluish shade which resists the explorer is frequently discovered in the enamel. Sometimes a milky white, translucid and non-circumscribed or a gray spot may be discovered, all of which indicate the presence of caries. If an effort is made to penetrate the enamel with a fine, sharp bur, the enamel behaves very much like a snow bridge over a glacier crevasse, that is, after some resistance it will break, allowing the bur to plunge into the softened dentin underlying it. Care is therefore required in guiding the bur in order to avoid severe pain or accidental pulp exposure. Careful differential diagnosis must be made between the enamel spots described and those due to calcarious concretions in the enamel, or to discoloration from an amalgam filling. The etiology of this form of caries is easily definable. Food débris lodged in the interstitial spaces undergoes fermentation and furnishes a most favorable medium for the bacteria whose toxins are responsible for caries, which, unless discovered and combated in time, will manifest its presence by pulpitis. The interstitial spaces, therefore, must always be subjected to a most rigorous examination by the dentist. Prophylaxis consists in painstaking oral hygiene, with a view to keeping the interstitial spaces free of food débris.

ACUTE OSTEOMYELITIS OF THE JAW. By Dr. W. Wayne Babcock, Philadelphia.

Babcock differentiates osteomyelitis of the jaw from the simpler infections and forms of necrosis by the following symptoms: Extensive involvement of the contents of the inferior dental canal, tendency to the widespread secondary destruction of the bone, and damage done to many or all of the lower teeth. Osteomyelitis in the young occurs in the lower jaw as well as in the long bones of the extremities, although at a somewhat later age. Its early diagnosis is to be based on the early severe systemic disturbances and the widespread involvement of the bone. The prophylactic treatment consists in drilling the bone under aseptic precautions. After the formation of pus, free drainage should be employed, which should be external if there be much necrosis. No teeth should be extracted, nor should teeth which merely hang from attached mucous membrane be removed. Dead portions of bone should not be removed until entirely detached or until new bone capable of maintaining the contour of the jaw is formed. Separated and loosened teeth with gum attachment usually become reimbedded and serviceable.

AVOIDANCE OF ACCIDENTS IN LOCAL ANESTHESIA BY A MIXTURE OF PEPTONE AND COCAIN, OR PEPTONE AND NOVOCAIN. By Dr. L. Fichot.

The increasing popularity of local anesthesia for dental operations, which, since the introduction of cocain substitutes or the modifications of cocain mixtures, has engaged so many researchers, is signally attested by Fichot's essay. Fichot, in collaboration with Billard, has made experiments showing that a solution of cocain mixed with a solution of from two to ten per cent. of Byla's peptone can be injected in guinea-pigs in large doses without producing death. While eight centigrams of cocain hydrochlorate is the lethal dose per one kilogram in guinea-pigs, the pepto-cocain solution is not lethal up to from eighteen to twenty centigrams. Billard has employed submucous injections of a 1:200 pepto-cocain mixture for dental operations in 172 cases, each dose injected containing from two to four centigrams of the alkaloid. The injections were painless, and full anesthesia was obtained as rapidly as usual, viz, within from four to five minutes. The anesthetizing power of the solution is the same as that of the alkaloid alone, as is also the duration of the anesthesia, viz, from fifteen to eighteen minutes. Cicatrization is rather accelerated than retarded, and no untoward symptoms have been observed in the 172 cases treated.

Solutions of one per cent. of pepto-novocain have been injected by Fichot in 248 cases. While novocain is usually injected in combination with adrenalin, the pepto-novocain mixture offers the following advantages: Its anesthetizing power is the same, also the duration of the anesthesia. The injection is painless and the maximum anesthesia is obtained within from four to five minutes as over against the ten to twelve minutes required with the novocain-adrenalin solution. Cicatrization is remarkably rapid as compared with the slowness of the healing process after novocain-adrenalin injection.

The cocain and peptone solutions must be made separately, and should never be mixed until just before the injection is made. A two per cent. peptone solution is usually sufficient.

COMBATING DENTAL CARIES AMONG SWISS MILITARY CONSCRIPTS. By A. Brodtbeck, Frauenfeld.

DENTAL HYGIENE IN THE SWISS ARMY. By Dr. T. Montigel.

DENTAL TREATMENT IN THE ARMY. By H. Matter, D.D.S., Zurich.

The remarkable progress of oral hygiene abroad is evinced by the symposium held at the annual meeting of the Swiss Odontological Society, during which the above-mentioned three papers were read.

Basing his remarks on the motto that "Not as cheaply as possible, but as well as possible, should the life and health of the citizen bearing arms be cared for," Brodtbeck makes the following demands from the Swiss military authorities: Establishment of the greatest possible number of dental clinics for school children; clinical treatment of both sexes from the sixteenth to the twentieth year of age, such treatment to be given either in clinics or in private practices, with a federal subsidy of up to 50 per cent.; examination ot the mouth and teeth of military conscripts by licensed Swiss dentists; records of the results of such examinations; instruction of the recruits as to the necessity of having their teeth treated before entering upon active service. The teeth are to be treated at regular intervals, as long as a man is liable to service in the reserves; the cost of treatment of conscripts and soldiers is to be borne by the federal government, or, if desirable, up to 50 per cent. thereof may be borne by the cantons. A uniform schedule of fees is to be worked out, subject to approval by the Swiss Dental Society; compulsory care of the teeth in the army (if a soldier suffers with toothache during active service, he is to be referred to a licensed dentist for treatment); military physicians are to be obliged to take a course of instruction in extracting, and another in diagnosis and therapeutics of dental disease; a special course of instruction is to be given to military dental surgeons; uniform records of examinations before and after treatment are to be kept. Brodtbeck mentions that 98 per cent. of all Swiss soldiers suffer with dental caries, and that over 50 per cent. are unable to masticate properly, thereby reducing their force of resistance, predisposing themselves to all sorts of acute infectious diseases, and seriously jeoparding their efficiency.

Besides giving a few detail statistics in regard to dental treatment of soldiers, Montigel recommends essentially the same course of procedure as Brodtbeck, but adds the necessity of assigning dentists efficient in immediate prosthesis to the sanitary corps in case of warfare.

Dr. Matter makes suggestions as to the dental armamentarium indispensable in case of war, and vigorously protests against the tendency of the medical profession to belittle the importance of the oral hygiene movement in the army.

[*Deutsche Monatsschrift fuer Zahnheilkunde,* Berlin, June 1912.]

CONNECTION BETWEEN OCULAR DISEASES AND INFLAMMATORY CONDITIONS OF THE TEETH. By Dr. F. Seydel, Breslau.

The assumption that a close relationship exists between the organ of vision and the teeth is an old one, as evinced by the popular term "eye-tooth." The justification of this assumption, however, is based more upon popular imagination than upon clinical observation. A relationship between diseases of the teeth and those of the eyes may exist, however, either by direct transmission or by reflex processes. In the former cases, inflammations of the orbit play an important part. Pus in pericementitis and alveolitis, as well as septic processes within the alveoli, may proceed along the cheek in the form of lymphangitis or thrombophlebitis, or through the maxillary antrum to the inferior orbital wall. The germs of the permanent canines or first bicuspids may be wedged between the deciduous teeth and the orbital wall in such a manner that a direct communication between the alveoli and the orbital wall persists in form of a delicate vascular canal. In both these ways a purulent orbital osteitis and periosteitis may be induced, and after the pus has invaded the orbit, orbital phlegmon of a rather severe nature results. If recognized early, the prognosis of periosteitis is favorable, while the purulent infiltration of the cellular tissue of the orbit may involve the optic nerve or the brain. Sometimes the pathological process is arrested by the orbital septum, producing abscess or gangrene of the eyelid, or dental fistulas opening so high up as to simulate ocular disease. If these fistulas open near the distal corner of the lid, they may give rise to confusion with tuberculous caries of the orbital margin; if at the mesial corner, they may be mistaken for lacrimal fistulas.

Seydel rejects the assumption of ocular disease caused by way of reflex. He denies that phlyctenular ophthalmia has anything to do with the first, or parenchymatous corneitis with the second dentition, or that glaucoma stands in causal relationship to dental disease. These two affections, in his opinion, exist either simultaneously by accident, or they owe their origin to the same cause, or the cause is being confused with the effect. Dental disorders, at best, might influence an ocular disturbance by way of sympathy, as in severe pain in the case of glaucoma. He claims that trigeminal neuralgia, like every other psychic or physical pain, is able to produce conjunctivitis and dilatation of the pupil only by way of reflex.

Seydel reviews two cases reported by Dutoit in the *Archiv fuer Augenheilkunde*, vol. 68, 1909, p. 311, in which ocular disturbances of apparently reflex origin were due to anatomical conditions in the teeth or jaws.

[*L'Odontologie*, Paris, November 1912.]

THE NATIONAL BREAD OF SWEDEN.

By G. Lagerheim, Stockholm.

The influence of the various kinds of bread upon the condition of the teeth has been given a great deal of well-deserved attention recently by those engaged in the international combat which is being waged against dental caries. Each country has one or more characteristic forms of bread. In southern countries, bread is made from wheat, in northern countries from rye, and from barley in countries bordering the cereal limit. Not only the flour used, but also the manner of preparing the dough and of baking are different in different countries. In some countries fresh yeast is used to make the dough rise, in others a portion of already fermenting dough, the latter especially in districts where rye is employed, as in northern Germany. Rye bread, thus prepared, has a more or less sour taste, which is disagreeable to a great many persons, as it is productive of nausea and gas in the stomach, and unsuitable for dyspeptics. It is also productive of dental caries, and may indirectly produce gastric disturbances. It cannot be preserved very well, as it molds very readily. In Sweden, rye bread has been used for a long time, called Spisbrod or Knäckebrod, which is known in America as "health bread." This truly national bread of Sweden has a very agreeable taste; it is shaped into thick round and flat or into small oblong cakes, is made of coarse, unsifted rye flour, spice and yeast, and is allowed to dry and harden before being consumed. If preserved carefully, it does not mold or deteriorate, and by reason of its hardness and friability, must be completely masticated, which is of great importance for the preservation of the teeth. Soft bread can be swallowed after having been chewed but little; only a small quantity of saliva, therefore, is mixed with the bread before deglutition, and gases irritating to the stomach are formed. Health bread, on the other hand, must be carefully masticated, therefore a large quantity of saliva is mixed with it, and the digestion of the starch is facilitated. In Sweden experience has shown that health bread given to children is productive of solid bones and healthy white teeth.

Periscope.

Prophylaxis in Cocain Injections.—Since cocain in the doses generally employed for hypodermic injections acts upon the vasoconstrictor system, producing pallor of the face, coldness of the extremities, elevation of blood pressure, and finally syncope, two and one-half centigrams of extract of opium in an infusion of coffee are recommended. This prophylactic mixture, which has a vasodilator effect, should be administered thirty minutes before injection.—E. Gruey, *Revue de Stomatologie.*

Root=canal Filling Material.—The following mixture is recommended for filling root-canals: Creasote, from one to four drops; trioxymethylene 0.02 gm.; zinc oxid, enough to make a stiff paste. This paste is claimed to be more suitable than one containing liquid formol, the trioxymethylene apparently retaining its power to generate formaldehyd indefinitely. Care must be taken not to employ an excessive quantity of the trioxymethylene, as the formaldehyd might produce a pericementitis.—C. Bourgeois, *Revue Odontologique.*

Antipyrin as a Local Anesthetic.—Antipyrin has often been employed as a styptic in hemorrhage. Its astringent action renders it suitable also in painful inflammations, such as stomatitis, gingivitis, etc. While its action is not as strong as that of cocain, relief is more lasting and effective, because the process of inflammation is abated. Even in ulcerative carcinoma of the tongue, antipyrin is very effective in alleviating the glossitis complicating these ulcerations. For these local applications by painting, a simple aqueous solution of 1:10 is employed. For mouth-washes or gargles a 1:50 solution is used. The disagreeable taste of antipyrin can be considerably improved by the addition of glycerin. —A. F. Plicque, *L'Odontologie*, per *Deutsche Zahnaerztliche Zeitung.*

Nerves in the Tooth Structures.—The compact nature of the dentin and enamel of the teeth has made it difficult, if not technically impossible, to carry out any adequate examination of a possible innervation of these tooth structures. Many have regarded it as highly probable that there is a nerve supply to the dentin of the human teeth by which very acute sensation is transmitted from the periphery of this tissue as in other parts of the body. Mummery has apparently been successful in tracing the nervous structures by means of the more modern methods of histologic study. He regards it as fully evident that the dentin is richly supplied with nerves from the pulp, which do not terminate, as has been hitherto generally supposed, at the inner margin of the dentin, but enter the tubules of that tissue and traverse them to their peripheral terminations at the enamel and cementum margins. There is some consolation, therefore, in the thought that our teeth are no longer to be deprived of the privilege of a suitable path for the transmission of those unique sensations which we are reminded at times to refer to these highly important organs.—Editorial, *Journ. Amer. Med. Association.*

Crumb and Crust of Bread.—Lay discussion not infrequently turns upon the relative merits of the crust and crumb of bread, but it has come to our attention that the matter is often referred to the family medical adviser, generally in the form of a question as to which of the two is more digestible. Analysis shows very little difference in regard to the constituents of each, but crust, of course, contains much less moisture, and so is richer in solid constituents. The crumb contains on an average 43 per cent. moisture, while the crust contains only 20 per cent. One important dietetic difference between crust and crumb is the fact that the former contains an increased amount of soluble carbohydrates, owing to the action of intense heat which the crust receives compared with the crumb during baking. Moreover, the crust has a more pronounced "bready" flavor than the crumb, a flavor which is attractive and which stimulates the flow of digestive juices. That the digestion of crust in the mouth is much more likely to be complete than is the case with the crumb everyone has generally found out for himself, as the plasticity of the crumb, and especially that of new bread, prevents to some extent the salivary attack.

If new bread were as thoroughly masticated as dry stale bread is bound to be, there would be no reason why it should be less digestible, but it seldom receives the necessary treatment in the mouth.—*Lancet.*

Clasps for Partial Dentures.—The application of clasps to partial dentures demands not only accuracy in the model, but great skill in their construction and adaptation, and should be started with an accurate plan, both in the pattern from which they themselves are cut and also in attaching them to the plate; otherwise the clasp is a menace to the tooth which it surrounds, and ignorance or neglect of these precautions will undoubtedly result in the loss of the teeth supporting the denture.

All clasps should be made concave before any bending is done at all, and should be constructed of platinous gold of No. 24 gage, the only solder being used to attach it to the plate at a point determined by the location of the tooth to be clasped. The plate should be cut out at this point, allowing the part of the clasp to be soldered to extend through to the plaster model, so that the minimum amount of solder can be used to attach it firmly. Yet how often do we see a clasp made of coin or 18-karat gold attached to its point of support by a huge lump of solder, which is so unyielding that it holds everything rigidly, and stress on either side will rock or tilt the piece itself. These creations are either too thick and too narrow, or too wide and of too thin a gage, with no attempt to concave the surface or clasp the tooth properly.—N. S. Essig, *Items of Interest.*

Castings in Prosthetic Work.—In my experience with casting I have made the following observations: (1) That nearly all prosthetic castings should be made in combination with iridio-platinum or gold in wire or plate form as a means of reinforcement. (2) That iridio-platinum, on account of its great strength and freedom from oxidation, affords the best reinforcement. (3) That 24-karat gold reinforced with iridio-platinum is the best for inlay abutments. (4) That the reinforcement plan expedites as well as strengthens the work and obviates bulkiness, which is so essential in many instances. (5) That it is best not to heat any alloy of gold containing base metals to the point of oxidation when casting upon it. (6) That it is unnecessary and detrimental to heat a flask to a red heat or anywhere near it when burning-out wax. (7) That the elastic limit of scrap or junk gold is practically *nil*, and it should not be used where much strain will be brought to bear upon it. (8) That alloys of gold with platinum will become very brittle when cast a few times. This Dr. Taggart tells us is due to contamination with silica contained in the investment. (9) That the casting process makes possible the employment of almost any forms of porcelain teeth, and that provision should be made for cementation rather than casting directly on to the porcelain. (10) That nearly all inlay abutments, regardless of size and shape of cavity, should have some form of supplemental pin anchorage.—F. E. Roach, *Journ. of the Allied Societies.*

Requirements of a Crown.—We must bear in mind—(1) The artificial crown must not in any way encroach upon the soft tissues. (2) At no point of its gingival circumference shall the continuity between the artificial crown and the dental organ be broken. (3) The artificial crown must restore to the broken-down tooth all the means of exercising the functions which nature intended it for—viz, mastication, trituration, incision, and prehension. (4) Whether it be a posterior or an interior crown, its phonetic service to the vocal organs must not be diminished, interfered with, nor made doubtful. (5) It must be perfect in its occlusal relations to the teeth opposing it, and (6) must be perfect in its occlusal relations to the teeth abutting it on either side. (7) It must be in perfect harmony with the soft tissues of the buccal cavity, the cheeks, the lips, and the tongue. (8) It must be so contoured that, if divided into three parts, gingivo-morsally (horizontally), its greatest circumference must be at the gingival plane of the morsal third, and its smallest circumference at the gingival plane of the gingival third. (9) The preparation of a tooth for the reception of scientifically constructed artificial crown includes the denuding of all its walls so that they be left minus enamel. (10) The proper preparation of a tooth for the reception of a crown implies the extirpation of the pulp—if vital—under cataphoresis, pressure anesthesia, or nitrous oxid; the proper treatment and filling of the root-canals, and such dressing-down of its walls and morsal surface as will permit the placing of a hood upon it, the vertical lines of the walls of which are at right angles to the horizontal plane of the gingival third of the tooth, regardless of its relative occlusal position within the buccal cavity.—H. E. S. Chayes, *Dental Forum.*

Care of Dental Instruments.—Instruments should not be allowed to rattle against each other, especially those with cutting edges, for the simple reason that the edges are soon destroyed. Excavators, enamel chisels, scalers, and suchlike should each have a separate compartment. Many of the cabinets now made have the drawers fitted to give effect to this. If one wished, however, to fit an ordinary drawer in this way, the use of corrugated paper makes a very simple and effective arrangement. It is better to allow short portions of the instruments to project beyond one of the edges of the paper, so as to enable the operator to pick them up easily. If this corrugated paper is enameled white, it can be washed when necessary. White porcelain dishes are very useful. There are several sizes; the smaller ones are useful for clamps, matrix bands, separators, etc., also for holding brushes, stones, disks, and various other articles, while the larger dishes are excellent for handpieces, scissors, tweezers. There are special dishes for forceps. For holding gutta-percha pellets, points, pulp caps, and similar articles used directly in the process of filling teeth, glass boxes with lids are preferable, as they are dust-proof. Glass jars with loose-fitting lids are very good for holding saliva-ejector tubes, sponges for anesthetic work, and cotton rolls. A jar might be made for holding mouth-mirrors, which could stand with the mirror portion in some antiseptic.—H. M. STURROCK, *Dental Record.*

Smallpox Vaccination from a Dentist's Point of View.—From a specifically dental point of view we ought to do all we can to discourage vaccination. We know how any disorder, and especially the eruptive fevers, affect the teeth of the child, and undoubtedly vaccination, if it "takes," must seriously interfere with the development of the teeth. Vaccination is supposed to take place in the second to the fifth month after birth. At the eruption of the deciduous teeth, practically all the crowns of the centrals and laterals are calcified, two-thirds of the canine crown, one-half of the crown of the first molar, and one-third of the crown of the second molar, so that, if at this time an eruptive fever is induced, it interferes seriously with the calcification of the deciduous molars, which perhaps may itself account for the prevalence of caries in these teeth. But worse than that, even, is the effect on the first permanent molar, the calcification of which commences just after birth. May not vaccination have something to answer for in regard to the appalling number of first molars which are lost at an early age? We found that ninety-nine per cent. of the children at the James st. school suffered from caries, and is it not our duty, then, to discourage vaccination, as it must undoubtedly do harm in interrupting the development and calcification of the teeth, while the good is to some minds problematical, and to others entirely absent? There is far more harm arising in this country from defective teeth than is ever likely to arise from smallpox.—C. O. TEBBUTT, *Commonwealth Dental Review.*

Hints for the Avoidance of Sepsis of Dental Origin.—Dentists should realize the seriousness of the most frequent operation they perform, namely, that of devitalizing and extracting pulps, since infection and serious bone destruction originate from this cause.

Destruction of the bony floor of the antrum does not necessarily mean perforation of the membranous floor or infection.

An alveolar fistula leading into a cavity where a considerable portion of a tooth is exposed requires extraction of the tooth before complete recovery can be expected.

Persistent headaches and general reduction in health are frequently caused by very insidious alveolar abscesses.

In destruction of the mandible, requiring removal of bone, it is advisable to establish drainage through the chin, and approximate the gingival margins with sutures so as to shut off a pus cavity from the oral cavity.

Naso-oral fistulas may be closed by a membranous flap from the roof of the mouth.

In all suppurative conditions of the mouth tincture of iodin, U. S. P., should be used as a disinfectant.

Blood-clot organization is typified in the repair of the maxillary process after the extraction of teeth. Here we may extract many teeth, leaving holes of considerable size, which are immediately filled in with blood, and even the patient never hears of it again. Why not larger cavities?

The practice of packing sterile cavities with gauze at every dressing is wrong, since it breaks down and destroys blood-clots and valuable plastic material thrown out by nature to rebuild damaged tissues.

Extensive areas of bone may be stripped of the periosteum, and, if sterilized and adjusted to the original position, will re-adhere and revitalize the bone, and necrosis will not result.—S. L. MCCURDY, *Dental Summary.*

Gangrene of the Mouth Following Injection of Salvarsan.—Dritsaki reports the case of a physician who since the age of fifteen years suffered from malaria, which was treated with quinin and methylene blue without permanent result. He then decided to submit to salvarsan injection, which was made intravenously. Following the injection, a marked reaction took place, followed by enlargement of the liver and spleen and a gradually developing gangrene of the lips, cheeks, and tongue. The patient gradually grew weaker and died from exhaustion.—*Roussky Vratch*, per *N. Y. Med. Journal.*

Localized Gangrene Following the Use of Quinin and Urea Hydrochlorid.—Rightor reports an instructive case in which he had used the one per cent. solution of quinin and urea hydrochlorid, marketed in ampules, as a local anesthetic. Although the anesthetization and operation were completed without any untoward symptoms, a great deal of swelling and discoloration occurred, the lack of sensation lasting for several days. There was a very foul odor, and a well-marked localized gangrene extending exactly to the end of the line of infiltration, though no suppuration. A second operation became necessary to repair the damage, attributable undoubtedly to the untoward action of the local anesthetic employed.—*Journal of the Amer. Medical Association.*

Measures in Accidental Perforation of the Maxillary Antrum.—Accidental perforation of the maxillary antrum is not very serious, if immediately discovered and remedied. The perforation is best ascertained by pinching the patient's nose and requesting him to blow air through the nostrils. The air will then issue from the mouth with a characteristic noise, unless, of course, the aperture is already closed by granulations or swelling. This measure first confirms the diagnosis; second, any blood that may have entered the antrum is blown out; third, the injured and torn portions of the mucosa of the antrum are approximated, thereby forming a provisional though loose closure of the antrum, the aim being to cover the wound in such a manner that the mucosa of the antrum will heal undisturbedly. The simplest procedure of closing, as recommended by Partsch, consists in laying a tampon of iodoform gauze in front of the aperture, and fastening it in in such a way that it cannot drop into the oral cavity. If there are teeth in the proximity of the perforated spot, this tampon is held in place by a figure-of-8 ligature of wire or silk; if the jaw is edentulous, a prosthetic appliance, such as a celluloid plate, is necessary. In edentulous jaws, the mucous membrane of the mouth may be loosened, part of the jaw-bone resected, and the oral mucosa drawn together by a suture, thus obtaining closure of the perforation—the object of each of these measures being the complete closure of the antrum. Healing is usually complete in four days.—Prof. Williger, *Deutsche Monatsschrift fuer Zahnheilkunde.*

Tackiness in Rubber—Tackiness in rubber, says the *India Rubber Journal*, shows itself, in the mild form, as a sticky appearance on the surface of the rubber. In its more serious aspect, however, it may cause the rubber to become a syrupy liquid. The agents responsible for the phenomenon have been considered to be: (1) Bacteria; (2) sunlight; (3) heat, and (4) chemical substances. Isolation of tacky rubber, on the assumption that it is due to bacteria, has been claimed to bring about a reduction in the affection. Tacky rubber usually contains a high proportion of proteids, and support is given to the idea that bacteria play a part in producing it by the fact that the condition can spread by contact, and smoked rubber does not frequently become tacky—probably because of the action of antiseptic substances in the smoke. The trouble sometimes develops more quickly under the influence of sunlight, but the true explanation of the action is not forthcoming. That it has some influence is seen in the fact that many factories use ruby or orange-colored glass in order to exclude the chemical rays of light. With regard to heat, this is most likely to produce tackiness when the rubber is warmed in an atmosphere rich in organic matter, but heat alone has no effect in this direction. Chemical agents give rise to the condition directly, much in the same way as sunlight. Enzymes may be largely responsible, but there is no direct evidence to show that they are so. Weak solutions of acids, for instance, acetic acid, which may be produced by bacteria, have a strong effect, but so also has carbolic acid, and this would indicate that the action of bacteria is indirect in its nature. The actual cause of the trouble still remains to be discovered.—*British Dental Journal.*

Hints, Queries, and Comments.

HOW TO TAKE CARE OF ROOT-CANAL CLEANSERS.

Root-canal broaches are first immersed in boiling water for about ten minutes, after which any débris caught in the barbs can be removed by a stiff handbrush and water. They are then boiled again, and finally transferred to glass-stoppered bottles containing alcohol.

K. Paul Carson.

Minneapolis, Minn.

SOLDERING HINTS FOR CROWN AND BRIDGE AND ORTHODONTIA WORK.

Many dentists, particularly the younger practitioners, occasionally have great trouble in soldering bands or cusps to bands in crown work, and in soldering accessories to arches or bands in orthodontia work. These unfortunates usually attribute the "burning" of the gold or material used, and the apparent refusal of the solder to flow, to the solder itself.

Until recently I was one of those unfortunate individuals, and my failures have led me to thinking and eventually to experimenting; and, now, while realizing that I may not be the first to solve this common difficulty, but nevertheless desiring to enlighten those who have not found the way easy as yet in the matter of soldering, I am anxious to submit the following, which is my solution of the problem of successful soldering.

Let us take the soldering of a band for an example: It will be noticed that when an unsoldered band upon the well-approximated joint of which a small piece of solder is placed, is placed in the flame, the band becomes red or cherry-colored before the solder presents any change whatever, showing that the plate is affected by the heat easier and sooner than the solder. Of course the solder receives just as much heat, but it absorbs more heat. This was my cue.

Here is how I do my soldering now, and it has proved infallibly successful.

After the band turns to a cherry color, I remove it from the flame for a sufficient length of time to allow the band to cool. There is then more heat stored in the solder than in the plate. The band is nearly cool and the solder quite heated.

Then I repeat this performance. When the band has changed color the solder is almost ready to flow. When I put it in the flame the third time, I find that just when the band changes to a cherry-red color the solder will flow easily.

By using this method one lessens the possibilities of burning his gold by allowing a red-hot band to remain in the flame until the solder is heated up to the melting-point.

I trust others will try this method, and I am sure that if they do so they will meet with more successes and fewer failures.

Respectfully submitted,

S. I. Russakov.

Kenosha, Wis.

Society Notes and Announcements.

INSTITUTE OF DENTAL PEDAGOGICS.

The next annual meeting of the Institute of Dental Pedagogics will be held in Pittsburgh, Pa., January 28, 29, and 30, 1913. An unusually interesting program has been arranged, and no progressive dental teacher can afford to miss this meeting.

Fred W. Gethro, *Sec'y,*
Chicago, Ill.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

The regular meeting of the Academy of Stomatology of Philadelphia will be held on Monday, January 28, 1913, at the College of Physicians, Twenty-second above Chestnut st., Philadelphia, Pa., at 8 p.m. Dr. E. J. Greenfield of Wichita, Kan., will read a paper on "Implantation of Artificial Crown and Bridge Abutments." The American Circulating Dental Clinic will be on exhibit at this meeting.

All members of the dental profession are invited to be present.

N. L. Jameson, *Sec'y.*

MINNEAPOLIS DENTAL SOCIETY.

Change of Date of Meeting.

The annual midwinter meeting of the Minneapolis Dental Society will be held in the Masonic Temple, Minneapolis, Minn., Friday and Saturday, January 17 and 18, 1913.

Space has already been reserved for even a larger manufacturers' exhibit than was given last year. Clinics will be given by some of the best men in the profession, who will demonstrate all of the newest and most useful methods.

The entire meeting is to be conducted along unique and original lines—a new method of arranging the exhibits, a different and better way of classifying clinics, also many other new things which will add to the pleasure and profit of each visitor.

For information address

O. DeForest Davis, *Sec'y,*
404 Donaldson Bldg., Minneapolis, Minn.

MARQUETTE UNIVERSITY, DENTAL DEPARTMENT.

Alumni Association.

The seventh annual meeting of the Alumni Association of the Dental Department of Marquette University will be held at the Milwaukee Auditorium, January 23 and 24, 1913, to which all ethical dentists are invited.

C. T. Rosenbaum, *Sec'y.*

CHICAGO DENTAL SOCIETY.

The officers of the Chicago Dental Society are planning a large celebration for Friday and Saturday, January 31 and February 1, 1913. The program includes two days of clinics by selected men from all parts of the country, one evening of papers by men of international reputation, and concluding the two days' meeting with a testimonial banquet to our esteemed *confrère*, Dr. Truman W. Brophy of Chicago.

The dentists of Chicago will make every effort to see that the entire program will eclipse all former meetings. Any dentist who has a new or interesting clinic to give at this meeting is cordially invited to correspond with

Fred W. Gethro, *Ch'man of Clinic Committee,*
917 Marshall Field Bldg., Chicago, Ill.

CONNECTICUT STATE DENTAL ASSOCIATION.

The next annual meeting of the Connecticut State Dental Association will be held in Waterbury, April 15 and 16, 1913.

A. V. Prentis, *Sec'y,*
New London, Conn.

INDIANA STATE DENTAL ASSOCIATION.

The fifty-fifth annual session of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, May 20, 21, and 22, 1913.

The officers of the association recently met at Indianapolis and perfected plans for a three-day "post-graduate course." The very best instructors and specialists are being secured for each day. The course will be as follows: Tuesday—"Humanitarian Dentistry." Wednesday—"Preventive Dentistry." Thursday, A.M.—"Prosthodontia; P.M., a great table clinic. The clinic will also be held in the hotel.

No tuition fee for the members of the association, or visitors from outside the state who are in good standing in their state association, but all others desiring to take this course must arrange their tuition fees with the secretary.

Otto U. King, *Sec'y*,
Huntington, Ind.

ST. LOUIS DENTAL SOCIETY.

At the December meeting of the St. Louis Dental Society the following officers were elected for the ensuing year: Otto J. Fruth, president; Frank Rodgers, first vice-president; H. F. Hageman, second vice-president; G. B. Winter, secretary-treasurer; Virgil Loeb, librarian.

G. B. Winter, *Sec'y*.

NEW JERSEY STATE DENTAL SOCIETY.

At the forty-second annual meeting of the New Jersey State Dental Society, held at Cape May, N. J., July 17 to 19, 1912, the following officers were elected for 1912–13: Wm. I. Thompson, president; Wm. H. Gelston, vice-president; Chas. F. Jones, treasurer; Edwin W. Harlan, secretary; Wallace F. Naylor, assistant secretary. Executive Committee—Wm. H. Gelston (chairman), W. F. Barry, Henry Fowler, J. I. Woolverton, and C. P. Tuttle. Membership Committee—Joseph Kussy (chairman), Franklin Rightmire, A. S. Burton, J. F. Crandall, and Horace I. Beemer.

In addition to these, Dr. Vernon D. Rood, Morristown, N. J., was elected for a term of five years as a member of the State Board of Examiners to succeed Dr. B. F. Luckey of Paterson, N. J.

Edwin W. Harlan, *Sec'y*.

RUTLAND COUNTY (VT.) DENTAL SOCIETY.

A meeting of the Rutland County (Vt.) Dental Society was held in Rutland, Vt., October 29, 1912. The following officers were elected for the coming year: P. Mahoney, president; H. H. Yarrington, vice-president; G. E. Dailey, secretary and treasurer.

G. E. Dailey, *Sec'y*,
Rutland, Vt.

ARIZONA DENTAL SOCIETY.

At the fourth annual session of the Arizona Dental Society, in Phoenix, October 29–31, 1912, the following officers were elected: J. A. Messinger, Phoenix, president; L. W. Downs Douglas, vice-president; H. H. Wilson, Phoenix, secretary-treasurer. Board of Censors—L. B. Cary, T. S. Lewis, and J. D. Holcombe. Board of Directors—J. A. Messinger, H. H. Wilson, W. P. Sims, Eugene McGuire, and R. J. Roper. Committee on Public Dental Education—J. L. O'Connell, H. H. Wilson, and L. C. Shaw.

H. H. Wilson, *Sec'y*.

PRIZE COMPETITION
OF THE
Zentralverband der Oesterreichischen Stomatologen.

In view of the tenth anniversary of its organization, the Zentralverband offers a prize of K.500.00 ($100.00) for the best heretofore unpublished essay on any subject of stomatology. Only those papers which are submitted by medical men and dentists to the president of the association (Vienna I, Graben 31) between March 1, 1912, and February 28, 1913, will be admitted to the competition.

An essay cannot be withdrawn after once having been handed in.

The judges reserve the right to divide the prize into two equal parts, should two essays of equal value be submitted. If none of the essays is adjudged worthy of the prize, the competition may be kept open for a further period not exceeding two years.

The author agrees to place his work at the disposal of the *Oesterreichische Zeitschrift fuer Stomatologie* for original publication.

The essays must be handed in ready for publication, and will if possible appear within the period open for the competition. Every essay published will be paid for at the usual rate of K.80.00 ($16.00) per galley. The cost of printing, including the illustrations, will be borne by the journal.

For the Zentralverband der Oesterreichischen Stomatologen:

Dr. W. Herz-Fraenkl, *Pres.*,
Dr. Rudolf Bum, *Sec'y.*

IDAHO BOARD OF EXAMINERS.

The Idaho State Board of Dental Examiners will meet for the examination of candidates for license to practice dentistry in Idaho, on January 6, 1913, in Boise.

Albert A. Jessup, *Sec'y,*
513 Overland Bldg., Boise, Idaho.

NORTH DAKOTA BOARD OF EXAMINERS.

The next meeting of the North Dakota Board of Dental Examiners will be held at Bismarck, N. D., January 14, 1913, and continuing four days. All applications for examination must be in the hands of the secretary by January 4th. No other meeting will be held until July 8, 1913. For further information apply to

F. A. Bricker, *Sec'y,*
Fargo, N. D.

INDIANA BOARD OF EXAMINERS.

The next meeting of the Indiana State Board of Dental Examiners will be held in the State-house at Indianapolis, beginning Monday, January 13, 1913, and continuing four days. All applicants for registration in the state will be examined at this time. No other meeting will be held until June 1913. No temporary permits are issued.

For further information address

F. R. Henshaw, *Sec'y,*
508 K. of P. Bldg., Indianapolis, Ind.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending November 16, 1912:

Chas. E. Sherwood, act.d.s., November 4th, reports for temporary duty at Fort Baker, Cal.

Wm. A. Squires, act.d.s., November 6th, reported for temporary duty at Fort Meade, S. D.

First Lieut. Edwin P. Tignor, November 10th, returned to Fort Monroe, Va., from detached duty.

Relieved from duty at the station designated, and will proceed to the Philippine Islands for duty: John W. Scovel, Presidio of San Francisco, Cal.; Chas. B. Seely, Jr., Fort Sam Houston, Texas, and Wm. A. Squires, Fort D. A. Russell, Wyo.

Relieved from duty in the Philippines Division, and will proceed to the United States for further orders: First Lieut. Ed. P. R. Ryan and Frank L. K. Laflamme.

For the week ending November 23d:

Chas. B. Seely, act.d.s., November 15th, reported for temporary duty at Fort Logan H. Roots, Ark.

First Lieut. F. L. K. Laflamme granted two months' leave of absence.

Relieved from duty in the Philippines Division, and will proceed to the United States: First Lieuts. Rex H. Rhoades and John R. Ames.

The following assignments of acting dental surgeons, recently appointed, are ordered: Edwin M. Kennedy, Fort Robinson, Nebr.; Lester C. Ogg, Letterman General Hospital, San Francisco, Cal.; Herman S. Rush, Fort D. A. Russell, Wyo.; Jay W. Smith, Fort Sam Houston, Tex., and Benjamin C. Warfield, Madison Barracks, N. Y.

First Lieut. Geo. L. Mason, November 14th, reported at Fort Benjamin Harrison, Ind., for temporary duty.

Albert R. White, act.d.s., November 16th, returned to Fort Des Moines, Iowa, from temporary duty at Fort Crook, Nebr.

First. Lieut. Franklin F. Wing is relieved from duty at Fort D. A. Russell, Wyo., and James F. Feely, act.d.s., is relieved from duty at Fort Hamilton, N. Y., and will proceed at the proper time to San Francisco, Cal., and take the transport to sail from that place on or about March 5, 1913, for the Philippine Islands, and upon arrival at Manila will report to the commanding general Philippines Division for assignment to duty.

For the week ending November 30th:

First Lieut. Frank P. Stone, November 24th, reports for temporary duty at Madison Barracks, N. Y.

James F. Feely, ACT.D.S., November 27th, left from temporary duty at Fort Hancock, N. J., *en route* to Fort Totten, N. Y., for temporary duty.

For the week ending December 7th:

Wm. A. Squires, ACT.D.S., November 26th, reported at Fort Mackenzie, Wyo., for temporary duty.

C. B. Seely, Jr., ACT.D.S., November 27th, returned to Fort Sam Houston, Texas, from duty at Fort Logan H. Roots, Ark.

Jay W. Smith, ACT.D.S., November 28th, reported for duty at Fort Sam Houston, Texas.

Lester C. Ogg, ACT.D.S., November 29th, *en route* from Mt. Vernon, Ohio, to take station at Letterman General Hospital, San Francisco, Cal.

Herman S. Rush, ACT.D.S., November 29th, reported for duty at Fort D. A. Russell, Wyo.

First Lieut. R. E. Ingalls, November 26th, from temporary duty at Fort Flagler for temporary duty at Fort Worden, Wash.

B. C. Warfield, ACT.D.S., December 2d, reported for duty at Madison Barracks, N. Y.

E. M. Kennedy, ACT.D.S., November 30th, reported for duty at Fort Robinson, Nebr.

A. T. Knoderer, ACT.D.S., December 2d, returned to Fort Oglethorpe, Ga., from temporary duty.

First Lieut. R. E. Ingalls, November 26th, reports for temporary duty at Fort Worden, Wash.

First Lieut. Geo. L. Mason, December 2d, returned to Fort Snelling, Minn., from temporary duty at Fort Benjamin Harrison, Ind.

ORIGINAL COMMUNICATIONS.

THE DEVELOPMENT OF THE TEETH AND OCCLUSION AS FACTORS IN THE DEVELOPMENT OF THE FACIAL BONES.

By FREDERICK BOGUE NOYES, B.A., D.D.S., Chicago, Ill.

(Read before the American Laryngological, Rhinological, and Otological Society, Philadelphia, Pa., May 14, 1912.)

THE object of preparing this paper is to present ideas that are constructively helpful both to the rhinologist and the orthodontist. To the rhinologist, because he is interested in securing normal conditions in the respiratory passages and the sinuses which communicate with them—and normal development is necessary for proper ventilation of those spaces, and ventilation is a prime requisite for normal conditions of the mucous membrane. To the orthodontist, because he is not simply concerned with the correction of crooked and irregular teeth, but with the development of a normally proportioned face and balanced and harmonious features.

It seems unnecessary to emphasize the importance to either profession of clear ideas of development and growth of the jaws and bones of the face forming the walls of the nasal cavity and sinuses, for without them it would seem impossible to avoid mistakes both of diagnosis and treatment.

It will be my endeavor to express as clearly as possible my own conception of the manner of growth and the changes occurring in development, and the interdependence of various factors upon which the normal process is dependent. The time is too short to make any attempt to present the work that has led to these conceptions, which have crystallized gradually in fifteen years of study of these tissues and their development, but the consideration of some fundamental principles is necessary.

RECENT LIGHT ON THE CHEMISTRY OF VITAL PROCESSES.

It is only through the brilliant work of Emil Fischer and others on the constitution of the proteid molecule and the discovery of the linking of amido-acids that any thinkable conception of the chemistry of vital processes has been arrived at. In the linking of amido-acid derivatives in ring form, with infinite possibilities of complication and extension in side chain, we have a basis for the consideration of metabolism; and only by gaining some conception of the relation and interdependence of the surrounding medium, the cytoplasm, and the nucleus in metabolism can we obtain any idea of the relation of cellular and intercellular substances in the organism. From a consideration of the physical character of living matter it is evident that no highly organized creature would be possible without the formation of substances possessing different physical character to furnish support and protection to the living matter. All living tissues are made up of cells and intercellular substances which have been produced by the cells and are dependent upon them for the maintenance of their chemical identity and proportion. The formation of these intercellular substances is in response to physical and mechanical conditions, and is a phase of adaptation. In the higher forms certain tissues have been specialized with reference to support and connection, and have been called the connective or supporting tissues. It is necessary to suppose that the cells of these tissues have been specialized to respond to physical and mechanical environment, with the formation of intercellular substances adapted to the conditions. To illustrate: In the evolution of the sense of sight certain cells of the epithelium have been specialized to respond to light stimuli by metabolic reaction of a special kind. In a similar way connective tissue cells have become specialized to respond to mechanical environment by metabolic reactions producing intercellular substances adapted to the conditions.

A study of the embryology of connective tissues strengthens these ideas, the nature and arrangement of the intercellular substance being often clearly the result of the mechanical conditions to which the tissue is subjected. For instance, we say the fibers of the peridental membrane are beautifully arranged to support the stresses to which the tooth is subjected; but they are so arranged because they have been produced in response to these mechanical conditions. In the development of fibrous tissue from embryonal tissue the cells are arranged with reference to the forces or stresses which it sustains, and the fibers appear in a corresponding arrangement. One of the most striking characteristics of the connective tissue is its adaptation and ability to transform itself from one variety to another better suited to a changed condition.

BONE AS A PLASTIC TISSUE.

Because of the fact that these tissues are largely made up of intercellular substances, which are the last to decompose after death, they are often thought of as unchanging, and it is very hard for us to get the idea that bone is a plastic tissue. Men are continually reasoning from experiments upon skulls or skeletons, forgetting that they represent only the remains of the intercellular substance and that even this is not in the same condition as during life. Not long ago a prominent scientist, whose name would be recognized by many, showed me a device of his invention for my opinion as to its surgical value. After looking it over I told him there was just one thing the matter—that he was experimenting with dead bone, which is not the same as living bone. Many men have commented upon the fact that nature never allows the bony framework of a creature to be either too heavy or too light, and this will perhaps be understood better if we come to realize that throughout life almost continual changes are going on. In studying bone-growth or bone-formation everyone is impressed with the alternation of formation and destruction, so that many have spoken of the process as wasteful. Viewed from another standpoint it would be seen that this is nature's method of adaptation—that the cells respond to the demands of increase of strength and rigidity by the production of more bone, that this proceeds until the weight and bulk is greater than necessary, which causes absorption, which proceeds until the tissue is too light for the stress, and so by oscillating a condition of balance is maintained.

BONE AS REGARDED FROM THE HISTOLOGICAL STANDPOINT.

It is true from one standpoint that a bone of the skeleton, whether a long, a flat, or an irregular bone, can be regarded as an organ of support and rigidity; but it is still more important to remember that it is only a portion of the connective tissue framework which, because of definite mechanical environment, has been made rigid by the formation of calcified tissue. This aspect we shall find particularly important to bear in mind when considering such questions as the opening of the maxillary suture. This attitude is difficult for one who has studied bone wholly or chiefly from the anatomical standpoint rather than from the histological or microscopic, but it becomes more and more strongly impressed by the study of bone-growth and the development of the jaws. In the formation of the membrane bones of the head and the face, calcification begins at points or centers in the connective tissue and spreads by the formation of spicules radiating from the center. The ossified portions gradually take on the form of the respective bones, but remain separated by more or less of the connective tissue on the line of the sutures for a long time. The presence of connective tissues in the sutures is an important factor in growth.

THE VARIETIES OF BONE.

Bone may be defined as a connective tissue whose intercellular substance is calcified and arranged in layers, or lamellæ, around nutrient canals or spaces. The cells are placed in spaces, lacunæ, between the layers, and receive nourishment through minute channels, canaliculi, which penetrate the layers. By the arrangement of the structural elements three varieties of bone are recognized.

Subperiosteal bone. In this form of bone the lamellæ are arranged parallel with the surface under a formative membrane or periosteum. This variety must always be considered a formative and more or less transient arrangement. It is never allowed to become very thick, but is partially removed and rebuilt into Haversian-system bone.

Haversian-system bone. This is often called true bone; it constitutes the greater part of the compact bone in the shafts of the long bones and the plates of flat and irregular bone. In this variety the lamellæ are arranged concentrically around canals cntaining bloodvessels, nerve, lymphatics, and embryonal connective tissue. A study of either ground or decalcified sections shows that this kind of bone is capable of and more or less constantly undergoes internal transformation by absorptions and rebuildings occurring in the canals.

Cancellous or spongy bone. This is composed of delicate irregular spicules composed of a few lamellæ arranged around large irregular spaces filled with embryonal connective tissue and containing bloodvessels, nerve, and lymphatics. There is no sharp line of demarcation between Haversian-system and cancellous bone, and we find all grades, between the most dense with the smallest Haversian canals and the most cancellous with the largest spaces, and the narrow cavities of long bones must be considered as enormous cancellous spaces.

TRANSFORMATIONS OF BONE.

In growth, bone is continually being transformed from one variety to another, and this occurs in a more or less oscillating fashion. In fact, these transformations continue throughout life and occur in either direction. We find subperiosteal bone being laid down within a periosteum, this being absorbed from the walls of the penetrating canals and converted into Haversian-system bone, and, after a sufficient thickness has been produced, absorptions and rebuildings in the Haversian canals convert them into cancellous spaces. In the opposite way, lamellæ may be laid down around large cancellous spaces, converting cancellous into Haversian-system bone, then absorptions under the periosteum may cut deep into the Haversian-system bone and rebuild a few layers of subperiosteal bone to smooth the surface. No proper conceptions of the growth of bone and the formation of the face with its inclosed sinuses can be had till these transformations are clearly understood.

Every detail of the minute structural bone is found to be most perfectly related to the stress and strain to which the bone as an organ of support is subjected. Or, as it should rather be stated, every detail of minute structure is formed in response to mechanical environment and conditions of nutrition, and as conditions change they are rebuilt in response to balanced forces. It may be said that both phylogenetically and ontogenetically bone has been developed in the species and is formed in the individual in response to mechanical stimuli and in adaptation to mechanical environment.

Phylogenetically, the teeth originated as appendages of the skin, and had no relation to the bone. Originally the teeth had only fibrous connective tissue support, and later in evolution, with the development of the teeth, bone was produced in response to mechanical environment, rendering them more useful to the individual. In the development of the individual, also, the formation of the teeth precedes the formation of the bone which is produced for their support.

RELATION OF THE TEETH TO FACIAL BONE DEVELOPMENT.

With these fundamental considerations in mind we may proceed to the consideration of the relation of the teeth and occlusion to the development of the bones of the face. This naturally presents three phases for consideration:

(1) The relation of the growth of the teeth to the formation of bone in the maxillæ.

(2) The relation of the use of the teeth in function to the growth of the bones of the face; for it must be borne in mind that in the normal individual the bones of the face are the result of the sum total of the mechanical conditions to which they are subjected, distributed in perfect balance and harmony through the mechanism of normal occlusion.

(3) The interrelation of the growth of the teeth themselves and the distribution of functional forces by occlusion.

FORMATION OF BONE IN THE MAXILLÆ.

As soon as the maxillary arches are complete, and while the only supporting framework of the mandible is Meckel's cartilage, the formation of the tooth germs for the temporary teeth begins. By the time these have taken on their characteristic form, the formation of spicules of bone begins in the mesodermic tissue in the region of Meckel's cartilage. This continues to spread until it incloses the cartilage and extends upon the buccal and lingual of the developing germs. In this section through the mandible of an embryo pig (Fig. 1) the bone is already taking form, and a periosteum is seen on its surface. From this time onward growth will proceed by the formation of bone under the periosteum, and in the articular cartilage its transformation within. Somewhere between the seventh and the ninth month after birth (Fig. 2) the growth of the incisors within their crypts causes absorption of the bony covering, and the teeth move occlusally, the bone from the margin of the crypt growing up to support them. The roots are not fully formed, and the multiplication of cells on the conical remains of the dental papillæ is a factor in this movement. At about one year (Fig. 3) the incisors have appeared. Notice the relation of the unerupted teeth in their crypts. The roots of the centrals and laterals are not completed, and each successively distal tooth lies deeper in the bone, so that their development transmits pressures which cause the already unerupted teeth to continue to move upward, forward, and outward in the lower jaw, and downward, forward, and outward in the upper. The crypt walls are continuous at their occlusal border with the dense cortical plates, and so in a sense are swung from the upper border of the bone; but the growth of the tooth germ exerts pressure which pushes the crypt walls through the cancellous bone until the resistance below is greater than the resistance above. The relation of the lower wall of the crypt of the temporary molars to the canal of the inferior dental nerve is worthy of notice in relation to the nervous phenomena so often accompanying the eruption of these teeth. (Fig. 4.) As soon as the teeth erupt, they and in fact the entire surface of the gums are subjected to pressures which are the result of the growth

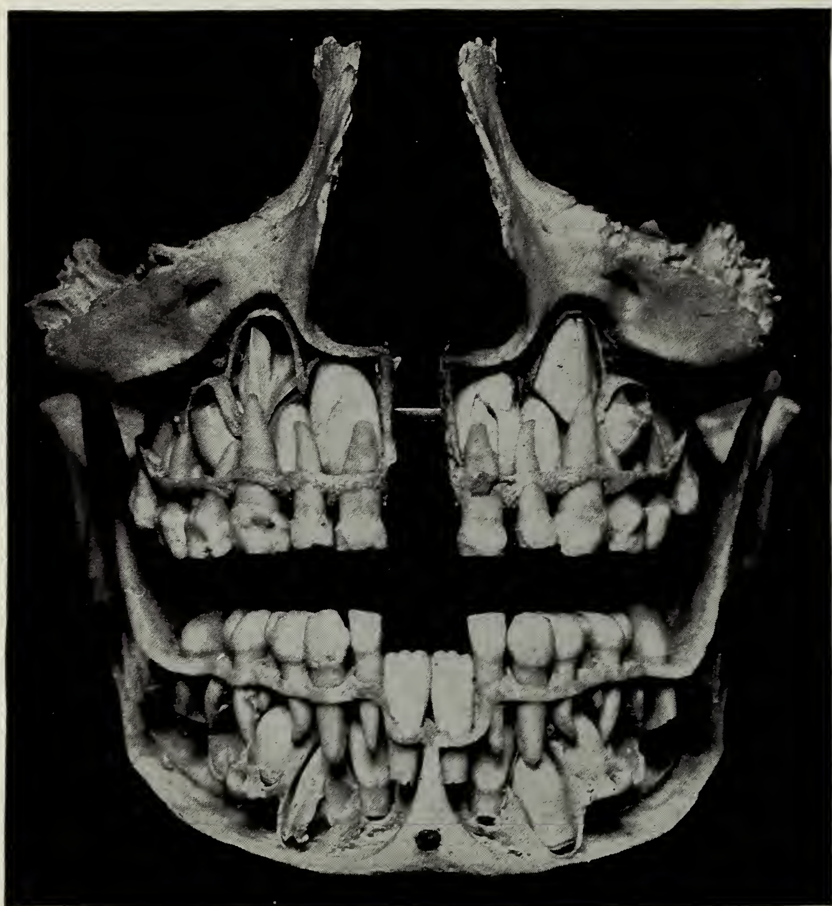
of the inclosed organs, and to stresses produced by the action of muscles attached to the periosteum and in constant use in function. We must picture the bone, not as the solid and unyielding structure it presents in a dried skeleton, but as an extremely active tissue very rich in blood supply and made up of millions and millions of cells all of which are very busy. The result of the growth and eruption of the temporary teeth one after another is the development of the maxillæ in an occlusal and outward direction, increasing the size of its arch and its thickness from above downward. (Fig. 5.) When all of the temporary teeth have taken their positions and are in full occlusion, growth continues in the same directions under the influence and function and development of the first permanent molars. At about six years the four first molars erupt and take their position in the arch. (Fig. 6.) The importance of these teeth and their normal relations to each other cannot possibly be overestimated. They are the largest and strongest teeth of the permanent set, and during the period in which the temporary teeth are being replaced by the permanent ones they not only do the chief

Fig. 7.



Front view of Fig. 6.

work of mastication, but maintain the proper relation of the maxillæ and distribute the forces of function. The mesio-buccal cusp of the upper molar should lock between the buccal cusps of the lower, but it often happens—usually, apparently, because of perversions of the functions of respiration and deglutition —that they lock with the disto-buccal cusps of the upper teeth between the buccal cusps of the lower, throwing the entire mandible half the width of the molar distal to its normal position. The locking of the cusps retains it permanently in this position, and not only disturbs the relation of each permanent tooth as it erupts, but entirely changes the distribution of functional forces upon the bone. During this period the first molar must be considered as the point upon which the action of the muscles which are attached to the condyle and ramus and those which are attached to the anterior portion of the jaw are balanced, and the change in the relation of the first molar profoundly alters the direction of forces upon the growing bones.

Fig. 8.

Dentition in the eighth year.

DENTAL FUNCTION IN RELATION TO FACIAL GROWTH.

During the entire period of the function of the temporary teeth they continue to move through three dimensions of growth of the permanent incisors and canines is very instrumental. (Fig. 7.) Between six and seven years of age the crowns of these teeth have been fully formed and occupy most of the space between the nasal floor and the roots of the

FIG. 9.

Dentition in the eleventh year.

space in an occlusal and outward direction under the influence of the development of the permanent teeth. This growth is at first chiefly in the anterior region, or from the symphysis to the mental foramen in the mandible and from the suture to the canine region in the maxillæ. In this development the teeth in the upper, and the inferior border of the mandible and the roots of the teeth in the lower. Growth of the canine has pushed its crypt wall through the cancellous bone until it is braced against the solid structure at the base of the malar process. (Fig. 8.) The lower canine has obtained its firm rest against the lower cortical plate of the mandible. The teeth lie to the lingual of the roots of the temporary teeth, and are arranged in phalanx, the lateral braced against the central, the canine against the lateral, and both canines against the cortical means of this arrangement the upper temporary incisors should be forced apart and stand widely separated before they are lost, and when at seven years this has not occurred we know that the development is below normal.

Fig. 10.

Maxillæ from young adult, about fifteen years.

plate. A similar arrangement is seen in the maxillæ. At about this time only the crowns of the canines have been developed, and as their long roots are formed, all of the previously erupting teeth are carried in the occlusal and outward direction. (Fig. 9.) It will be seen that normal proximal contact is necessary for the carrying out of this mechanism. By

From nine to fourteen years, growth is largely from the mental foramen to the ramus and in the corresponding portions of the mandible, and is brought about by development of the bicuspids under the temporary molars and of the second molars to the distal of the first. (Fig. 9.) When, at thirteen or fourteen (Fig. 10), all of the permanent teeth except the molars are in occlusion, the growth in an occlusal and outward direction should continue until development is complete. If the vitality of the cells in the bone has been maintained by the mechanical stimuli of full normal function, the development of the third molars behind the seconds, together with functional pressure, should be sufficient to continue this occlusal outward movement. (Fig. 11.) Notice the relation of the apices of the incisor roots to the floor of the nose and the inferior border of the mandible in the skull of a child of fifteen years and in the normal adult. (Figs. 10 and 11.) Unfortunately too often, the tissues are not sufficiently vigorous or the necessary mechanical stimuli are lacking to carry out this development, and the third molars remain unerupted. In the development described the transformations of bone are continually going on. Bone is formed on the surface by the periosteum and the pericementum at the alveolar border and the articular cartilage, and is rebuilt and transformed within. The periosteum molds the surface by absorption, cutting deep into the part already formed, and then re-forms a few layers on the surface. A study of decalcified sections give a record of these changes in the arrangement and character of the lamellæ.

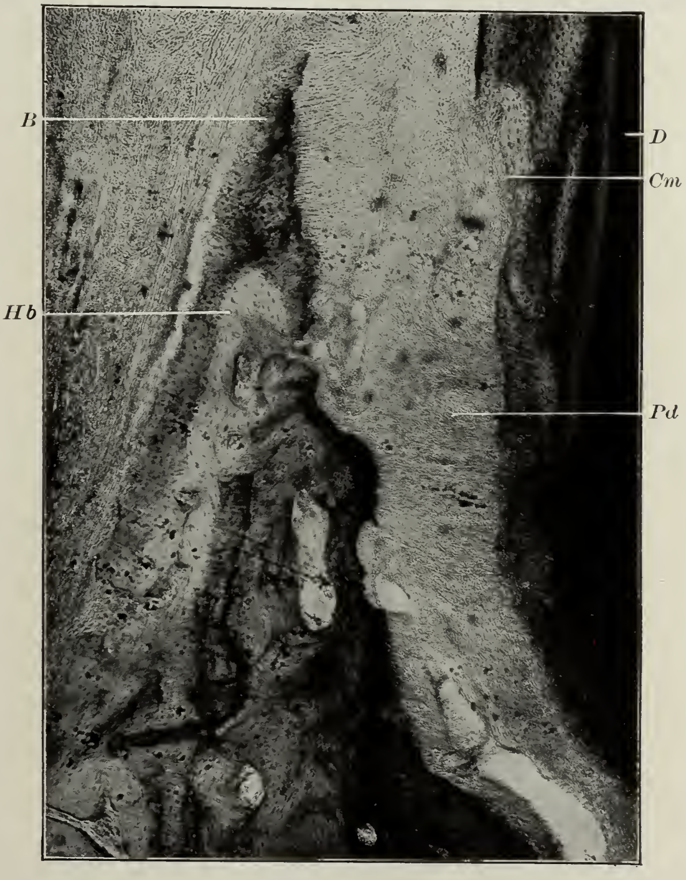
Fig. 11.

Adult.

MUTATIONS OF BONE EXEMPLIFIED IN THE MANDIBLE.

The tissue changes in the mandible furnish a good example of the mutations of bone in growth. A section through the alveolar process of a temporary tooth shows the connective tissue at the border of the process being converted into subperiosteal and subperidental bone, which is absorbed from within and rebuilt in Haversian systems. The process around the temporary tooth about to be shed appears as a regular patchwork. (Fig. 12.)

FIG. 12.



Longitudinal section through the tip of the alveolar process of a temporary tooth about ready to be lost. *D*, dentin; *Cm*, cementum, showing absorption and rebuilding; *Pd*, peridental membrane; *B*, bone growing occlusally at the border of the process; *Hb*, rebuilt Haversian-system bone.

In the buccal cortical plate of the mandible the formation under the periosteum, the transformation into Haversian-system, and the change to the cancellous variety may be seen in one field. (Fig. 13.) In connection with the advocacy of the operation of opening the maxillary suture for the increase of nasal space, many statements have been made as to the character of the suture and its function in the growth of the bone, but none of these that I have seen is based upon the study of the tissue, or shows any photomicrographs of the tissue. In general, I think the statement can be made that the connective tissue in the line of the suture is not important as an osteogenetic structure; that the formations of bone that occur are rather mutations like those going on elsewhere within the tissue. In other words, the maxillæ are not pushed apart by formation of bone in the median suture, and the direction of growth is not in that direction. On the other hand, the sutures are important as allowing the changes of adjoining bones to each other during the growth of inclosed organs or surrounding parts, and sutures do not ossify until inclosed structures have obtained their full development.

Fig. 13.

Bone from the buccal plate of the mandible, showing the transformations of bone.

Some years ago I received through the kindness of Dr. A. H. Ketcham of Denver a portion of bone removed by Dr. Carmody in an operation for carcinoma, and containing the intermaxillary suture in the incisal region. I cut sections at right angles to the alveoli of the incisors, and as nearly as possible parallel with the floor of the nose. Six photomicrographs of the tissue accompany this article. (Figs. 14–19.) The bone was somewhat broken by the manner of removal, but is in fair condition. The character of the tissue in the suture is found to be much more densely fibrous than that of the cancellous spaces and is not of the same embryonal character. It does not show the appearance of the osteogenic layer of the periosteum. There is no indication of bone formation as there is under the periosteum, especially in the region of the nasal spine, and only slight indications of rebuilding as occurs in cancellous bone.

DISTRIBUTION OF FUNCTIONAL FORCES BY OCCLUSION.

In the preceding description of the relations of the growth of the teeth to the formation of the maxillæ, reference was

Fig. 14.

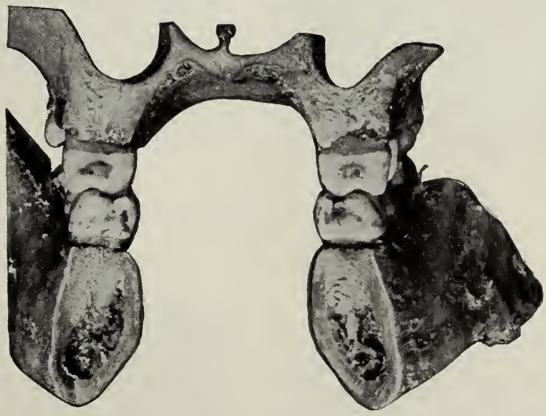
several times made to functional forces which exert an influence in producing mechanical stimuli. These forces are exerted to a considerable extent upon the surfaces of the bone through muscular contraction and through the attachment of muscles to the periosteum covering them, but their most important means of distribution is through the teeth and their interlocking inclined planes in occlusion. Dr. E. H. Angle deserves the greatest credit for having discovered in the occlusion of the teeth a mechanism through which forces are distributed and upon which the normal development of the face is dependent. The locking of the buccal cusps of the lower teeth between the cusps of the upper causes the movements of the teeth in mastication to mold the form of the arch. In the lateral grinding movements the buccal slopes of the cusps of the lower teeth press against the lingual slopes of the uppers and exert a powerful influence in widening and rounding the arch. This can be appreciated by closing the jaw firmly and grinding the teeth, when the lateral pressure will be felt, or by examining a vertical section of the skull in the molar region. (Fig. 20.) If the jaws are used chiefly with an up-and-down motion and from front to back, as in the chopping and crushing of meat fiber, the arch will be longer and narrower, and if there is no vigorous use of the teeth in mastication the bones will be under-developed and the respiratory spaces consequently narrowed.

Fig. 20.



Section of the skull in the molar region. (Dr. Cryer.)

Normal respiration during the developmental period exerts the greatest influence upon the growth of the bones. With the mouth closed the lips are pressed against the labial surfaces of the incisors, the lower lip covering about one-third of the upper incisors. The tongue fills the vault of the palate and pushes against the lingual surfaces of the teeth and bone. The air being partially exhausted by the soft palate lying against the base of the tongue, there is a downward pressure on the floor of the nose. With every vigorous inspiration there is a depression of the hyoid bone and consequent pull upon all the muscles extending from it to the mandible and tongue; this increases the pressure on the lingual surfaces of the teeth and the downward pressure on the palate. If breathing is carried on with the mouth open all of these influences are lacking, and the result is shown in the typical deformities of class I, division 1. Unless the incisors are in normal relation the closing of the lips in normal relation is impossible, and consequently, whatever the condition of the respiratory passages, normal breathing is impossible. If the first molars have locked their cusps in abnormal relation, the relation of the incisors cannot be normal, consequently operations for adenoids in children of seven years or older has seldom much effect alone in the cure of mouth-breathing. The function of deglutition is quite as important as that of breathing, and is seldom if ever normal in abnormal breathers. The normal individual swallows about once in two minutes night and day. With each deglutition the teeth are pressed firmly together by the contraction of the elevators of the mandible; this produces the greatest pressure upon the lingual cusps of the upper teeth and the buccal cusps of the lowers, and is an important factor in the development of normal nasal space, for it carries the apices of the roots buccally. At the same time the hyoid bone is elevated and the tongue flattened, pressing on the lingual surfaces of the teeth and pulling upon the roof of the mouth. In the intervals

the exhaustion of air partially sustains the weight of the mandible. If the lips do not close normally the whole mechanism fails.

Fig. 25.

Fig. 26.

Figs. 25–32 are front views of the series of skulls, photographed with the same arrangements of the camera so as to preserve relative proportions and illustrating the development of the bones of the face.

Fig. 27.

Fig. 28.

CONCLUSION.

Enough has been said to show that throughout growth the nasal cavity increases in depth and width, by the distribution of functional forces through the bone by means of the occlusion of the teeth. The changes in the bone in growth may be best illustrated by viewing the maxillæ from the median line. The four bones were photographed with the same

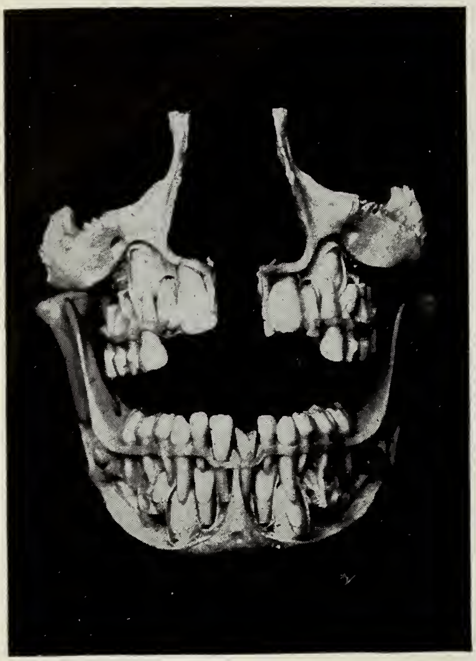

Fig. 29.

Fig. 30.

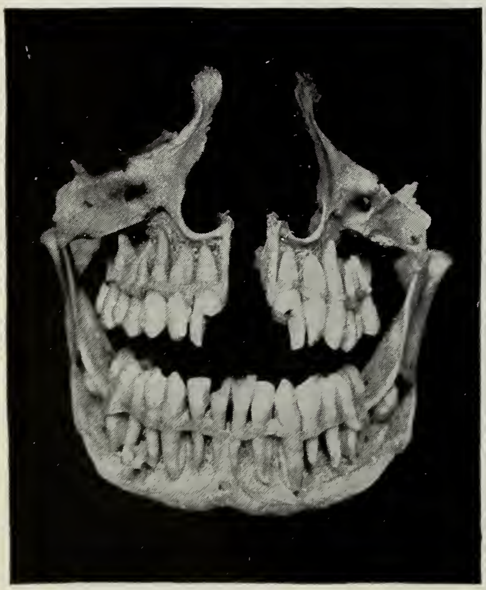

Fig. 31.

Fig. 32.

lens and bellows length, so as to preserve the relative size. (Figs. 21–24.)

In closing, let me repeat that in the development from the infant to the adult the bones are growing under the influence of mechanical stimuli, and for full normal development vigorous normal function is necessary. It is useless to establish normal occlusion of the teeth if normal functional stimuli are not distributed by it, and it is equally useless to clear out obstructions from nasal passages if malocclusion renders normal function impossible. The direction of growth is downward, forward, and outward, increasing the distance from the floor of the nose and the floor of the orbit to the incisal edges of the teeth, and increasing the depth and width of the nasal cavities. We may follow the process in a series of photographs from skulls in the museum of the Northwestern University Dental School, made of the same relative size to show the direction of growth. (Figs. 25–32.)

REMOVABLE AND STATIONARY CROWN AND BRIDGE WORK.

By ALBERT W. JARMAN, D.D.S., Philadelphia, Pa.

(Read before the Cleveland Dental Association, at its monthly meeting, at Cleveland, Ohio, October 7, 1912.)

OVER a year ago I gave a clinic in your city, at the annual meeting of the National Dental Association, on "Removable Bridge Work," and was much gratified with the manner in which the subject was received. The invitation to me to come to your city in order to read a paper on this occasion convinces me that the dental profession of Cleveland is interested in advancing crown and bridge work of a thorough and substantial character.

INDIVIDUALIZATION A REQUISITE IN CROWN AND BRIDGE WORK.

We have in dentistry successful bridge work and unsuccessful bridge work—one a blessing, the other a curse. We cannot reach perfection in all our operations; we are working upon human beings, therefore the success of our work is sometimes hampered by conditions which may develop afterward and over which we have no control.

To obtain success in bridge work, as in everything else, we must have ideals toward which to strive, and scientific principles which must be observed; we must think as well as work. The most interesting feature of bridge work is the fact that each case requires individual consideration and treatment; each case is a rule to itself. Many failures in bridge work are due to lack of consideration of this fact.

THOUGHTFUL CALCULATION OF CROWN AND BRIDGE WORK REQUIRED.

Let us consider bridge work with a view toward the ideal. First, the abutments must be thoroughly and carefully prepared, making each one suitable for its duty of serving as an anchorage for a bridge, in which capacity the tooth or root must sometimes assume the duty of performing double or triple the amount of work which a normal tooth is required to perform, all of which is readily accomplished when the proper preparation and mechanical construction of the bridge has been observed.

Crown and bridge work, well executed

from the beginning of the preparation of the abutment until it reaches the stage of completion of the bridge or crown, should represent thoughtful work. The kind of attachment to be used for joining the bridge to the abutments should also be chosen with due consideration of the mechanical stress exacted. Work constructed upon these principles is not only pleasing to the dentist, but will also be a blessing and a comfort to the patient by its efficiency in restoring the much-needed mastication.

SOURCES OF FAILURE.

Inadequate time for construction. Owing to the many shortcomings existing among dentists, bridge work is sometimes unsuccessful. Fighting against time, on the part of the patient, is somewhat to blame; the patient wants a bridge or crown placed quickly, which means lack of thoroughness in preparing the abutments, as well as poor laboratory construction. Failures are also due to lack of consideration on the part of the dentist who does not take the time required to study thoroughly the needs of the case which is under his care. If a patient is unreasonable regarding the allowance of reasonable time to the dentist for the construction of crown and bridge work, or asks him to perform that which cannot be successfully accomplished, the latter will not lose by his refusing to do the work. *Never attempt the impossible* in bridge work, or failure will be your reward!

Commercialism. Another case for unsuccessful crown and bridge work lies in the commercial side of dentistry, viz, the advertiser with his "teeth without plates" (whatever that may be), the man who welcomes the opportunity afforded him in crown and bridge work for robbing the patient. This work is preyed upon by these people perhaps more than any other specialty of dentistry, as it is a field from which they reap a great harvest.

Ready-made crowns. Many dentists who desire to save time use ready-made crowns regardless of fit. They likewise construct crowns and bridges of all varieties with but one object in view—that of placing something in the mouth that will look like a crown or bridge. To get the money seems to be their goal.

Lack of mechanical skill. Unsuccessful crown and bridge work is not confined to the advertiser. Work of this class is turned out by the practitioner who thinks he is a conscientious worker, but who unfortunately has had no mechanical training. He lacks the mechanical ability to construct the bridge work that will be best suited for his patient, although he may be successful in other departments of dentistry.

SYSTEM REQUIRED IN THE CONSTRUCTION OF CROWN AND BRIDGE WORK.

Crown and bridge work is such an important subject that one paper can never do it justice; books could be written without even touching all the conditions that will arise and explaining how to remedy them. Therefore, to avoid a long paper, I will try to outline as briefly as possible what constitutes, to my idea, a somewhat systematic way of treating the many cases for bridge work as they present themselves in the practice of dentistry. I think the origin of a great many errors lies in the fact that crown and bridge work is pursued without a system, and therefore let us here devote a little time to a systematic way of studying and constructing crown and bridge work.

In some branches of dentistry there seems to be a system laid down for us to follow. To Dr. Black we all owe a debt of gratitude for the system upon which he has placed operative dentistry, as well as for the many other services he has rendered the dental profession. Dr. Angle did much in giving the dentist a system to follow in orthodontia. Let us, therefore, consider the examples these men have set, and try in our own humble way to give consideration to the systematic development in crown and bridge work, applying any principles that may be of service to us.

In crown and bridge work, more than in any other specialty of dentistry, the opportunity is offered of gathering various mechanical principles and using them to further the work. The crown and bridge worker who will not accept new methods which are better than the antiquated ones he is using, is standing in his own light. All of us should be willing to welcome new ideas in dentistry, and gladly give to them the consideration they deserve. The importance of study of our cases cannot be too strongly emphasized; therefore, let us begin our system with a method of studying our cases.

Preliminary study casts of individual cases. In orthodontia, the dentist's first procedure is to procure an impression in plaster, from which he pours casts representing the condition of the patient's teeth in articulated casts of plaster of Paris. These casts he studies carefully preparatory to undertaking the task of regulating teeth. In crown and bridge work the dentist seldom proceeds in that manner. He usually allows a patient to hold a mirror in one hand so that he can see, while he looks hastily over the mouth —considering simply the general condition and the spaces for bridges, without properly taking into account articulation, mechanical stress involved, length of bite, and many other features. This places the dentist sometimes in the awkward position that, after a few visits of the patient, he is forced to change his mind, because he has too hastily jumped at conclusions; he has told the patient that he will make a certain kind of bridge, when he finds upon a later visit that a different kind is required.

In addition, he often makes one bridge, when later on he finds that another bridge in the mouth should have been made first, which would have borne the stress of the bite and thus would have enabled him to construct the second bridge in a more thorough manner. He is also liable to other errors in bridge construction, as one can readily understand when he considers the importance of studying the articulation or bite preparatory to such work. The better way is to make study casts of each individual case. This is not nearly as troublesome as it may seem at first sight, and it will prove a time-saver after all. We do not need plaster impressions to make study casts; a modeling composition impression will serve the purpose very well. If, however, one should desire to use plaster of Paris for these study casts, there is certainly no objection other than that offered by the patient.

FIG. 1.

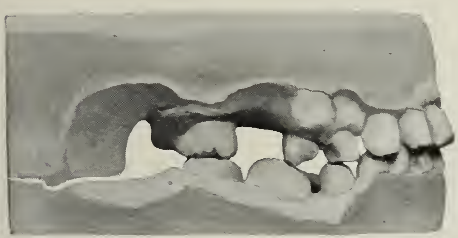

FIG. 2.

The orthodontist must use plaster for impressions, as he has irregular teeth to deal with, and it is necessary that the irregularities be brought out in the impression in their true light. He also desires to construct appliances upon his casts, therefore they must be accurate.

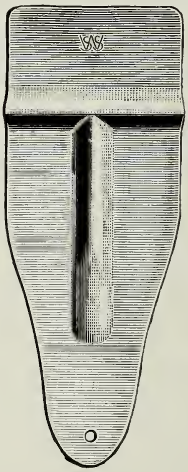
The crown and bridge study casts present to us most clearly the spaces due to missing teeth (Figs. 1 and 2); they also show the length of the bite, which is a very important factor. We can further observe the number of teeth and the mechanical stress which they must withstand if used as abutments. The occlusion must be carefully studied, with a view toward restoring the missing teeth.

Taking impressions. If a patient desires bridge work, the operator should explain exactly the number of bridges required, their construction, and all other details. How much better it is to tell the patient that he will be required to bite into some modeling compound, which can be quickly prepared with hot water, than to give him a mirror and hastily examine the teeth.

To obtain the modeling compound impression, a large piece of compound is softened properly, rolled into a roll, bent into U shape, and placed in the mouth; then the patient is directed to close the mouth, the operator observing that this is done in a proper manner. This whole operation requires but a few minutes. An appointment is made with the patient with instructions for the next visit, on which occasion the kinds of bridges that will be required, and the reasons for the decision, can be fully explained.

Pouring casts. In the interval between these two first visits, the operator has the

Fig. 3.



opportunity to pour the articulating casts in plaster of Paris, after the following manner: The lower cast is poured first, and an articulating plate is placed upon it (Fig. 3). After the plaster has hardened, the articulating plate is removed, and the impression made by the plate is sandaracked. Then the upper cast is poured, and both casts are trimmed in a thorough manner, when the operator will have nicely trimmed articulating casts of the patient's upper and lower jaws. These casts are separated by using hot water to soften the modeling compound, and, by trimming with a sharp knife, are made presentable. These casts having been studied thoroughly, the operator will then be able to decide upon the bridge work which he thinks most suitable for the patient. Having arrived at his conclusions, he can make notes directly on the casts, if desired, as to just what is intended to be done. When the patient returns, he can be shown the casts and told what will be done. Anyone who has never tried this method will be surprised to see the lively interest manifested by the patient, and furthermore, how much the case is simplified by the study casts.

This procedure is also a great timesaver, and time spent in the laboratory is not so valuable as time wasted in trying to study directly from the mouth of the patient.

DECIDING THE CHARACTER OF BRIDGE WORK WITH THE PATIENT.

Shall we educate our patients as to the kind of bridge work we are going to construct for them, or is it best to look wise, and try to practice the mysterious?

In this day of general education, when the public press is discussing various subjects pertaining to professional knowledge, people hear a great deal about different methods pursued in different professions; it is therefore not surprising to note the amount of interest which patients display in professional topics. Casts of their mouths will always interest rather than annoy our patients, and they will even be startled by the limited masticating surface apparent from an examination of the casts of their mouths.

Let us contrast this procedure with the direct examination by the dentist. The patient is looking at his mouth by the aid of a mirror, and not only does he fail to understand, but often the dentist himself fails to discover, the real necessity as to articulating surfaces; in fact, he cannot realize his patient's need for so much bridge work unless he has made articulated study casts. (See Figs. 1 and 2.)

Granting that our examination has been profitable, let us consider the construction of bridges, and the restoration of the deficiencies in mastication which the study casts have shown to exist.

RESTORATION OF NORMAL MASTICATION IMPERATIVE.

Too often dentists complain that they would like to do a certain class of bridge work, but that the patients do not permit it, or that they would like to place bridges in the posterior part of the mouth as well as in the anterior, but the patient fails to understand the need therefor.

This condition, I feel, is largely due to failure on the part of the dentist to educate patients to understand the great need of high-class dental work, which in such cases would constitute a true restoration, or as near a restoration of the natural organs as is within the power of dentists to make. I have never seen a patient who did not thoroughly appreciate the improvement in the conditions from which he had long been suffering. Most patients who ask to have bridge work inserted apply for restoration of anterior teeth, but give practically no consideration whatever to the restoration of lost bicuspids and molars. If a patient loses an anterior tooth, he is anxious to have a bridge or crown, regardless of any other restoration of masticating surface, unless we educate him to the contrary.

In the models which I will show later. I shall endeavor to accentuate the importance of molar and bicuspid restoration in bridge work. (Figs. 4 and 5.) I have called attention to the fact that neither dentists nor patients realize the importance of molar and bicuspid occlusion; dentists are to blame, oftentimes, as much as patients, for some of the smash-ups we have in crown and bridge work.

As members of the dental profession we must proclaim that we will no longer submit to the dictation of patients, nor should we consider it a *bona fide* excuse when a dentist says: "I wanted to make a certain kind of restoration, but the patient would not permit it." In making a bridge as ordered by the patient, but which in his own mind he knows will be very shortlived at best, the dentist commits error in cold blood.

Our first consideration in studying the casts is the molar and bicuspid occlusion. How often we find a mouth that looks fairly well, but in observing our study casts (see Fig. 2) we are brought face to face with the fact that the patient has occlusion only in the six or eight anterior teeth. The majority of cases examined for bridge work show a very limited articulating surface in the posterior part of the mouth. In other cases we find about the same condition, with the feeble assistance of a distal cusp of an inclined molar on each side. Often we note in a mouth lower right or left bicuspids and molars with very few teeth to occlude with in the upper jaw, or upper molars and bicuspids with few or no teeth to occlude with in the lower jaw.

A look at the study casts emphasizes the need of bridge work in such cases, and reveals another important condition —namely, elongated teeth without antagonists, of which condition I will speak later.

What brings patients to us for bridge work? They come principally on account of the loss of anterior teeth, or else on account of their looseness or projecting. The wearing down of the anterior teeth is also very common in these cases.

CROWN AND BRIDGE WORK IN CONNECTION WITH FILLING OPERATIONS.

Often we find operative dentists applying excellent contour fillings in the six or eight anterior teeth, only to have these fillings worn down, together with the retentive tooth structure which contains them; the fillings thus weakened in their retention, drop out. The patient says that "Dr. X's fillings do not stay in," while the real fault lies in the fact that the dentist has not assisted his operative dentistry by using good crown and bridge work to restore the molar and bicuspid occlusion. We must not allow the stress of mastication to be borne by the anterior teeth, which were especially designed for the purpose of incising food. In many patients the faulty occlusion observed could be restored by bridges or crowns, thereby relieving the stress which is threatening the remaining normal teeth with destruction. (See Figs. 4 and 5.)

Let us consider what happens when undue stress is thrown upon the anterior teeth, compelling them to perform the function of mastication.

RESULT OF UNDUE STRESS UPON THE ANTERIOR TEETH.

In a healthy person, sometimes, the anterior teeth remain firm, but are worn down by abrasion until they become sensitive. In some cases the sensitiveness is avoided, by the gradual recession of the pulp, and the incisors are thus worn down to nearly the gum line. In other patients the anterior teeth will spread outward, causing ugly spaces and also protrusion, which is most disfiguring.

FIG. 4.

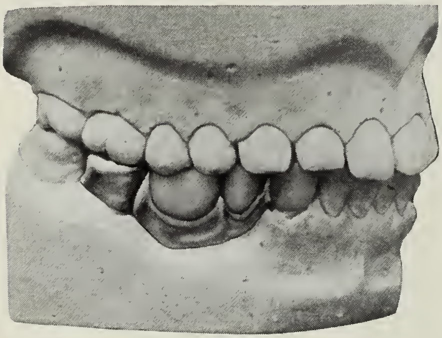


FIG. 5.

If a patient is in a condition of reduced vitality, or has some systemic disease, these teeth loosen, and the pericementum becomes necrotic, and this is due entirely to the excessive work exacted from them. Good bridge work, therefore, which restores the molar and bicuspid occlusion, is often a cure for pyorrhea. Does not a careful study of these conditions prove that it is our duty to place bridges in the posterior part of the mouth, where they will bear the force of the bite, before we make anterior restorations? The patient will often demand to have only the anterior teeth restored, but the dentist must not yield. Such work is sure to result in failure, and give the dentist the reputation among the patient's friends that his bridge work will not last.

THE DENTIST, NOT THE PATIENT, TO DETERMINE THE KIND OF WORK.

I once knew a German whose specialty was framing pictures, which work he executed in a most pleasing manner. If you went into his store to have a picture framed, and the style of frame suggested by you was not appropriate, according to his idea of how the picture should be framed, he would come out very strongly in his denunciation, and then, if you still insisted upon having it framed your way, he would refuse to do it. I asked him one time for his reason for taking this attitude, and his reply was that, if he were to frame pictures in the way that people sometimes wanted them framed, it would sometime be asked, "Who made that hideous frame?" and the customer would disclose his name, but would not think of saying, "I told him to frame it that way."

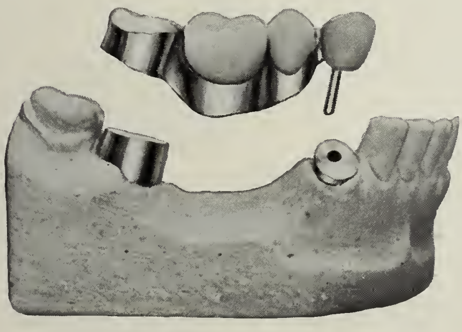
Now, if the honest German could hold to his principles in framing pictures, it seems to me that our professional advice should be followed by our patients, not only for the reason that our stamp is upon our work, or that the patient would not say that he himself insisted on the dentist's doing the work in that way, but also because, if dentistry means anything, and our knowledge of crown and bridge work is based upon scientific facts, we must insist upon work being done in the way which we consider most suitable for the case, or refuse to do it at all.

Let us now adopt a few fixed rules which we may safely follow in constructing crown and bridge work.

SEQUENCE IN CONSTRUCTION OF UPPER OR LOWER BRIDGES.

In cases where both upper and lower bridges are to be made, the lower bridge should always be made first. (Fig. 6.)

Fig. 6.



The anatomical articulation must be restored as nearly as possible by arranging the cusps of the lower bridge to form the curve for the occlusion, and then, when the upper bridge is being constructed, it is adjusted to conform to the lower.

If the upper molars and bicuspids are left on one side, and consequently only a lower bridge is required on that side, while on the other side of the mouth both upper and lower bridges are required, it would be the rule first to make the lower bridge on the side first mentioned, for receiving the stress of the bite. The other side of the mouth can then be bridged by making the lower bridge first, obtaining the proper curve for occlusion, and then constructing the upper bridge last. In large bridges it will be found advantageous to use the anatomical articulator, but in smaller bridges I prefer small articulated plaster casts.

TREATMENT OF ELONGATED TEETH.

We have spoken of the importance of obtaining the proper curve for the occlusion of our teeth, or of imitating as nearly as possible the curve found in normal occlusion. When teeth have been extracted, and the corresponding teeth in the opposite jaw are elongated, it is necessary to shorten these natural teeth rather than to make a dip-down in the masticating surface of the bridge with which they are to occlude.

Bridge work is often made on straight lines in the molar and bicuspid region without any attempt whatever at restoring the natural curve. Elongated teeth must not be allowed to dip down into the masticating surface of any bridge, as it will only lock the occlusion and interfere with normal mastication.

In addition to this, the elongated tooth will have so much leverage thrust upon it owing to the movement of the jaws that, in a short time, it will loosen and be of no value to the patient. Such a tooth, or series of teeth, is therefore ground off, and if the elongation is so pronounced that grinding leaves the teeth sensitive, we must devitalize these teeth, and in some cases crown them.

We often hear patients say that they do not want a tooth sacrificed. Often, when we are obliged to grind a cusp off an elongated tooth, the patient will complain, and say that he does not want this tooth sacrificed, and frequently the dentist will take the same view. A tooth, however, is more often sacrificed by not grinding than by grinding, as, if allowed to remain in an elongated state it will but loosen, owing to the prizing motion to which it is subjected. The dentist, therefore, is fully justified in devitalizing and crowning such a tooth if necessary. Normal occlusion must always be restored as nearly as possible.

REMOVABLE VS. FIXED BRIDGE WORK.

Removable and fixed bridge work both have their use in dentistry. If the bite be long and the abutments strong, removable bridge work is generally the more advisable. All large cases of bridge work should be removable.

A few years ago it was necessary to explain what removable bridge work meant, for there were many plates on the market which were fastened with clasps, also many appliances with various kinds of patent attachments to vulcanite plates, all of which passed under the name of removable bridge work.

The establishing of a recognized system, practical in every way, has given crown and bridge work the highest place in dental prosthesis, which it certainly deserves. Removable bridge work is made possible by using telescope caps, tube and split-pins, and many forms of attachment for abutments. (See Fig. 6.) These are made in a manner and of such material as to withstand the wear caused by the force of mastication without altering their adjustment.

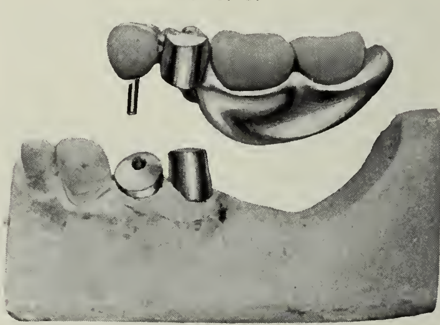
FIG. 7.

Removable bridge work, however, is not always indicated where bridge work is required, and for that reason we must consider stationary bridge work also, so that, with an unbiased knowledge of both, the dentist can see for himself the kind of work suitable for each particular case.

It is needless to say that all crowns are made stationary, there being no advantage in having single crowns removable. Stationary work is positively indicated in cases where the abutment teeth are loose. In these cases a stationary piece well made, of light construction, will act as a permanent splint to the abutments, and thus prolong the life of the teeth. They are not to be used, however, when pus is present, upon teeth which do not respond to treatment. Stationary work can also be used in very small cases of bridge work, depending upon the dentist's judgment.

In many cases of loose abutment teeth carrying removable bridge work, the taking off and inserting of the bridge shortens the life of the already crippled abutment teeth, whereas, under a properly made fixed piece they will often grow firm again. This is particularly true in cases where the looseness of these teeth has been caused by too much leverage being thrown upon them owing to improper articulation.

FIG. 8.



Again, if on two abutments one of which is solid and the other loose a removable bridge were placed, the tight abutment might become loose owing to the strain imposed upon it by the lack of support from the other abutment which is loose and allows the bridge to move when taken off or replaced in the mouth by the patient; in such cases, therefore, stationary bridges should be used.

SADDLE BRIDGES.

Saddle work is a very necessary branch of removable bridge work, and one notable feature contributing to its importance is the fact that it assists the abutments by throwing the strain upon the alveolar ridge. Saddles also restore lingual and buccal contour, and do away with the unpleasant spaces existing under ordinary bridge work. It is of great advantage in the lower jaw to have the lingual contour restored, thereby avoiding all interference with the movements of the tongue.

Restoration of the lingual and buccal contour is, moreover, of great assistance to the patient from its relation to articulate speech.

There are saddles which are continuous between two abutments, and which we call auxiliary saddles, their purpose being to help support, in long bridges, the strain that is imposed upon the bridge by mastication, and also to restore lingual contour. (See Fig. 6.) Another form is the extension saddle, which unites two abutments which are close together. (Fig. 7.) If, for instance, in the lower jaw two abutments consist of the two bicuspids, no molars being present on that side, a saddle should be used extending toward the posterior part of the mouth and supplying the missing molars. (Fig. 8.)

The materials used in crown and bridge work should be the best obtainable, enabling us, with the aid of good and conscientious workmanship, to construct for our patients durable and esthetic work.

My object in presenting this paper was to emphasize some of the points which I find many dentists do not stop to consider, and I trust that a strict attention to the explanations given will assist them in constructing better crown and bridge work.

CASE OF SEVERE, LONG-STANDING TRIFACIAL NEURALGIA CURED BY AVULSION OF THE INFRA-ORBITAL NERVE.

By HENRY GLOVER LANGWORTHY, M.D., Dubuque, Iowa.

THE following case is of considerable interest to stomatologists, first as illustrating that comparatively simple operations on the nerve branches themselves constitute the best treatment in many of these conditions, and second, for the reason that sufficient time has already elapsed to demonstrate that the result achieved in the case under consideration may rightfully be classified as a genuine cure.

CASE HISTORY.

On November 5, 1909, a young farmer, thirty years of age, who had worked on the farm all his life, consulted me in regard to paroxysms of severe pain originating about the right upper lip and about the right cheek. He had first noticed these facial pains some twelve years before, and could assign no reason for their origin. The pain originally began with a small pricking or jerking sensation starting along the right ala of the nostril, and rarely lasted more than a few seconds. During the first seven years of the time mentioned, the intermittent neuralgic attacks on the right side steadily continued, with increasing severity, often lasting from three to seven days. The painful area was limited to a small region on the right cheek, the right side of the nose, and the upper lip—superior maxillary nerve distribution. The pain during this period arose mostly at night. During the past four years the paroxysms of facial pain have continued as before, averaging from five to seven attacks a year, which were so painful that the right eye would water and the upper lip become puffy and exquisitely tender, often remaining so for long periods of time. The patient was treated medicinally by various physicians, with but little benefit. Surgical treatment had been limited to the removal of nasal turbinal tissue in the right nostril and the probing of the lacrimal duct. His teeth had been examined and treated repeatedly by competent dentists, with practically no benefit. As the agony of pain had lately become so acute, the patient pleaded for any operation which would give him some hope of permanent relief. He had spent a thousand dollars, a large sum for him, in trying to obtain some freedom from pain, but never had obtained complete relief.

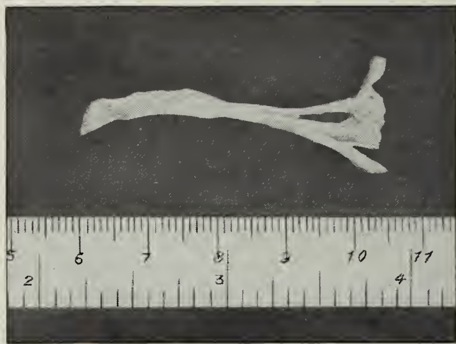
EXAMINATION.

On examination, the region of the upper right half of the lip, the right side of the nose, and a small area over the right cheek proved tender to the touch. Manipulation of the skin over this region was sufficient to start pains. Eating was also said to cause pain at times.

As the area of pain was distinctly limited to the region of a half circle corresponding to the distribution of the infra-orbital nerve, the only treatment recommended was peripheral exposure and avulsion of the entire infra-orbital nerve and its branches. Medicinal palliative treatment was instituted for two weeks, until the patient could adjust some business affairs and return for the operation.

OPERATION.

The operation was performed on December 10, 1909, under chloroform anesthesia. A small incision was made along the lower bony orbital rim, one inch in length, rather close to the nose and above the notch containing the infra-orbital nerve. The infra-orbital nerve was well exposed at its exit from the bony foramen on the face. No special landmarks are here necessary to follow, as the nerve is not difficult to find. Ordinarily, the location of the foramen, while not really palpable in this case, "lies about one-third of an inch below the infra-orbital bony margin and on a line from the supra-orbital foramen to a point between the two bicuspids in both jaws." The nerve with its radiating branches was picked up with a stout hook, and its branches were followed for a short distance out into the tissues of the cheek, and downward toward the nose and lip. A heavy suture was then passed around the main trunk, and all peripheral branches were divided with scissors. Although a fairly careful search was made for the infra-orbital artery and vein, they were not found,



owing to trauma necessary in exposing the nerve. A strong pair of hemostats was used to grasp the nerve, and by slow traction and winding the trunk around the forceps the entire nerve was torn out from its connections posteriorly, and a long piece of the nerve avulsed (see figure). As a matter of fact, the entire length of the infra-orbital nerve was drawn out, and all of the posterior dental branches were probably torn across in their bony canals. Hemorrhage was brisk for a moment after the avulsion of the nerve, but subsided immediately upon introduction of a temporary plug, which was withdrawn in three minutes. The foramen in this case was quite large. The wound was closed with a single subcutaneous stitch of silk braid, and a small pressure bandage was applied.

The length of the operation was about twenty minutes. Quick recovery from the anesthetic was made.

REMARKS.

No post-operative hemorrhage or oozing or untoward accident of any kind occurred. The night of the operation the patient was resting easily, without any of the pain experienced during the hours before the operation. The upper lip, the side of the nose, and the immediate region of the cheek the following day felt numb, but nothing more. There was no special soreness of the teeth. A slight puffiness of the upper lip on the right side gradually disappeared.

Four days after the operation the patient was discharged, primary union of the operative wound having taken place. He left the hospital with the remark that he had the feeling that the "seat of his pain has been removed."

A short time ago, in reply to my request as to how he was getting on, the patient informed me that he has not felt any of the old trouble since the operation, and is grateful for the benefit received.

The only observation of interest that I have to make further is the fact that for the past few years there has been a persistent slight anesthesia of the lip and cheek, and an occasional soreness of the inside of the nose. If the patient should ever develop a similar neuralgia in any one of the other accessible branches of the fifth nerve, I should not hesitate to follow the same procedure.

A WARNING AGAINST THE INDISCRIMINATE USE OF FORMALDEHYD PREPARATIONS.

By CARL J. GROVE, LL.B., Ph.G., D.D.S., St. Paul, Minn.

In common with most scientific branches of learning, the laboratory has rendered a valuable service in the upbuilding of dental medicine. The aid of the laboratory is very important, and the application of this method is indispensable to the advance of dental medicine.

LIMITATIONS OF LABORATORY EVIDENCE.

I fear, however, that the prevailing impression gained by the student of today is that, unless they rest on laboratory confirmation, all diagnosis is doubtful and all therapeutics unscientific.

The laboratory, like all other methods of research, has its limitations. This fact does not mean that the test tube, the culture tube, and the microscope are not of great value. Owing to the great advance achieved through these means of investigation, there is manifested an increasing, perhaps an unconscious tendency to place too much reliance upon laboratory tests at the expense of careful clinical observation.

Laboratory methods of research, to which we owe so much, should be regarded as a supplementary aid upon which to base conclusions, and not as the only means for solving the problems encountered in a practice.

The therapeutic qualities of many of the remedies offered to the dentist today are based only upon laboratory results. Many of the things said and written regarding the action of formaldehyd, when employed in the treatment of septic root-canals, are conclusions derived from these methods.

INJURIOUS EFFECTS OF FORMALDEHYD.

The view held by Dr. Buckley maintaining that a chemical action occurs has been accepted by some as being a correct explanation. But since the presentation of this theory much evidence has been offered which proves its incorrectness.

In June 1910, Dr. J. A. Vuilleumier read a paper before the Massachusetts State Dental Society, published in the *Items of Interest*,* which contains conclusive evidence to show that the chemical theory is erroneous.

It is not my intention to enter into a discussion of the hypothesis at this time, as I have at a previous writing endeavored to show that the conclusions were based upon laboratory experiments unlike the conditions found in a putrescent pulp-chamber. (See December 1911 issue of the DENTAL COSMOS.) The prime object of this paper is rather to show the injurious effect following the use of formaldehyd, and why, as a therapeutic agent, it should be employed with more discretion. That formaldehyd has properties of a very irritating nature, including the power of producing inflammation, is a matter of general knowledge. In view of these facts, it can hardly be expected that formaldehyd can hold its place among the remedies of better therapeutic methods.

The results which appear to be of a curative effect are often of uncertain duration. It is, however, impossible to acquire an adequate conception of the frequency with which pathological conditions are produced by the action of formaldehyd, if we rely for our information upon what is contained in the dental literature on this subject. But as time goes on, I believe formaldehyd will be known as a contributor at least to the production of many incipient pathological conditions. The beliefs contained in this discussion are based upon clinical evidence derived from experience in the use of formaldehyd for a period of years, with experimental proof to confirm these observations. Owing to its gaseous condition, formaldehyd passes through the open apical foramen, coming in direct contact with vital tissue, exerting its influence in the production of inflammation. If the vitality of the tissue is impaired to a considerable extent, a destruction of the affected parts may take place.

No matter whether or not the irritation is sufficient to cause extended destruction of the tissue, there are some very important facts established regarding the action of formaldehyd which must be acknowledged by all:

(1) That formaldehyd has irritating properties.

(2) That it has the property of producing inflammation, and it is well known that, when inflammation is produced, there occurs an alteration of the tissue, and a fluid exudate with a high proportion of albumin is poured out.

(3) That formaldehyd is capable of hardening albuminous tissue, consequently this extravasated fluid resulting from inflammation becomes an insoluble mass, which is not conducive to healthy tissue.

(4) That proteid tissue is hardened by the action of formaldehyd.

These are significant facts, which should not be regarded lightly, or disregarded, when considering this question.

EFFECT OF FORMALDEHYD GAS PASSING THROUGH THE APICAL FORAMEN.

I am of the opinion that it is possible for formaldehyd gas to pass through the dental tubuli and cause serious irritation if not a destruction of the pericemental membrane.

Knowing that the albuminous fluid mentioned is a product of inflammation, it can safely be assumed that whenever formaldehyd is used in the treatment of teeth when soreness exists, whether inflammation follows its use or not, the gas will escape through the root, converting the fluid present to an insoluble elastic mass, unless, perchance, some obstruction has closed the apical foramen. Such a condition may result in suppuration or absorption of the adjacent tissue may occur, ultimately resulting in suppuration. Because no marked disturbance immediately follows the treatment, naturally formaldehyd has not been regarded as

* See *Items of Interest* for September 1910, vol. xxxii, p. 720.

being the specific offender in these conditions. Rather than make a search for the real cause, we allow ourselves to believe that the affliction is due to some condition making perfect root-filling impossible, but fully realize that these sad experiences may be the result of negligence or ignorance.

The investigations which have been made regarding root-fillings show that a large per cent. of these operations are faulty, and while I am of the opinion that a slight imperfection in a root-filling might exert some influence in the production of these disturbances, I am inclined to believe that the method of treatment employed previous to filling the canals is more often the important factor.

True it is that one cannot consistently contend that formaldehyd does not possess much therapeutic virtue, if viewed by laboratory tests, yet, as I have already stated, scientific laboratory deductions cannot be taken as final, for clinical proof is required from that complex laboratory—the human body—to establish its true worth, and often we err in the interpretation of these results.

I do not mean to imply, however, that the result following the use of formaldehyd is always a complete failure, but I am fully convinced that whenever formaldehyd preparations are employed where contraindicated, much harm will follow.

Some assert that, because many of these treated conditions do not immediately reveal serious disturbances, no abnormal condition is produced by the use of these remedies. Conclusions based upon such reasoning are illogical; for experience has shown that often an abscessed condition of the teeth exists, without any discomfort being manifested. Similar conditions are undoubtedly produced by the action of formaldehyd, as I shall endeavor to show.

EXPLANATION OF ILLUSTRATIONS.

Fig. 1 shows what occurs if only a small amount of the albuminous product of inflammation is present, and in direct contact with the apical end, after formaldehyd has converted the substance into an insoluble mass.

Fig. 2 shows the condition produced by formaldehyd if the fluid has entered the root-canal. If the coagulated substance is not sufficient to cause much irritation, it can readily be seen that no further treatment of the affected tissue existing in that region would be permitted.

Fig. 3 shows the condition which undoubtedly follows the action of formaldehyd where some destruction of the tissue surrounding the root has taken place when being supplied by albuminous fluid.

Fig. 1.

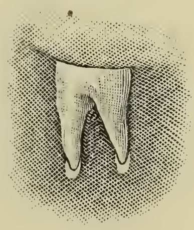


Fig. 2.

Fig. 3.

These drawings are made from results obtained by experiments as shown in Fig. 3. In the mouth of the bottle containing albumin, the root of the tooth was inserted, sealed to prevent the liquid from escaping. Formocresol was sealed in the pulp-chamber. In a short period of time the formaldehyd contained in the formocresol mixture escaped through the root, producing the above results.

DR. BUCKLEY REFUTED.

Dr. Buckley recognizes the dangerous irritating properties of formaldehyd, but maintains that if formaldehyd is diluted with cresol, the irritating properties of the gas are altered by the anodyne action of cresol.

It is rather difficult to accept this statement, in view of the fact that formaldehyd is a gas which would undoubtedly immediately escape from the cresol, thus reaching the tissues undiluted. Even though it could be shown that such an action was exerted, would it not be a dangerous procedure to render the tissue insensible even to the slightest degree to prevent irritation?

It seems needless to enter into further discussion or offer further evidence to show that formaldehyd possesses properties which make its use unsafe in the treatment of pathological conditions resulting from decomposed pulps.

Suffice it to say that, when there are other methods for the correction of these conditions equally satisfactory as, and free from the dangerous properties of, formaldehyd, one is hardly justified in the indiscriminate use of formaldehyd preparations.

The writer wishes to acknowledge his indebtedness to Dr. C. H. Goodrich for the drawings included in this paper.

CHRONIC ALVEOLAR OSTEOMYELITIS (PYORRHEA ALVEOLARIS) —ITS CAUSES, AND TREATMENT WITH VACCINES:

With a Bacteriological Study and Report of 115 Cases.

By LEON S. MEDALIA, M.D., Boston, Mass.,
LATE INSTRUCTOR IN PATHOLOGY AND BACTERIOLOGY, TUFTS COLLEGE MEDICAL AND DENTAL SCHOOLS, PATHOLOGIST AND VISITING PHYSICIAN FOR VACCINE THERAPY, MT. SINAI HOSPITAL, BOSTON, MASS.

(Read before the National Dental Association, Section I, at its sixteenth annual meeting, Washington, D. C., September 11, 1912.)

(Continued from page 36.)

GROUP III: *Far Advanced Stage* (85 *cases*).

Description. The cases under this heading were the advanced cases with marked suppuration, the symptomatic picture of which is well known to you all. The lesions varied from looseness of a few teeth, with marked recession, sponginess, suppuration, and deep-seated sinus formation of the affected teeth, to conditions in which all the teeth were found affected. In some of the cases there were also present necrosis, destruction of the alveolar process, and displacement of the teeth. In a few cases the disease was marked by a series of acute exacerbations in individual teeth, with marked swelling and excruciating pain, coming on all of a sudden and continuing until the affected tooth was removed. Such patients lost three to five teeth in that way before they were referred for vaccine treatment. The majority of the cases in this group, however, were of the slow, insidious, chronic type, with little pain except on mastication. All of the cases had systemic disturbances of one form or another.

Bacteriological findings. The findings of the direct smears of the pus have been described elsewhere. The cultural findings are—

	Cases.
Pneumo. (strepto. lanceolatus pneumoniæ)	18
Staphylo.	1
Pneumo. and staphylo.	49
" " strepto.	3
" staphylo., and strepto.	10
" and M. catarrhalis	1
" and mucos. capsul.	1
Staphylo. and M. catarrhalis	2
Total	85

By far the most frequent organism according to this table is the pneumo. in chains, either alone or in combination with the staphylo. The combination of the pneumo., staphylo., and strepto. is next in frequency. The other organisms appeared only rarely.

Opsonic findings. The opsonic index test was made in 49 of the 85 cases, with the following results:

Opsonic index.

	Below normal.	Above normal.	Normal.	Not tested.	Total.
Pneumo.	39	2	7	1	49
Staphylo.	25	1	20	3	49
Strepto.	4	—	32	13	49
Colon (B. coli) .	18	3	12	16	49

The opsonic findings in this group, as in the preceding groups, were found, with very few exceptions, to corroborate the cultural findings.

Treatment. The average number of treatments of those that were cured in this group was 17, with a maximum of 38 and a minimum of 3, at intervals of from four to seven days in the beginning up to two to four weeks or longer later, according to the local amelioration of the disease. The *duration* of treatment in the cured cases was on an average four and three-quarter months, with a maximum duration of nine months and a minimum of five weeks.*

* One case (No. 65, H.H.) in this group is recorded as cured at the end of one week, after receiving three treatments. She had an acute osteomyelitis of the socket of the lower left third molar. The tooth was removed, and the socket curetted. She was brought to me by her physician for vaccine treatment three weeks after the operation. She had a high temperature and felt very sick all over. Locally there was a big hole discharging pus at the place where the tooth had been removed. All the other teeth were loose, and pus present around several of them. The gums as a whole were markedly inflamed. At the end of three treatments the whole condition of the gums subsided and the operated socket made an uneventful recovery. When she was last seen, nineteen months later (July 10, 1912) the gums were found in healthy condition and no looseness of teeth was present.

Results. In this group of 85 cases, 37 were cured, 40 were markedly benefited, 4 unimproved, and 3 dropped out. One was treated by his dentist and no record obtained from him of the case.

Of the cured cases, 5 remained cured for from thirty to thirty-six months, 11 from twenty-six to twenty-nine months, 8 from twenty to twenty-four months, 9 from fifteen to nineteen months, and 5 from five to twelve months. The improved cases remained improved for several months or years, some getting progressively better even after discontinuing treatment, while others remained stationary.

The permanence of cure in this group is, of course, as would be expected, smaller than in the earlier groups—43 per cent. as compared with 91 per cent. in the former two. However, the dentists who, following a prolonged local treatment, sent those cases to me have assured me that practically all these far advanced cases would have gone on progressively from bad to worse, until all the teeth would have been lost. Under such circumstances 43 per cent. of cured and 47 per cent. markedly improved is, I believe, very encouraging.

Systemic disorders. Of the 85 cases, 45 suffered from rheumatism, 42 had gastro-intestinal disturbances, 3 had chronic furunculosis, 4 post-nasal catarrh and chronic sore throat, 2 had diabetes, and 3 nephritis; besides, 4 had eczema, 3 urticaria, and 1 purpura hemorrhagica. Most of the patients had a combination of two or more of the above systemic troubles.

The cases with rheumatism in this group were of the most advanced types of polyarthritis, arthritis deformans, or severe general muscular rheumatism. The severity of the rheumatic symptoms seemed to be in direct relation to the severity and chronicity of the alveolar osteomyelitic condition, and the improvement of the two were also in direct relation to each other. Of these rheumatic cases, 23 were cured or relieved, 11 were improved, 1 showed no improvement, and 1 was slightly improved. The others either discontinued treatment against

advice or were beyond any hope at the beginning of the treatment.

Almost all of those suffering from gastro-intestinal disturbances were relieved or cured by diet, lactic acid milk, and vaccine. The same was true of the eczema, chronic urticaria, and chronic furunculosis cases. (See Table III.) Only 6 of the 85 cases showed no general symptoms.

Urinalysis. The urine was examined in 53 of the 85 cases. Of these, 44 were found acid in reaction, 7 alkaline, and 2 neutral. In 27 of the 85 cases marked indicanuria was present; 3 of the cases showed albumin, and 2 sugar.

Feces examination. The feces were examined bacteriologically in 52 of the 85 cases, with the following results:

B. coli (colon)	39	cases.
" and diplo.	11	"
" " strepto.	2	"

In this group we find in addition to the presence of pneumo. in the feces, also two cases with strepto. It is difficult to determine what these findings actually mean, but, as said before, it may be supposed that they are an extension of the infection due to the swallowing of the pus.

The feces were examined chemically in 30 of these cases: 19 showed an excess of undigested meat remains; the other 11 showed an excess of undigested starch remains. The fermentation test in 11 of the 19 cases that showed an excess of undigested meat showed putrefactive changes, while the remaining 8 showed a carbohydrate fermentation with marked gas formation. All those 11 cases that had an excess of undigested starch remains also showed a typical picture of carbohydrate fermentation, with very marked gas formation.

These findings again seem to indicate, as in the preceding groups, the tendency to an improper digestion of meat in the majority of cases—63 per cent. On the other hand, it also shows the presence in the lower part of the bowels in the majority of cases of an excessive flora capable of fermenting carbohydrates with the production of gas, which is responsible for the flatulence complained of by so many patients.

General Summary.

The causes of the disease, as we said, are mechanical and infectious. Under mechanical causes I called attention to tartar and calculi, which are by far the most important. To these may be added the careless use of the tooth-brush and infected instruments.

The important infectious agents, we said, are the pus-producing bacteria, such as pneumo., staphylo., strepto., and M. catarrhalis. As stated, the disease is not

ADVANCED CASES (*Continued*).

in all cases due to one and the same organism, but to a variety of organisms capable of causing infection. The bacteria are responsible for keeping up the disease, though mechanical injuries are responsible for starting it. The same is true of the systemic disorders, which may play only a secondary part (lowered resistance) in starting this local disease, while after it is once established the systemic diseases certainly play an important part in keeping it up.

The results obtained in this series of 115 cases treated with vaccines are (A):

The number and duration of treatments of this series were—(see B).

Thus, according to the above figures, the number of cures, the duration of treatment, and the number of treatments are in direct relation to the chronicity and severity of the disease, particularly the former, as would be expected.

The frequency with which the most important systemic disorders occurred in the whole series is—(see C).

The rheumatic disturbances are apparently in direct relation to the severity of this disease. They increase both in

Far advanced (" III)	53	50	13	5

frequency and severity as the disease goes on. The other important complaints are the gastro-intestinal disturbances and neuralgic pains, so called. All the patients seemed to be particularly susceptible to acute coryzas, or "colds," which were at times sufficiently severe to lay them up in bed.

Various other affections were met with, such as asthma, diabetes (2 cases), nephritis (3 cases), purpura hemorrhagica (1 case); but I feel from their rarity that they were not necessarily related to the chronic alveolar osteomyelitis.

The systemic affections accompanying this disease are of great importance, as shown by the above figures, and are to be taken into consideration by the dentist, who at the present day and for many days to come will be the only one to tell the physician of the existence of this disease and make him acquainted with its consequences. These systemic diseases are all ordinarily treated merely symptomatically, while no attention is paid to the local trouble. There is a crying need to get the medical profession awakened to the consequences of this disease, and to consider no physical examination complete without the routine examination of the gums.

Conclusions.

(1) Pyorrhea alveolaris, so called, is in reality a *chronic alveolar osteomyelitis*. It should be known and treated as such.

(2) The sockets are enlarged medullary spaces of the maxillary bones, while the so-called "peridental membrane" is in reality a ligament which keeps the tooth suspended in the alveolar cavity.

(3) The mechanical causes are responsible for starting the disease, while the pyogenic bacteria are responsible for keeping it up—pneumococcus, staphylococcus, streptococcus, and M. catarrhalis.

(4) Chronic alveolar osteomyelitis is a specific disease, though not in the sense that it is always due to one and the same organism; it is due to a variety of organisms, already enumerated.

(5) Systemic diseases play only a secondary part in starting the disease, but may be caused by it, and in turn become responsible for keeping up the local condition.

(6) A great many rheumatic diseases, so called, also a great many gastro-intestinal affections, are, in my opinion, directly related to chronic alveolar osteomyelitis—"Riggs' disease."

(7) The vaccine treatment of this disease, together with the proper attention to diet, cures or relieves the systemic diseases, especially the rheumatic affections.

(8) Vaccine treatment (immuno-therapy), together with local mechanical treatment, yields by far the best results in this intractable disease — CHRONIC ALVEOLAR OSTEOMYELITIS.

Case Reports.

GROUP I: *Incipient Stage* (14 *cases*).

[All the cases were treated with autogenous vaccine in combination with the corresponding stock vaccines (pneumo. and staphylo. stock vaccines usually.]

(1) C. O. B. July 22, 1911. Female, 48 yrs. Gums swollen, bleed easily, receded over left lateral incisors. Continuous menorrhagia with marked secondary anemia; intestinal flatulence. Treated 1 mo. (2 tr.). Gums improved; good in color, no bleeding. General symptoms improved. A year later, gums still in good condition.

(2) L. H. B. May 8, 1912. Male, 30 yrs. General recession of gums, inflamed at margins. Cultures showed pneumo. and staphylo. Chronic constipation; skin of hands cracked and dry (hypothyroidism). Treated 2 mo. (8 tr.). Gums cured. Other symptoms relieved by thyroid. No recurrence.

(3) E. C. Aug. 18, 1910. Female, 35 yrs. Recession of gums, boggy and inflamed at margins. Cultures showed pneumo., staphylo., and macrococci. Rheumatism, intestinal flatulence, chronic constipation, general debility. Treated 2 mo. (7 tr.). Gums healthy and firm. Other symptoms relieved. No recurrence, 22 mo.

(4) G. L. D. Mar. 25, 1912. Female, 44 yrs. Recession and slight inflammation of gums; visible pus present in two sockets. Cultures showed staphylo. and some pneumo. Articular rheumatism, general adiposity (hypothyroidism?), intestinal flatulence. Treated 10 weeks (9 tr.). Gums healthy, no pus. Rheumatism relieved. Lost 28 pounds by diet and thyroid.

(5) S. W. D. Feb. 10, 1912. Male, 29 yrs. General recession of gums, pale and inflamed at margins. Cultures showed pneumo. and staphylo. Intestinal fermentation, rheumatic pains

(muscular) and lameness; psychasthenia. Treated 4 weeks (4 tr.). Gums healthy in color; no inflammation. Feeling well otherwise.

(6) R. E. May 9, 1911. Female, 25 yrs. Recession of gums; bleed easily, inflamed at margins: little visible pus present in three sockets. Cultures showed pneumo. Pustular acne, intestinal flatulence, and chronic constipation. Treated 7 weeks (9 tr.). Gums healthy, no bleeding nor pus. No recurrence. Acne improved.

(7) H. H. Apr. 30, 1910. Female, 35 yrs. Recession, tenderness, and inflammation of gums of five years' duration. Bad taste in mouth. Cultures showed staphylo. and chains of pneumo. Indigestion, chronic constipation, rheumatic pains. Treated 5 weeks (5 tr.). Gums not inflamed, and feels well. Other symptoms relieved. No recurrence.

(8) C. M. K. Dec. 13, 1910. Female, 28 yrs. Recession of gums increasing gradually for seven years. Cultures sterile. General malaise, severe neuralgic headaches. Treated 5 weeks (3 tr.). Recession checked, 20 mo. Other symptoms relieved.

(9) H. K. Sept. 11, 1911. Male, 32 yrs. Gums receded, boggy and inflamed at margins. Cultures showed pneumo. and few staphylo. Marked gastro-intestinal disorders. Treated 6 weeks (2 tr.). Gums firm and healthy. No recurrence. Other symptoms improved.

(10) S. W. M. Sept. 21, 1911. Male, 60 yrs. Recession and slight inflammation of gums. Cultures showed staphylo. and strepto. Chronic empyema of left antrum; facial eczema. Treated 6 weeks (4 tr.). Gums healthy, recession checked. Antral trouble improved; skin well. (Continuing vaccine treatment for antrum by family physician.)

(11) G. H. M. Oct. 21, 1911. Female, 40 yrs. Recession, sponginess, and bleeding of gums. Cultures showed pneumo. and staphylo. Chronic bronchitis, "continuous colds," general malaise, constipated. Treated 2 mo. (8 tr.). Gums firm, no bleeding. Bronchitis and "colds" relieved. No recurrence.

(12) M. M. Sept. 14, 1910. Female, 43 yrs. Recession, bleeding and bogginess of gums; little visible pus present. Cultures showed pneumo. and staphylo. Asthma, rheumatism. Treated 3 mo. (11 tr.). Gums firm, no pus, looking healthy. Other symptoms relieved. No recurrence, 21 mo.

(13) K. W. M. Sept. 19, 1910. Female, 29 yrs. Gums receded and inflamed, bleed easily, tender; gumboils present. Cultures showed pneumo., staphylo., and macro. Stomach and intestinal distress and gas. Treated 1 mo. (7 tr.). Gums in good condition. Other symptoms somewhat relieved. (Left town.)

(14) E. M. P. Oct. 13, 1911. Male, 35 yrs. Recession around a few teeth; one tooth slightly loose. Chronic pustular acne, distress in stomach, and intestinal fermentation. Cultures showed pneumo. and staphylo. Treated 6 weeks (4 tr.). Gums in good condition; tooth firm. Acne improved (is still being treated for it); otherwise well.

Group II: *Moderately Advanced Stage* (16 *cases*).

(15) A. A. Apr. 1, 1911. Male, 45 yrs. General recession and bleeding of gums with some visible pus around lower bicuspid. Cultures showed pneumo. and macro. Psychasthenia. Treated 4 weeks (7 tr.). Recession checked; no pus or tenderness. Other symptoms improved. No recurrence, 17 mo.

(16) W. B. B. Aug. 19, 1910. Male, 50 yrs. Gums receded and inflamed; pus present round few molars for several years; lost one molar. Pain on mastication. Cultures showed pneumo. and staphylo. Rheumatic pains; general debility. Treated 7 mo. (19 tr.). Gums healthy; no tenderness or pus. No recurrence, 18 mo. Other symptoms relieved.

(17) F. C. B. Feb. 17, 1910. Male, 29 yrs. Marked recession of gums; bleeding; pus in socket of right third molar. Cultures showed pneumo. in chains and staphylo. Treated 9 weeks (12 tr.). Marked improvement after second treatment. Gums in good condition, 2½ yrs.

(18) L. B. July 9, 1910. Male, 47 yrs. Receded, boggy, and inflamed gums; some pus visible; few teeth slightly loose. Cultures showed staphylo. and pneumo. Marked rheumatic pains, intestinal flatulence, chronic constipation. Treated 6 mo. (17 tr.). Teeth firm at 8 weeks. Continued treatment for rheumatism, of which he was finally relieved. Gums healthy in color, no pus. No recurrence.

(19) J. B. Mar. 24, 1910. Female, 43 yrs. Marked recession; pus visible; teeth slightly loose. Cultures showed pneumo. and staphylo. Muscular rheumatism, chronic constipation, general debility. Treated 7 mo. (22 tr.). Teeth firm; recession checked. No recurrence, 2 yrs. Other symptoms relieved.

(20) D. J. C. Oct. 7, 1910. Male, 44 yrs. Gums inflamed and receded; pus present in several sockets. Cultures showed pneumo. in chains and groups, and staphylo. Muscular rheumatism, intestinal flatulence, and constipation. Treated 4 weeks (8 tr.). Inflammation subsided. Recession checked. No recurrence, 2 yrs. Other symptoms improved.

(21) C. F. C. Sept. 27, 1909. Female, 41 yrs. Gums receded and anemic, tender, and bleed; front teeth "too long." Cultures showed pneumo. Intestinal flatulence, chronic constipation. Treated 5 mo. (15 tr.). Gums in good condition, 36 mo. Other symptoms relieved.

(22) S. G. Nov. 27, 1910. Female, 42 yrs. Recession and bleeding of gums; very little pus present. Cultures sterile. Rheumatism, gastritis, intestinal flatulence. Treated 7 weeks (8 tr.). Recession checked. No recurrence, 19 mo. Other symptoms improved.

(23) F. R. K. June 7, 1911. Male, 49 yrs. Gums receded, inflamed, and boggy; several teeth loose; visible pus. Cultures showed pneumo., yeast fungi, and many long, thin bacilli. Chronic furunculosis, intestinal flatulence. Treated 1 mo. (6 tr.). Gums looked healthy;

teeth firm; recession checked. No recurrence, 14 mo. Other symptoms relieved. Furunculosis cured.

(24) F. E. K. July 19, 1910. Female, 33 yrs. Marked recession; pus present in sockets of upper bicuspids and molars and lower molars. Seven years' duration. Cultures showed pneumo. General adiposity, intestinal flatulence. Treated 6 mo. (15 tr.). Gums harder and good color; recession checked; no pus. No recurrence. Other symptoms relieved.

(25) P. L. July 26, 1910. Male, 42 yrs. Gums receded, tender, and bleed easily; three teeth loose; pus in sockets of several teeth. Cultures showed pneumo., staphylo., and macrococci. Marked intestinal fermentation, stomach distress, general malaise. Treated 2 mo. (7 tr.). Gums seem healthy; teeth firm; no pus. No recurrence, 12 mo. Other symptoms relieved.

(26) J. M. Feb. 4, 1910. Male, 33 yrs. General recession; gums tender; pus in several sockets. Cultures showed pure staphylo. aur. Treated 6 mo. (22 tr.). Gums in healthy condition; no pus. No recurrence, 24 mo. Other symptoms relieved.

(27) H. F. S. Feb. 13, 1910. Male, 30 yrs. Gums boggy and inflamed, bleed easily, receded in places; pus in several sockets. Pneumo. and staphylo. on cultures. Constipation, chronic tonsillitis. Treated 5 mo. (18 tr.). Gums in healthy condition. No recurrence, 24 mo. Other symptoms improved.

(28) E. S. Oct. 4, 1910. Female, 66 yrs. Gums spongy and inflamed. Root with crown on, loose, pus around it. Cultures showed pneumo. and many macrococci. Indigestion, gas in stomach and bowels, rheumatism. Was advised to have root removed. Treated 2 weeks (3 tr.). Gums healthy. No recurrence. Other symptoms relieved.

(29) G. N. T. Oct. 20, 1911. Male, 46 yrs. Marked recession; gums tender, bleed easily; pus present in a few sockets. Cultures showed staphylo. and pneumo. Intestinal flatulence, general malaise. Treated 9 weeks (9 tr.). Gums in healthy condition. No recurrence, 8 mo. Other symptoms improved.

(30) S. L. May 14, 1911. Male, 40 yrs. Recession of gums; a little visible pus; teeth slightly loose. Pneumo. on cultures. Stomach distress, asthma, intestinal flatulence. Treated 5 weeks (4 tr.). Gums improved. (Discontinued treatment against advice.)

Group III: *Far Advanced Stage* (85 cases).

(31) F. A. May 16, 1911. Male, 66 yrs. Marked recession and looseness of all teeth; profuse suppuration. Pneumo. and staphylo. on cultures. Rheumatism, intestinal flatulence, and urticaria. Treated 3 mo. (7 tr.). Gums markedly improved; teeth firmer; very little pus. Feeling generally better.

(32) W. B. B. Aug. 19, 1910. Female, 46 yrs. Marked recession. Gums painful and sensitive; one tooth very loose, others slightly loose. Much pus. Pneumo. and staphylo. on cultures. Chronic constipation, headaches, general malaise. Treated 4 mo. (13 tr.). Gums in healthy condition; no pus; loose teeth tightened up. No recurrence, 21 mo. Other symptoms relieved.

(33) M. F. B. June 29, 1911. Female, 54 yrs. Bleeding and soreness of gums; several teeth loose; lost one tooth from looseness. Eczema and intestinal flatulence. Treated 2 weeks (3 tr.). Gums improved. Other symptoms benefited. (Discontinued treatment.)

(34) W. A. Nov. 1910. Male, 45 yrs., traveling salesman. Marked recession; all teeth loose; marked suppuration; severe pain on mastication. Treated irregularly for several months. Gums slowly improved. (Became discouraged at slow progress; had all teeth removed against advice, and artificial dentures put in.)

(35) A. F. B. Jan. 12, 1911. Female, 63 yrs. Marked recession and tenderness; two teeth very loose; lost two teeth from looseness; considerable pus. Strepto., pneumo., and staphylo. on cultures. Rheumatism, chronic constipation. Treated 4 weeks (6 tr.). Gums markedly improved and feel comfortable; teeth firmer. (Discontinued treatment against advice.)

(36) A. A. B. Feb. 25, 1911. Female, 55 yrs. Gums markedly receded; several teeth very loose; pus in many sockets. Cultures showed pneumo. in chains and strepto. Colon cystitis and pyelitis of 20 years' standing. Treated with B. coli (autogenous) of urine, and autogenous vaccine of gum pus for 3 mo. (11 tr.). Gums healthy; teeth firm; no pus. Other symptoms relieved. No recurrence, 16 mo.

(37) E. B. Sept. 14, 1910. Female, 28 yrs. Gums boggy and inflamed; several teeth loose; abundant pus. Pneumo. and staphylo. on cultures. Convalescing from abdominal operation. Treated 11 days (3 tr.). Gums looked better. (Discontinued treatment against advice.)

(38) J. P. B. Mar. 4, 1911. Male, 57 yrs. Lower incisors and one bicuspid loose; pus in sockets of loose teeth; general recession of gums. Pneumo. and many long, thick bacilli on cultures. Treated irregularly 6 weeks. Gums improved; teeth firmer. General health improved.

(39) J. B. B. Dec. 23, 1911. Male, 47 yrs. Several teeth loose, several lost from looseness. Abundant pus. Cultures showed staphylo. and pneumo. Chronic furunculosis, chronic constipation. Still under treatment (by dentist). Gums markedly improved; teeth firmer. Other symptoms relieved.

(40) A. H. B. Apr. 30, 1910. Male, 46 yrs. Lost six teeth from looseness; one tooth very loose, several slightly. Profuse pus. Pneumo. and staphylo. on cultures. Polyarthritis, general debility. Treated 1 mo. (8 tr.). All but the very loose tooth tightened up; pus greatly diminished; mouth looked better generally. Obliged to discontinue treatment. Heard from 30 mo. later: Very loose tooth dropped out; other teeth well; gums in healthy condition.

(41) M. B. Nov. 1, 1909. Female, 26 yrs. Gums show general recession, are sensitive, discolored, and boggy. Little pus. Cultures showed strepto., pneumo., and staphylo. aur. Chronic constipation, headaches, general malaise. Treated

2 mo. (12 tr.). Gums healthy. No recurrence, 32 mo.

(42) J. H. B. Oct. 30, 1909. Female, 49 yrs. Lost all upper and several lower teeth from looseness, all remaining teeth loose; gums tender, receded, painful on mastication. Cultures showed pneumo. and staphylo. Indigestion, flatulence, headaches, and general malaise. Treated 6 mo. (11 tr.). Gums well; no pus; no tenderness on chewing; teeth firmer. General health improved.

(43) L. A. B. Nov. 12, 1909. Female, 43 yrs. Gums tender, bleed easily; several teeth slightly loose; pus present in sockets. Pustular acne, muscular rheumatism. Treated 3 mo. (14 tr.). Teeth firm; no tenderness of gums. Other symptoms relieved. No recurrence, 21 mo.

(44) S. E. G. Oct. 26, 1911. Female, 72 yrs. Gums receded, tender, and inflamed, three loose teeth, several lost from looseness. Pus in sockets. Staphylo., pneumo. in chains, and strepto. on cultures. Advanced rheumatoid arthritis, intestinal flatulence, and gastritis. Treated 8 weeks (11 tr.). Teeth firmer; little pus. Other symptoms slightly improved. (Discontinued treatment; had to leave town.)

(45) F. C. June 16, 1910. Female, 55 yrs. Gums markedly receded, boggy, tender, and inflamed; several teeth loose; pus in a few sockets. Staphylo. and diplo. on cultures. Rheumatism, articular and muscular. Treated 2 mo. (12 tr.). Teeth firm; gums look healthy. No recurrence, 24 mo. Rheumatism improved.

(46) H. S. C. Apr. 22, 1910. Female, 56 yrs. Gums receded, inflamed, and bleed easily; several teeth loose; pus in a few sockets. Staphylo., a few diplo. chains and bacilli on cultures. Rheumatism, general malaise. Treated 8 mo. (24 tr.). Teeth firm, recession checked; no pus. Other symptoms disappeared. No recurrence, 21 mo.

(47) R. F. D. Aug. 19, 1910. Male, 60 yrs. Physician. General recession and tenderness of gums; one tooth very loose, others slightly; pus in several sockets. Cultures showed pneumo. and staphylo. Muscular rheumatism. Treated irregularly for 8 weeks. Gums improved.

(48) A. M. D. Nov. 30, 1909. Female, 34 yrs. Gums markedly receded, tender, and bleed easily; two teeth very loose; pus in several sockets. Cultures showed staphylo., pneumo., and bacilli. Rheumatic pain in leg, intestinal flatulence. Treated 5 mo. (26 tr.). Teeth firmer; no pus; gums healthy. Other symptoms relieved.

(49) C. T. D. Apr. 13, 1911. Male, 55 yrs. Gums markedly receded, swollen, boggy, and inflamed; one tooth very loose, others slightly; pus in several sockets. Pneumo. in chains, staphylo, and strepto. on cultures. Rheumatism. gas in stomach and bowels. Treated 6 weeks (8 tr.). Gums markedly improved; teeth firmer; no pus. Feels well generally.

(50) C. J. D. Feb. 17, 1910. Male, 38 yrs. Gums receded, painful and bleed easily; several teeth loose; great deal of pus. Cultures showed pneumo. and strepto. Lupus erythematus, intestinal flatulence. Treated 5 mo. (28 tr.). Gums in healthy condition; no pus; teeth firmer. No recurrence, 26 mo. Skin trouble improved; other symptoms relieved.

(51) J. D. Nov. 11, 1910. Male, 44 yrs. Gums very sore, bleed easily, boggy, swollen, and painful; all teeth loose; considerable pus surrounding each tooth, lost eight teeth from looseness. Pneumo. in chains, staphylo., and bacilli on cultures. Gastritis, chronic diarrhea, rheumatism. Gums too tender for instrumentation. After third injection gums sufficiently improved for local dental treatment. Treated with vaccine 3 mo. (13 tr.). Gums in healthy condition; teeth firm; no pus; comfortable on mastication. Other symptoms relieved. Has prophylactic treatment every 3 or 4 mo.

(52) A. E. Jan. 9, 1911. Female, 51 yrs. Gums markedly receded and inflamed; several teeth loose; little pus; lost one tooth from looseness. Cultures showed pneumo. in chains and macrococci. Atrophic arthritis, arthritis deformans of all joints, intestinal flatulence. Treated 5 mo. (33 tr.). Loose teeth firmer; gums look healthier; mouth feels better. Rheumatism slightly improved; other symptoms markedly improved.

(53) A. W. F. Apr. 22, 1909. Male, physician. Several teeth loose; marked recession, tenderness, and marked suppuration of gums. Cultures showed pneumo., staphylo., and a few strepto. Intestinal flatulence. Treated irregularly for several months (7 tr.). Gums felt better; less pus. (Felt comfortable. Too busy to attend to it.)

(54) M. F. Oct. 25, 1911. Male, 51 yrs. Gums receded and inflamed. Painful on mastication; two teeth very loose, two lost from looseness. Great deal of pus present. Cultures showed pneumo. and strepto. Gastritis, intestinal flatulence. Treated 5 weeks (6 tr.). Pus diminished; teeth firmer. (Felt comfortable. Discontinued treatment against advice.)

(55) A F. July 21, 1910. Female, 34 yrs. Gums receded and inflamed, bleed easily; one tooth very loose; little pus. Cultures showed staphylo. Purpura hemorrhagica of lower part of body, 2½ yrs'. duration. Treated 9 mo. (29 tr.). Gums healthy; tooth firm; no tenderness or bleeding. No recurrence, 15 mo. Purpura relieved by thyroid and diet.

(56) L. A. G. Mar. 31, 1910. Male, 50 yrs. General recession; all teeth loose; pus discharging freely from sockets. Cultures showed pneumo. and staphylo. Rheumatism, stomach distress, intestinal flatulence, and general malaise. Treated 10 weeks (12 tr.). Teeth firm; no pus; gums healthy. Other symptoms improved. No recurrence, 27 mo.

(57) H. G. Apr. 23, 1910. Male, 28 yrs. Gums receded; two teeth very loose; pus in sockets of loose teeth. Cultures showed pneumo., staphylo., and bacilli. General malaise. Treated by family physician for 8 weeks. Very little improvement.

(58) A. F. G. July 8, 1910. Female, 35 yrs. All teeth loose, and profuse discharge of pus; lost three teeth from looseness. Pneumo. and staphylo. on cultures. Muscular rheumatism, chronic diarrhea, dyspepsia. Vaccines sent to

her dentist to follow out treatment. No improvement.

(59) G. A. H. Mar. 6, 1912. Male, 37 yrs. Gums receded and inflamed, tender on mastication; lost two teeth from looseness, several teeth loose, pus present around them. Pneumo. and staphylo. on cultures. Chronic furunculosis, intestinal flatulence. Treated 5 weeks (6 tr.). Gums in healthy condition; no pus; teeth firm. Other symptoms relieved.

(60) A. S. H. Sept. 9, 1910. Male, 52 yrs. Gums receded, boggy, and tender; several teeth loose; one very loose· pus in sockets of loose teeth. Cultures showed pneumo., staphylo., and strepto. Rheumatism, continuous "colds," cough. Treated 2 mo. by his family physician. Gums healthy; very loose tooth tighter, others tight; no pus. Feeling well generally. No recurrence, 21 mo.

(61) Mar. 21, 1912. Male, 42 yrs. Two very loose teeth, discharging pus freely; lost fourteen teeth from looseness; marked general recession of gums. Staphylo. and pneumo. on cultures. Bad carbuncle on neck; diabetes. Treated 3 months (27 tr.), primarily for carbuncle. Gums improved; no pus; teeth firmer. Carbuncle cured.

(62) W. W. H. June 23, 1909. Male, 40 yrs. Very marked recession; four loose teeth; profuse pus; difficulty in chewing. Cultures showed pneumo., staphylo., and strepto. Intestinal flatulence, rheumatism. Treated 5 weeks (6 tr.). Gums improved; little pus; teeth firmer; no tenderness. Other symptoms relieved.

(63) F. E. H. Apr. 4, 1911. Male, 59 yrs. Gums receded and inflamed; three teeth loose; profuse pus. Cultures showed pneumo., staphylo., and macro. Chronic naso-pharyngitis, rheumatism. Treated by dentist. No report received.

(64) C. F. H. Oct. 1, 1910. Female, 50 yrs. Gums receded, tender on chewing, and bleed easily; one tooth very loose; pus. Cultures showed pneumo. and staphylo. Rheumatism, eczema, gas in stomach and bowels. Treated 2 mo. (8 tr.). Gums in healthy condition, tooth firm; no pus. No recurrence, 21 mo. Other symptoms relieved.

(65) H. H. Nov. 12, 1910. Female, 33 yrs. Acute general inflammation of gums. All teeth loose, profuse pus. Left lower third molar removed, socket curetted, and some necrotic bone removed, three weeks before she was brought to me by her physician. Wound slow in healing. Cultures showed diplo., staphylo., and long and short bacilli. Subacute pharyngitis and laryngitis. Treated 1 week (3 tr.). Marked improvement in gums; acute inflammation and suppuration subsided; wound healing rapidly; teeth firmer. Discontinued treatment. Seen 19 mo. later: Gums healthy. Feeling well generally.

(66) S. E. J. Jan. 10, 1910. Female, 30 yrs. Gums very markedly receded, painful, tender, and inflamed; four teeth lost from looseness, the rest remaining loose, two very loose; pus in many sockets. Cultures showed pneumo. Intestinal flatulence and chronic constipation. Treated 6 mo. (18 tr.). Gums looked healthy; all teeth firm except the two that were very loose; no soreness or pus. Feeling "unusually well."

(67) P. A. J. Jan. 12, 1910. Male, 36 yrs. Marked recession; lost two teeth from looseness, four teeth loose, one very loose; profuse pus. Was advised to have very loose tooth removed. Pneumo. on cultures. Gas in stomach and bowels, severe headaches. Treated 5½ mo. (19 tr.). Gums in good condition; very loose tooth removed, others firm; no pus. No recurrence, 26 mo. Other symptoms relieved.

(68) J. T. J. Nov. 17, 1908. Female, 36 yrs. Gums receded, painful, and bleed easily; four teeth loose; pus in sockets of loose teeth. Cultures showed pneumo. and staphylo. aur. Rheumatism, colon cystitis. Treated 4 weeks (6 tr.). Teeth firmer; little pus present; gums felt comfortable. (Discontinued treatment.)

(69) M. A. K. Mar. 3, 1911. Female, 53 yrs. Marked recession and inflammation of gums; one tooth very loose, lost four teeth from looseness; considerable pus in socket of loose tooth. Cultures showed pneumo. and staphylo. Rheumatism, intestinal flatulence. Treated 4 mo. (9 tr.). Gums improved; tooth firmer. Other symptoms relieved. Seen a year later. Gums in healthy condition.

(70) C. A. L. Oct. 19, 1909. Female, 64 yrs. Gums receded and anemic; lost all upper teeth and eight lower, remaining teeth loose; profuse pus. Cultures showed pneumo. and a few bacilli. Gastro-intestinal disturbances, rheumatism, general debility. Treated 4 mo. (13 tr.). Gums markedly improved; teeth firm; very little pus present. Other symptoms relieved.

(71) W. S. L. Dec. 11, 1910. Female, 59 yrs. General recession; several teeth loose and pus around them. Cultures showed pneumo. Stomach and intestinal flatulence, rheumatism. Treated 1 week (2 tr.). Obliged to leave town. Gums felt better; little improvement as to pus and looseness.

(72) M. S. L. Feb. 24, 1911. Male, 52 yrs. Gums receded; lost one tooth from looseness, several teeth loose; profuse pus. Cultures showed staphylo., M. catarrhalis, and fusiform bacilli. Treated 2 weeks (3 tr.). Gums slightly improved; pus lessened. Felt comfortable. (Discontinued treatment against advice.)

(73) T. R. M. Aug. 19, 1909. Female, 36 yrs. Gums inflamed and boggy, receded in places; mastication painful, one tooth very loose; pus in socket. Cultures showed pneumo. in chains and M. catarrhalis. Rheumatism, constipation, intestinal flatulence. Very loose tooth removed. Treated 4 mo. (22 tr.). Gums in good condition. Felt well generally. No recurrence, 33 mo.

(74) A. J. M. Feb. 9, 1910. Female, 46 yrs. Gums receded, congested, bleed easily; one loose tooth; pus in socket. Cultures showed pneumo. in chains and a bacillus. Rheumatism, chronic constipation. Treated 10 weeks (9 tr.). Reces-

sion checked; no bleeding or tenderness; tooth firm. No recurrence, 28 mo. Other symptoms relieved.

(75) H. V. M. Jan. 12, 1911. Male, 48 yrs. Gums receded, tender on chewing; lost two teeth from looseness, all others loose. Pneumo. on cultures. Stomach and intestinal flatulence, general malaise. Treated irregularly for 6 mo. (15 tr.). Gums felt better. Other symptoms improved. (Too busy to continue treatment.)

(76) E. B. M. Jan. 17, 1910. Female, 38 yrs. Gums receded and tender; lost two teeth, all others loose; profuse pus. Cultures showed staphylo. and pneumo. Chronic naso-pharyngitis and laryngitis, intestinal fermentation. Treated 5 mo. (by family physician). Gums healthy; teeth firm. Other symptoms relieved.

(77) J. M. Feb. 24, 1912. Male, 44 yrs. Gums receded, boggy, and tender; three teeth loose; pus in sockets. Cultures showed pneumo. and staphylo. Chronic furunculosis, bronchitis, rheumatism, and intestinal flatulence. Treated 2 mo. (11 tr.). Gums in good condition; teeth firm; no pus. Feels comfortable. Other symptoms relieved.

(78) F. M. July 31, 1911. Female, 36 yrs. Gums very spongy, inflamed, and tender on chewing; one tooth very loose, four other teeth lost from looseness. Profuse pus. Cultures showed pneumo. and staphylo. Stomach and intestinal flatulence, headaches. Treated 4 mo. (14 tr.). Tooth firm; gums in healthy condition. No recurrence, 11 mo. Other symptoms relieved.

(79) C. H. M. Mar. 29, 1910. Male, 43 yrs. Gums markedly receded and inflamed; has difficulty in talking; three teeth very loose, had two of them removed; profuse pus. Cultures showed pneumo. and staphylo. Rheumatism, intestinal fermentation, eczema. Treated 8 mo. (28 tr.). Gums in good condition. Other symptoms relieved.

(80) C. M. Nov. 17, 1909. Female, 39 yrs. Gums receded, inflamed, boggy, and very sensitive; several teeth loose; pus in sockets. Cultures showed pneumo. and staphylo. Chronic bronchitis, postnasal catarrh. Treated 7 mo. (35 tr.). Gums look healthy; teeth tight. No recurrence, 28 mo. Other symptoms improved.

(81) F. M. Dec. 31, 1909. Female, 50 yrs. Gums markedly receded and inflamed, tender on chewing; one tooth very loose, others slightly; lost two teeth from looseness. Pus cultures showed pneumo. in chains and diplo. Rheumatism, gas in stomach and bowels. Treated 2 mo. Felt comfortable. Discontinued treatment against advice; returned later. Treated 4 mo. (19 tr. altogether). Gums healthy; tooth firm. Other symptoms relieved.

(82) R. N. Jan. 19, 1910. Male, 45 yrs. Gums receded, spongy, and painful on mastication; several teeth loose. Profuse pus from sockets. Cultures showed pneumo. Stomach and bowel distress, rheumatism. Treated 9 mo. (27 tr.). Gums in good condition; teeth firm. No recurrence, 22 mo. Other symptoms relieved.

(83) H. N. Feb. 8, 1912. Female, 47 yrs. Gums receded, sore, spongy; lost two teeth from looseness, all teeth slightly loose; little pus. Cultures showed pneumo. and staphylo. Stomach distress and gas, articular rheumatism. Treated 5 mo. (15 tr.). Gums healthy; teeth firm; no pus. Other symptoms relieved.

(84) W. J. N. Mar. 12, 1911. Female, 50 yrs. Gums tender, receded, boggy, and inflamed; three teeth very loose, all slightly, lost 6. Profuse pus. Cultures showed pneumo. Intestinal fermentation, hay fever. Treated 3 mo. (11 tr.). Gums markedly improved; teeth firmer; no pus. No recurrence. Was free from hay fever the following year.

(85) E. C. O. June 21, 1909. Female, 42 yrs. Gums sore, very boggy and inflamed; several teeth very loose; profuse pus. Cultures showed pneumo. and staphylo. Treated 3 mo. (18 tr.). Gums improved; little pus; no soreness; teeth firmer. (Discontinued treatment against advice.)

(86) S. L. P. May 29, 1911. Female, 64 yrs. Gums markedly receded; lost several teeth, several very loose now; profuse pus. Cultures showed pneumo. and yeast fungi. Chronic rheumatoid arthritis, intestinal fermentation. Treated 4 mo. by family physician. No apparent improvement.

(87) C. C. P. Mar. 19, 1912. Male, 52 yrs. Gums receded and spongy; all teeth affected and slightly loose; pus. Cultures showed pneumo. and staphylo. Had 1 treatment and dropped out. (Of value for cultural findings.)

(88) W. J. P. Jan. 27, 1911. Male, 40 yrs. Marked recession and inflammation of gums; several teeth loose; little pus present. Pneumo. and yeast fungi on cultures. Stomach and bowel distress, marked flatulence. Treated 2 weeks (2 tr.). Gums looked better. Felt comfortable. (Discontinued treatment.)

(89) M. P. Nov. 28, 1911. Male, 56 yrs., physician. Very marked recession; all teeth loose; acute abscess formation and inflammation; profuse pus. Cultures showed strepto., pneumo., and staphylo. Stomach and bowel distress. Marked gas formation. Treated 5 mo. (16 tr.). Gums markedly improved; no pus; teeth firmer. Other symptoms improved.

(90) G. A. R. Nov. 1, 1911. Male, 49 yrs. Gums receded and inflamed; lost four teeth from looseness; little pus. Cultures showed staphylo. and pneumo. Stomach and intestinal distress, neuralgic pains of face, general malaise. Treated 2 mo. (6 tr.). Marked improvement of gums. Other symptoms relieved.

(91) D. P. R. Sept. 29, 1910. Male, 34 yrs. Gums markedly receded and boggy; difficulty in chewing; all teeth loose. Pus cultures showed pneumo. and staphylo. Psoriasis, marked intestinal flatulence. (Had 1 treatment; objected to diet. Discontinued treatment.)

(92) J. C. R. Jan. 12, 1910. Male, 43 yrs. Gums swollen, sore; two teeth loose, lost one from looseness. Profuse pus. Cultures showed pneumo. Diabetes, indigestion, general debility. Treated with vaccine by dentist for 6 months. Gums healthy; no tenderness; teeth firm; no pus. Other symptoms relieved. No recurrence, 26 mo.

(93) G. W. R. Dec. 15, 1911. Male, 41 yrs.

Gums very receded and inflamed; six teeth very loose, lost three from looseness; pus in one socket. Cultures showed pneumo. and staphylo. Stomach and intestinal flatulence, general malaise. Treated 3 mo. (12 tr.). Gums healthy; teeth firm; no pus. Other symptoms relieved.

(94) S. J. R. Dec. 2, 1909. Female, 43 yrs. Gums tender and receded; lost several teeth from looseness, all teeth affected, two very loose; profuse pus. Cultures showed pneumo. and staphylo. Rheumatism, stomach and intestinal disturbances. Treated 3 weeks (5 tr.). Gums improved; less pus; teeth firmer. General condition better. (Left town.)

(95) D. P. R. June 24, 1910. Male, 41 yrs. Gums very sore and receded; three teeth loose; pus. Cultures showed pneumo. and staphylo. Chronic sore throat. Treated 5 mo. (20 tr.). "Gums fine." Teeth firm. No recurrence, 21 mo. Other symptoms improved.

(96) F. R. R. June 5, 1911. Male, 57 yrs. Gums receded and tender on chewing; teeth slightly loose; little pus. Pneumo. and staphylo. on cultures. Stomach and intestinal flatulence, constipation. Treated 5 mo. (13 tr.). Gums healthy; teeth firm. No recurrence, 9 mo. Other symptoms relieved.

(97) A. W. R. Jan. 26, 1910. Male, 61 yrs. Gums receded, boggy; lost all teeth but six, those present loose; profuse pus in sockets; artificial dentures troublesome. Cultures showed pneumo. and staphylo. Chronic rheumatism, fistula in ano for thirty years with strepto. infection (operated upon three times unsuccessfully). Treated 2 mo. (7 tr. with autogenous gum and autogenous strepto. vaccine from fistula). Gums improved; teeth firmer; no pus. Fistula operated upon successfully by Dr. T. C. Hill. Other symptoms relieved. No recurrence, 29 mo.

(98) C. H. R. Dec. 19, 1911. Female, 37 yrs. Gums spongy and receded, fifteen years' duration; teeth sore, several loose teeth now; lost four teeth; pus in sockets. Cultures showed pneumo. and staphylo. General debility, stomach and intestinal disturbances. Treated 1 mo. (5 tr.). Gums not sore; look healthy; no pus. "Feeling fine." No recurrence, 8 mo. (Serumal deposits on roots would cause an acute purulent inflammation with unbearable pain. Teeth would loosen rapidly and have to be removed. No salivary deposits. Lost four teeth that way.)

(99) M. F. S. Oct. 19, 1909. Female, 59 yrs. General recession; several loose teeth, two very loose. Profuse pus. Cultures showed pneumo. in chains and diplo. forms. Rheumatoid arthritis with severe pain in muscles and joints, stomach and bowel distress. Treated 8 mo. (33 tr.). One very loose tooth removed. Gums in good condition; other teeth firm. Arthritis previously treated unsuccessfully by able orthopedic surgeon cured while under vaccine treatment for gums. Other symptoms relieved. No recurrence, 28 mo.

(100) L. T. S. Jan. 28, 1910. Female, 34 yrs. Gums very spongy and painful; lost six teeth from looseness, all remaining teeth loose; submaxillary gland swollen; pus. Pneumo. and staphylo. on cultures. Urticaria, indigestion, chronic constipation. Treated 4 mo. regularly and 8 mo. irregularly (38 tr.). Gums in good condition; teeth firmer; swollen gland normal. Feeling well otherwise.

(101) R. S. Sept. 9, 1910. Female, 37 yrs. Gums boggy and receded; several teeth loose; pus. Cultures showed pneumo. Rheumatism, indigestion, stomach distress. (Had 1 treatment. Dropped out.)

(102) K. J. S. Apr. 14, 1912. Female, 42 yrs. Gums boggy and receded in places; several teeth loose; pus. Cultures showed staphylo., pneumo., and spirilli. Rheumatism, intestinal flatulence, chronic urticaria. Treated 1 mo. (3 tr.). Pus diminished; teeth firmer. Other symptoms improved. Felt comfortable. (Discontinued treatment.)

(103) W. H. S. Apr. 4, 1912. Female, 60 yrs. Gums receded, bleed easily; several teeth loose, lost five from looseness; pus. Cultures showed pneumo. and staphylo. Stomach and intestinal flatulence, general malaise. Treated 10 days (3 tr.). Gums improved; teeth firmer; little pus. Comfortable generally. (Obliged to leave town. Discontinued treatment.)

(104) J. H. S. Feb. 28, 1911. Male, 53 yrs. Gums markedly receded; one tooth very loose, all others slightly, had lost three; pus. Cultures showed pneumo., strepto., and staphylo. Marked intestinal fermentation. Treated with vaccine by dentist for 6 weeks: Gums in good condition; teeth firm. Other symptoms relieved.

(105) M. S. Mar. 30, 1909. Male, 40 yrs. Gums receded and very painful on mastication; two teeth very loose, dentist advised removal; pus in sockets of loose teeth. Cultures showed pneumo. and staphylo. Intestinal flatulence, severe headaches (neuralgic?) Treated 5 mo. (25 tr.). Gums healthy; teeth firm; no pus. Other symptoms relieved. No recurrence, 36 mo.

(106) F. M. S. Sept. 28, 1910. Female, 49 yrs. Gums markedly receded, spongy, and inflamed; three teeth very loose, all others affected, lost two teeth from looseness; profuse pus. Cultures showed pneumo. and staphylo. Rheumatism, indigestion, gas, constipation, eczema. Treated 7 mo. (22 tr.). Gums in good condition; teeth firmer; no pus. Other symptoms relieved. No recurrence, 15 mo.

(107) G. S. Jan. 22, 1910. Female, 50 yrs. Gums painful, receded (fifteen years' duration); six teeth loose, lost five others from looseness; pus in sockets. Cultures showed pneumo. and staphylo. Rheumatism, intestinal fermentation. Treated 2 mo. (12 tr.). Gums markedly improved; all but very loose tooth firm. Comfortable on chewing. Other symptoms improved.

(108) W. P. S. June 8, 1911. Male, 52 yrs. Gums receded and very tender, spongy; lost six molars from looseness, all other teeth loose; difficulty in talking and chewing; profuse pus. Cultures showed pneumo., strepto., and staphylo., and many long bacilli. Rheumatism, stomach and intestinal flatulence. Treated 8 mo. (27 tr.). Gums fine in color and firm; no pus, no bleeding or tenderness; teeth firm. Feeling well generally. Seen one year later: Gums still in good condition.

(109) A. B. S. Aug. 16, 1910. Female, 41 yrs. Gums receded, boggy, and painful, bleed easily; several teeth loose, lost two from looseness; pus in sockets of loose teeth. Cultures showed pneumo. in chains and staphylo. Rheumatism, dermatitis exfoliativa. Treated 3 mo. (14 tr.). Gums in good condition; teeth firm. No recurrence, 22 mo. Other symptoms improved.

(110) L. S. Sept. 8, 1910. Female, 35 yrs. Gums receded and inflamed (fifteen years' duration); lost five teeth from looseness, three teeth very loose, all others loose; pus in sockets. Cultures showed pneumo. in chains, staphylo., and macrococci. Rheumatism. Treated 4 mo. (16 tr.). Gums in good condition; two teeth still slightly loose, all others firm. No recurrence, 21 mo. Other symptoms relieved.

(111) G. N. T. June 4, 1911. Female, 45 yrs. Gums very spongy, bleed profusely; teeth slightly loose; pus in several sockets. Cultures showed pneumo. and mucosus capsulatus. Rheumatism, intestinal fermentation, general malaise. Treated 7 mo. (26 tr.). Gums in good condition; teeth firm; no pus; no bleeding. Other symptoms relieved.

(112) C. A. V. Jan. 23, 1911. Male, 72 yrs. Gums anemic, flabby, and markedly receded; three teeth loose, lost several from looseness; pus in sockets of loose teeth. Cultures showed pneumo. Rheumatism, intestinal fermentation. Treated 2 mo. (2 tr.). Gums well; teeth firm. Other symptoms relieved. No recurrence, 18 mo.

(113) L. W. Oct. 22, 1911. Female, 45 yrs. Gums spongy, sore, and markedly receded; teeth slightly loose; pus in sockets of loose teeth. Cultures showed pneumo. and staphylo. Severe backache, walking very painful, chronic constipation. Treated 2 mo. (6 tr.). Gums improved; teeth firmer; no bleeding or pain. Pain in back remained about the same.

(114) F. B. W. Oct. 12, 1911. Male, 49 yrs. Gums receded, bleed easily; difficulty in chewing; several teeth loose, lost two teeth from looseness; pus in sockets of loose teeth. Cultures showed pneumo. and staphylo. Rheumatism, stomach and intestinal fermentation. Treated 2 mo. (7 tr.). Gums improved; teeth firmer; no pus. Felt generally well.

(115) F. H. W. Mar. 2, 1911. Female, 42 yrs. Gums markedly receded, sore, and bleed easily; one tooth very loose, nearly all others slightly; pus present around loose tooth. Cultures showed pneumo., staphylo., and some macrococci. Rheumatism, stomach and intestinal distress, periodic headaches. Treated 3 mo. (9 tr.). Gums looked healthy; no pus; teeth firm. No recurrence, 15 mo. Other symptoms improved

ACCESSORIES OF NITROUS OXID AND OXYGEN.

By THEODORE D. CASTO, D.D.S., Philadelphia, Pa.,
INSTRUCTOR IN ANESTHESIA, POSTGRADUATE SCHOOL OF DENTISTRY OF PHILADELPHIA.

(Read before the Academy of Stomatology, Philadelphia, Pa., October 22, 1912.)

YOUR presence here tonight is an assurance that you are interested in the methods of relieving pain in dental operations. It is not my object to compare the relative value of methods, but to explain the accessories for the gas-oxygen treatments.

CONFIDENCE REQUIRED BY OPERATOR AND PATIENT.

There is a fear to be overcome both in the operator and the patient, and to be replaced by confidence. One of the prime essentials is the confidence of the operator, viz, his intimate acquaintance with physical symptoms which will remove the stage fright that every operator probably experiences when he finds that he has produced unconsciousness in his first patient. This awe of the inexperienced operator when he finds himself alone with the unknown, this lonesomeness when he sees for the first time the conscious self tied, by his request and by agents used by him, is overcome in a day or two, when he becomes familiar with the process. Then he begins to feel some of that confidence which he must impart to his patients.

The technique of operating on the anesthetized patient must be mastered. I have seen experienced hands shake and usually skilfully manipulated instruments break owing to the fear and anxiety of the operator, who was unable to perform the operation which under other conditions would be so easy.

When administering the gas to the patient, the operator should always speak of it as nitrous oxid and oxygen, disregarding the old term "laughing gas."

Each operator has his own way of instructing his patients, and telling of the advantages of this anesthetic mixture; but with a patient who presents an exposed pulp or cervical cavities, a very short talk will be convincing.

METAL SALIVA EJECTOR.

A metal saliva ejector must be used, for even under the most careful observation a patient may lose consciousness, and close the mouth slowly, but most tightly. The breaking of a glass tube in the mouth at this time would be a serious and inexcusable accident. The fragments of glass when swallowed might not do any harm, but they would at least cause the operator two sleepless nights.

MOUTH-PROPS, MOUTH-WEDGE, AND TONGUE FORCEPS.

All operating rooms are provided with mouth-props of rubber or metal covered with rubber in the parts which come in contact with the teeth. I always keep in readiness a small wooden wedge with ratchets. This wedge can be forced between the teeth without injuring them, if the mouth is so tightly closed that the ordinary mouth-opener is useless. Opening the mouth is necessary when the prop inserted in the beginning has been misplaced. In my anesthesia practice, extending over eleven years, I have used this wedge three times, but in these cases it was worth its weight in gold each time. Of equal importance is the tongue forceps. I have never used this instrument, and trust that it will never be necessary for me to do so, but I would not think of operating without having this wedge and forceps at hand. Even in analgesic work the readiness-to-hand of these instruments seems necessary to me.

It is always possible for the patient to drift into profound anesthesia, and the operator should therefore be equipped to confront the dangers that may arise in this condition.

GAS-OXYGEN MIXERS.

There are nineteen or twenty mixers for gas-oxygen on the market today, all of which have some good points to recommend them. The mixer is not a thing of importance; it is only necessary that each operator should use the one which seems the most convenient to him.

For dental practice in the tropics, it is always recommendable to use a heater, as the patients have never breathed air of the snowstorm variety, which is the condition of that which comes from an ordinary nitrous-oxid cylinder. It is generally agreed that heated gas is always more readily absorbed than cold gas.

The ideal mixer has not yet been designed. Such an ideal mixer must take care of the expired nitrous oxid and carbon dioxid gases, collecting them in a separate bag, and passing them through a chemical bath and filters, thereby removing the waste products of exhalation from these gases. When we consider the benefits to respiration of carbon dioxid inhalation, the necessity of this kind of mixer becomes evident. By such an appliance the exhaled nitrous oxid would be stored and could be rebreathed, and an abundant quantity of carbon dioxid supplied, which may become necessary at any time for stimulating respiration.

In administering the gas-oxygen mixture, there must be some contrivance for controlling the pressure of the gas. One of the best means for this purpose was the gasometer, consisting of a closed cylinder over a water-bath, which furnished an excellent automatic vapor-warmer, as the water was at room temperature and soon absorbed the cold of the gas. If one of these gasometers were connected with the nitrous oxid and one with the oxygen, and these in turn were connected with a modern mixer, an excellent means of controlling the pressure would be afforded.

The regulating gage has taken the place of the gasometer, and it is indeed one of the most essential portions of the modern outfit. By its application equal pressure can be obtained in either bag, and the percentage given can be calculated accurately.

A whistle may be attached to the nitrous-oxid cylinder. If the gas is turned on, an increased noise is heard, due to the increase of gas caused by the contraction of the frozen gage; at other times it will sputter and stop, showing that it is frozen by the escaping gas. If this whistle is attached to a larger cylinder with a regulating gage, a little noise is heard, showing the constant flow of the gas. By its use the flow is controlled with great ease.

For the preparation of cavities or the grinding of teeth for crowns, little pressure, viz, a just perceptible flow, is required. For anesthesia, however, a pressure of fifteen pounds or more is required, many operators preferring a pressure of fifty pounds.

THE BLOOD.

The blood absorbs the forty-five volumes of nitrous oxid necessary for anesthesia. The gas is held by the blood in some loose union which is difficult to understand. The corpuscles are believed to remain unchanged. There is, however, a change in the color, producing the condition of blueness which is the sign of approaching danger.

The blood pressure is raised from 20 to 25 millimeters of mercury, and the sphygmomanometer should always be kept in readiness on the operating table. If there is a blood pressure of from 25 to 35 points above normal, and by the administration of nitrous oxid this pressure is raised another 25 or 35 points, rupture of a sclerotic artery might be caused, giving rise to a very serious condition. The increase in blood pressure is the most marked physical change, and should be watched with care.

A practical demonstration of a nitrous oxid and oxygen analgesia is more instructive than words. Who can understand the sensations of the eye or the ear, unless he has himself been subjected to analgesia? The first movement toward unconsciousness, manifested by closing the mouth, must be seen to be appreciated. The cyanosis in the lips or the fingers, which is so readily controlled by an increase in oxygen, is readily recognized by any operator who has seen it a dozen times.

Gas-oxygen analgesia is a fact which every operator must recognize if he wishes to relieve pain; it is a solution of dental difficulties.

PROLONGED NITROUS OXID AND OXYGEN ANESTHESIA FOR SURGICAL OPERATIONS.

A short time ago it was my pleasure to see Dr. A. E. Smith administer gas-oxygen for three surgical operations. The first operation consisted in colotomy for the removal of gall-stones. Four minutes after the first inhalation, the incision was made. The gas in the oxygen bag was kept at some pressure, and the indicator was placed at from five to six points most of the time. There was rebreathing after the first five minutes. A slight lividity was observed, but never a marked cyanosis. When the surgeon lifted out the liver, and began to manipulate it to determine if gall-stones were present, the patient seemed to lose the respiratory power, and this was evident whenever any traction was made on the internal viscera. This was a beautiful operation from the anesthetist's standpoint, lasting one hour and five minutes. The relaxation was good and satisfactory to the surgeon.

The second operation was an appendectomy lasting forty-five minutes. Constant lividity was observed, though no real blueness, and a marked flinching on the first incision, which often occurs and is claimed to be due purely to reflexes. The same hesitancy in respiration was noted when movements of the omentum or intestines were made.

The third operation was undertaken on the tibia, and lasted thirty minutes. In each of these three cases, the patients were practically conscious in five minutes. In the third case, the patient had nausea for a short period on recovery; the others were entirely free from it. It seems remarkable that this combination which dentists fear so much can be made to do such wonderful things.

In these cases the patients lived for the time during which anesthesia lasted on nitrous oxid, oxygen, and the carbon dioxid of rebreathing, for the greatest care was taken to exclude the air. Nitrous oxid and air have never been friends of anesthesia, but it must be remembered that nitrous oxid, air, and oxygen are requisites of analgesia.

ALBUMINURIA.

A patient was given the gas for cavity preparation, the analgesia lasting twelve minutes. He had had an attack of nephritis twelve weeks before, and there was a marked albuminuria, which was increased after giving the gas. This does not prove anything. The patient was acquainted with the condition, and did not wish to take the gas until he would be free from albumin. After three weeks, a cavity was prepared under analgesia lasting fifteen minutes. Analysis showed no increase of albumin. Another analysis was made for a patient who had no albumin before, and none following forty minutes of analgesia.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

LOCAL ANESTHESIA IN DENTISTRY, WITH SPECIAL CONSIDERATION OF NOVOCAIN.

By RICHARD H. RIETHMÜLLER, Ph.D. (Univ. Pa.), Philadelphia, Pa.,
DENTAL DEPARTMENT, MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, October 22, 1912.)

IT is a fact which even the most enthusiastic advocate of, or specialist in, general anesthesia cannot dispute, that every general anesthesia represents a serious intoxication of the central nervous system. Yet the operations called for in the oral cavity, which are so extremely painful as compared with operative interventions in other parts of the human body, have from the very beginning of surgical history prompted a special desire to diminish or to abolish entirely the sensitivity of the teeth and neighboring tissues; and this solicitude has become all the more justified since the general enervation of dental patients, accruing from the wear and tear of the modern struggle for existence, is daily increasing.

DENTAL CARIES AND ANESTHESIA.

We are indeed living in a nervous age, and our patients become daily less fit to tolerate pain which their ancestors bore with ease; our hypermodern, hypersensitive, not to say effeminate culture demands imperatively from us the abolition of pain in dental operations, if we would conscientiously heed the cry that has gone forth so loudly over the civilized world within the last decade: "Save the human teeth!" For who would deny that the destruction of these most essential, most vital organs in the human economy has assumed most alarming proportions, and that we dentists, if we really wish to live up to the importance of our profession in regard to social economy, must have recourse to all possible means to inhibit this universal disease.

Thus the plea for efficient dentistry becomes identical with that for humanitarian dentistry. Indeed, the advent of painless dentistry, which by ethical dentists has been timidly yearned for as an ideal most devoutly to be cherished, and by the dental quack has been impudently heralded as an accomplished fact, is close at hand, and although some minor imperfections in the agents and methods for dental anesthesia are still to be overcome, it behooves the ethical dentist to make his operations painless by a mastery of anesthetic technique, thereby competing successfully with the most unfair competitors mentioned, saving his patients' altogether-too-much-imposed-upon nerves, incidentally also his own, and banishing forever that dread and fear of the dental office which seems to inhere almost ineradicably in the vast majority of patients, and which is in a large measure responsible for the appalling ravages of dental caries in all classes of civilized society.

LOCAL VS. GENERAL ANESTHESIA.

While it is not the writer's intention to weigh the relative merits of local versus general anesthesia, one can hardly refrain from conjecture as to how much the general adoption of the safe and efficient methods of local anesthesia in dentistry about to be described would contribute to an armistice in the bitter conflict that is being waged in some countries between the medical and the dental professions over the medico-legal question of the right to, and the responsibility in, the administration of general anesthetics by physicians or dentists respectively, and what beneficent effect such adoption would have upon the status of dentistry as an independent profession.

HISTORY OF LOCAL ANESTHESIA BY HYPODERMIC INJECTION.

The efforts in the field of local anesthesia are synchronous with and even antedate those toward general anesthesia, and an historical review of these efforts from antiquity to modern times, such as is given by most text-books on anesthesia, notably by G. Fischer in his "Local Anesthesia in Dentistry," and by Hermann Prinz in an essay on "A Rational Method of Producing Local Anesthesia," published in DENTAL COSMOS for September 1908, makes most instructive and interesting reading. Suffice it to say here that the method of general medication by means of hypodermic injection, introduced in 1853 by Alexander Wood, inspired a long series of unsatisfactory experiments with morphin, tincture of opium, and other drugs, for the purpose of local anesthesia, which culminated in Koller's demonstration of the remarkable anesthetizing power of cocain at the Congress of Ophthalmology held in Heidelberg in 1884. Great havoc was wrought, however, by the sudden popularity and injudicious application of this drug before more satisfactory methods of its application had been devised, and the frequency of untoward results due to the high toxicity of cocain caused a regrettable setback to the progress of local anesthesia, until Schleich and Reclus introduced their method of infiltration anesthesia by means of considerably smaller doses. Conductive or regional anesthesia, which in its present perfection is being so successfully employed, was first suggested in 1885, by Halstedt, who dispensed with injecting cocain in the vicinity of a tooth, but injected within the mouth in the vicinity of the trunk of the inferior dental nerve. Braun's suggestion of the addition of the extract of the suprarenal capsule to the injecting solution marked such a signal advance in the cause of local anesthesia that it earned for him the title of "Father of modern local anesthesia."

SUBSTITUTES FOR COCAIN.

An army of notable investigators and reputable drug firms has combined during the last decade or two in efforts to do away with the toxic effects of cocain, and innumerable substitutes have been offered, such as eucain, neurocain, akoin, holokain, tropacocain, orthoform, nirvanin, anesthesin, stovain, alypin, Wilson's anesthetic, adralgin, subcain, andolin, udrenin, perinephrin, orthonal, aneson, subcutin, dolantin, etc.; of these, stovain and alypin have found some noteworthy advocates, although the toxicity of these two anesthetics is only twice or three times less than that of cocain. A great many of the other cocain substitutes contain admixtures of highly toxic drugs, they have other untoward properties, and generally produce hemolysis of the human blood corpuscles. Moreover, the large majority of these drugs are proprietary preparations, and should therefore be shunned, for that if for no other reason, by any practitioner who respects the scientific standard of his profession. From a merely practical point of view it should be remembered that the price of these proprietaries is too high in comparison to their efficiency, and the mystery in which the manufacturers shroud the composition of their products puts the operator at a great disadvantage medico-legally in case of suit for damage following any accident. Novocain alone of these substitutes for cocain involves none of the disadvantages mentioned, and the great popularity—almost to the exclusion of all other anesthetizing agents—which this local anesthetic has gained abroad, especially in France and Germany, where the pioneer work of perfecting the methods of injection and determining the most suitable dosage has been carried out, is bound to be emulated in this country.

QUININ AND UREA HYDROCHLORID.

Certain quinin compounds have, within recent years, been successfully employed for the production of local anesthesia in general surgery, and the combination of quinin and urea hydrochlorid has received quite some discussion in dental literature. A great many untoward sequelæ, however, have been produced by its use hypodermically. (See DENTAL COSMOS, February 1911, p. 253; [*ibid.*, January 1913, p. 111].) Hermann Prinz, in a paper entitled "The Anesthetic Value of Quinin and Urea Hydrochlorid in Dental Operations" (published in DENTAL COSMOS, January 1911, p. 31) scrutinizes the value of this anesthetic compound, and reaches the following damaging conclusions: While it is true that quinin and urea hydrochlorid is not poisonous in the doses in which it is injected for local anesthesia purposes, yet, since it reacts strongly acid, it severely damages the tissues in the injected area, edema and induration being the usual sequelæ. The injection is more or less painful, and the mixture interferes with the progress of wound-healing. The excessive length of duration of the anesthesia, and the paralysis persisting from several hours to several days, is most disagreeable and often alarming to the patient. If applied in concentrated solution to the mucous surfaces, this compound is only sparingly absorbed, and very little anesthesia is produced. Besides, its most persistent bitter taste renders its use undesirable for this purpose.

REQUIREMENTS FOR AN IDEAL LOCAL ANESTHETIC.

The classical researches of Braun have established the following as the principles which must be required from, and fulfilled by, the ideal local anesthetic to be used for hypodermic injection: (1) While equally effective, equal doses of the ideal local anesthetic must be less toxic than cocain. (2) The ideal anesthetic must be absolutely indifferent toward the tissues, and must not in the least interfere with the healing process in wounds. (3) It must be readily soluble in water, must be stable, and must permit of reliable sterilization by simple means. (4) It must allow of the addition of adrenalin or suprarenin without interfering with the vaso-constrictor power of the latter drugs. (5) When applied to mucous membrane, it must possess ready penetration.

Cocain. This list represents a severe condemnation of cocain, the toxicity of which needs no further comment, since any practitioner who has used it extensively without experiencing more or less severe accidents ought to consider himself exceptionally well favored by luck. For while the toxic dose of cocain according to the German Pharmacopeia is 0.05 gm., according to the American Pharmacopeia only 0.03 gm., such a small dose as 0.01 gm. is known to have produced death. The symptoms of cocain intoxication in cases of idiosyncrasy are truly formidable, the effects of this drug on the heart, the nerves, and the kidneys are very undesirable, and the contra-indications in diseases of these organs, as well as in general debility, old age, convalescence, anemia, chlorosis, neurasthenia, and nephritis demand the taking of careful heed, since cocain is a decided protoplasmic poison, acting upon the vasomotor center and inhibiting diapedesis of the leucocytes. Moreover cocain cannot be sterilized, as it is quickly decomposed by heat, and is very perishable, especially when combined with adrenalin or suprarenin.

NOVOCAIN THE ANESTHETIC OF PREDILECTION IN MINOR AND MAJOR SURGERY.

On the other hand, all the above-cited requirements are fulfilled by novocain, which was discovered by Einhorn in 1904—being para-amino-benzoyl-diethyl-amino-ethanol hydrochlorid—and with phenomenal rapidity has conquered the European medical and dental worlds. After this drug has been employed in a good half-million cases of minor and major surgery without any serious accidents from the action of the drug itself, it may be safely said to have passed the experimental stage. In fact, general surgery in Europe has adopted local anesthesia by novocain suprarenin for cranial and cerebral operations, skull trepanations, suppurations in the frontal and ethmoidal sinuses, extirpation of the tongue, tumors, and glands, removal of bone fragments, in carcinoma, etc. To cite only one report (by Braun):

> The course of operation under local novocain-suprarenin anesthesia is very different from that under general anesthesia. No interruption of the operation for the sake of continuance of the general anesthesia is required, and the operation can be completed in a minimum of time. Owing to the anemia from the suprarenin, the continual flooding of the field of operation with blood is avoided, and any slightly oozing vessels can be quickly compressed. The unimpededness of the operative area permits of operating exactly and neatly. If blood flows into the pharynx, the patient is always able to prevent its aspiration, since all reflexes are maintained. The patient can also co-operate in making minor changes in position. The patients' condition after the operation is most favorable; they leave the operating table perfectly well, and rarely have to be put to bed. If given a very small dose hypodermically of scopolamin they frequently have little or no reminiscence of the operation. It is not too much to say that, with the application of novocain-suprarenin anesthesia, resection of the maxillæ has lost all its terrors. Local anesthesia is not equivalent to general anesthesia, but is far superior to it.

A review of the early and surprisingly favorable results obtained abroad by novocain-suprarenin anesthesia in dentistry was published by the writer in the August 1908 issue of the DENTAL COSMOS under the title of "Recent Studies on Novocain." This was followed in the September issue of the COSMOS of the same year by an enthusiastic article by no less an authority than Dr. Hermann Prinz, entitled "A Rational Method of Producing Local Anesthesia," and in the August 1910 COSMOS by a paper from Dr. B. H. Masselink's pen—who confidently heralded "The Advent of Painless Dentistry"—and in the February 1911 COSMOS by an epitome of "Local Anesthesia in Dentistry," by Dr. Guido Fischer, whose text-book on this subject has since appeared in an English translation.* A great many articles and reports of thousands of practical cases have appeared in close sequence in other American dental journals, and especially in the special literature of foreign countries, notably Germany, where a lively and in several instances even acrimonious exchange of opinion between the advocates of general and local anesthesia is taking place, quite apparently in favor of the latter. From all this fruitful controversy it appears plain that novocain comes as close to being the coveted ideal local anesthetic as can reasonably be expected from a drug which by the very character of its physiologic action and purpose is a poison, no matter how mild.

Novocain is a white powder, readily soluble in water in the proportion of one to one, the solution giving a neutral reaction, and allowing of being heated up to 120° C. without undergoing decomposition. In animal experiments novocain has proved to be seven times less toxic than cocain, while from clinical evidence in man it may even be said to be ten times less toxic. The maximal dose for subcutaneous injection is variously stated as 0.5 gm. (Liebl), 0.75 gm. (Fischer), and 1.00 gm. (Fichot), which considering the fact that only from 1 to 2 per cent. solutions are used for injection, allows of an extremely wide margin of safety, especially when we consider that the largest single dose for dental purposes, viz, in conductive anesthesia of the mandibular half by way of the mandibular foramen, only 2 cc. of a 1.5 per cent. solution is injected. For major operations very much larger quan-

* "Local Anesthesia in Dentistry, with Special Reference to the Mucous and Conductive Methods. By Prof. Dr. Guido Fischer. Translated from the second German edition by Dr. Richard H. Riethmüller. Philadelphia and New York: Lea & Febiger, 1912." (See also review in COSMOS for October 1912, p. 1174.)

tities of novocain solution can be injected than is possible with cocain solutions. Dr. M. Wegner of Greifswald, for instance, has injected up to 24 cc. of the novocain solution without ill results to the patient for regional and terminal anesthesia in resection of the maxilla and mandible. In surgical clinics up to 125 cc. of a ½ per cent. novocain-suprarenin solution are injected, and Dr. G. Hesse of Jena reports a case in which for extirpation of one breast and curettage of the axilla for the removal of a carcinoma in a woman suffering with myocarditis and totally unfit for general anesthesia 250 cc. of a ½ per cent. novocain-suprarenin solution was injected, the patient making a good recovery.

Novocain when injected penetrates the tissue cells and the red blood corpuscles without producing any irritation, hence the injection itself is painless; it in no wise impairs the hemoglobin, and it permeates even the nerve substance itself, so that its full anesthetic power remains unchecked throughout. It produces a local anesthesia as profound as that obtained by cocain and of longer duration, though it requires a slightly longer time to exert its full anesthetic power than cocain. It is constant in its action, can be sterilized by boiling, consequently a solution can be kept and used for a great length of time; it can be administered immediately after food; it produces no shock, no cardiac or respiratory failure, no after-pain or sloughing of the gums. It can be safely applied in arterio-sclerosis, diabetes, nephritis, cardiac and pulmonary disorders, anemia, chlorosis, pregnancy, and lactation. It combines with suprarenin without interfering with the physiological action of the latter, this combination rather increasing the action peculiar to either drug, thus necessitating the injection of but a very small quantity of the mixture. It is readily absorbed by the mucous membrane. It most favorably influences and even hastens the process of wound-healing, if dusted in powder form or swabbed in 20 per cent. solution, at the same time doing away with pain. Fresh extraction wounds can be induced to heal quickly if flushed with a 3 per cent. hydrogen dioxid solution, and tamponed with gauze impregnated with iodoform—or preferably one of its modern substitutes without odor and of better taste—and dressed with novocain crystals. When combined with adrenalin or suprarenin the action of novocain is confined to a small area, thus its absorption is retarded, intoxication of the general system avoided, and deep anesthesia of the injected area insured, lasting, according to the quantities employed in dental operations, from twenty minutes to three hours. Novocain is not a secret preparation, but a drug of definitely known chemical composition, and is being sold in practical form by several American drug firms and dental depots; its price is lower than that of cocain, even; in its utilization by various methods no bulky or expensive apparatus is required, but simply that which is necessary to insure absolute sterility of the solution, and the instrumentarium, which calls for little more than a suitable hypodermic syringe and needles. It can be employed in weaker or stronger doses, according to the patient's age and general health, with the same perfect results. Last, not least, its general adoption will make the dentist appreciate the absolute necessity and great practical value of asepsis, which is so sadly neglected in routine practice.

SUPRARENIN AND ITS ACTION IN COMBINATION WITH NOVOCAIN.

Of the greatest importance for the development and perfection of local anesthesia by hypodermic injection was the discovery of the astringent action of suprarenal extract by Oliver and Schaefer in 1894. Suprarenin, the active principle of the suprarenal gland, preparations of which are offered under the trade names of epinephrin, suprarenalin, suprarenin, adrenalin, adrenin, paranephrin, renoform, hemostasin, and others, by its powerful vaso-constrictor action raises the arterial blood pressure and produces local anemia, thereby preventing a too rapid absorption of an injected local anesthetic by the circulation, and permitting of a considerable reduction in the quantity of anesthetic solution to be introduced. It is the most powerful of all chemical substances thus far known; its action is recognized even in a dilution of 1:100,000. A minute quantity suffices, therefore, to produce the effect desired for our purposes, the maximal dose being about 5 drops of a 1:1000 suprarenin solution.

The impurities and lack of stability inherent to the organic preparations derived from the suprarenal glands of sheep and oxen have been largely done away with through the synthetic preparation of suprarenin, which represents a triumph of chemical science due to the labors of Stolz and Flaecher. Synthetic suprarenin is fairly stable, and if put up in suitable vessels and kept under suitable conditions may, according to tests, be preserved as long as six months, without changing color to pink, red, and finally brown, with the formation of a flocculent precipitate, when the solution is no longer fit for use. While in itself suprarenin has no anesthetizing power, it markedly increases the anesthetizing effect of novocain, and by the anemia which it produces in the field of injection largely prevents the obstruction of the operative area by blood. The discussion of the physiologic action of suprarenin, further than has already been briefly summarized, would lead too far, and is ably discussed by Fischer and Prinz in the papers mentioned above.

THE INJECTING SOLUTION.

The preparation of a suitable novocain-suprarenin solution for routine practice is, of course, of the greatest practical interest to the dentist. To the painstaking efforts of Fischer, Buente, and Moral we owe the so-called normal solution, in which due consideration is given to isotonia, osmotic pressure, sterility, permeability of the tissues, etc. This normal solution was originally given as follows: Novocain, 1.5 gm.; sodium chlorid, chem. pure, 0.92 gm.; thymol, 0.025 gm.; distilled water, 100 gm. The small addition of thymol was originally recommended owing to its energetically antiseptic, antizymotic, and anesthetizing action. It has been abandoned, however, because thymol, while being a strong anesthetic, is painful upon introduction, is more or less cauterizing to the mucous membrane and the tissues closely underlying the same, and has been found to cause swelling following injection.

As the novocain solution is boiled before use, the demands of asepsis are satisfied without the addition of an antiseptic. Thus the "normal solution" most suitable for dental purposes may be prepared according to Prinz' formula, as follows: Novocain, 10 grains; sodium chlorid, 4 grains; distilled water, 1 fl. ounce. Boil. To every thirty minims of this solution, viz, to each syringeful, two drops of suprarenin solution (1:1000) are added immediately before use, the drops to be measured with a tested Standard pipet, as designed by Dr. Schoenbeck of Leipzig, or with a Whitall-Tatum Co.'s dropping bottle.

ISOTONIA OF ANESTHETIC SOLUTIONS.

The advantages of the isotonia of the injected solution are apparent, in consideration of the absence of osmotic pressure and consequent irritation in the tissue cells, which may assume the form of edema or even necrosis of the tissue. The non-isotonic character of a great many of the proprietary anesthetics offered in the market is another strong argument against them, in addition to those already mentioned, and Buente and Moral have shown that quite a few of these proprietaries induce the formation of methemoglobin and hemolysis, with the untoward sequelæ. For those operators who for busy private or clinical practice prefer to make their own solutions from the novocain powder, it is recommended to keep a stock of isotonic salt solution made after the following formula: Chemically pure sodium chlorid, 2 parts; one-tenth dilute hydrochloric acid, a trace; aqua destillata, 300 parts.

SUGGESTIONS FOR THE PREPARATION AND PRESERVATION OF NOVOCAIN-SUPRARENIN SOLUTIONS.

Owing to the unstable character of suprarenin, viz, its decomposition through the presence of the slightest traces of alkali, by light, air, and heat, a few details in the preparation and preservation of our injecting solutions must be rigidly observed. It is a fact known to every chemist that glass, which is more or less strongly of an alkaline nature, is dissolved by cold and hot water, and these traces of alkali, however minute, seriously affect the stability of suprarenal preparations. Some operators for this reason employ only the scientifically manufactured brown non-alkaline glassware of the Jena glass works. How sensitive to alkalis the suprarenal preparations are is strikingly illustrated by a report of Dr. E. Paul in the *Deutsche Zahnaerztliche Wochenschrift* of February 10, 1912; he found that, four weeks after purchase, the contents of an unopened bottle of suprarenin manufactured by a reputable drug firm had become turbid. For this reason, most drug firms date every bottle of suprarenin, and in case of decomposition exchange it for an equal quantity of the drug freshly manufactured. It is advisable, therefore, to purchase only the smallest quantity of suprarenin required, and in the smallest containers possible; also, a bottle after once having been opened should be used up as quickly as possible, since the oxygen from the air, and the nascent oxygen from the water with which the suprarenin is diluted, is also detrimental to the drug. If kept in a cool, dark place, preferably in a purchased or home-made thermostat, the life of the suprarenal solution can be materially prolonged. Williger distributes his stock solution in several sterile brown glass bottles with ground glass stoppers which have been previously boiled in hydrochloric acid to render the glass as free from alkaline traces as possible, and uses a bottle up as quickly as feasible, thus incidentally preventing the introduction of bacteria from the air, which is always more or less contaminated with dust and minutely distributed saliva globules from the exhaled air. A reliable test for the purity of suprarenin is the following: It must give a clear solution in dilute hydrochloric acid, and 0.1 gm. must leave no residue if evaporated in a platinum dish placed over a flame. Brown discoloration is a certain sign that a suprarenin solution is unfit for use. In order to insure the sterility of the anesthetic solutions, it has become customary with many operators to add one drop of one-tenth dilute hydrochloric acid to the normal novocain solution, to admix the suprarenin to this solution, and boil the whole, which can be done without jeoparding the action of the suprarenin.

It goes without saying that only aqua destillata should be used in making up a solution. Boiled water is by no means sterile, moreover it may contain quantities of alkalis, these varying in different districts, which detrimentally affect the solution, as will be indicated by a pink or rose discoloration. Even the aqua destillata as bought in pharmacies is by no means reliable, as everyone familiar with the slipshod methods by which it is made—usually in the darkest spare corner, and frequently by none too careful or skilled clerks—knows very well. It frequently contains bacteria that have been introduced from the air or the dust collected on the large bottle in which it is kept, and on close scrutiny is often found to have particles of dust, filter paper, or even hair, suspended in it. The acquisition of a small filter apparatus will therefore prove a boon to the conscientious operator, and in a busy and clean practice will soon pay for the initial investment, especially since aqua destillata must be employed for the sterilization of the instrumentarium employed in connection with local anesthesia, as we shall see immediately.

For reasons similar to those given in favor of the preparation of aqua destillata by the operator himself, the purchase of official physiologic salt solution is undesirable. The purchased product often contains impure or incorrect dosage of sodium chlorid and slight traces of soda. A purchased salt solution should always be tested for alkaline traces; if present, the alkalis must be neutralized by the addition of dilute hydrochloric acid, which, as has been said, compensates at the same time for the alkalinity of the glass containers and prevents the catalysis of oxygen in the anesthetic solution, either of which unfavorably influences the suprarenin.

Stock solutions of novocain are best preserved in small brown glass bottles with ground glass stoppers previously sterilized by steam. If kept in large bottles with wide opening, the solution becomes easily contaminated with microorganisms from the air. These microorganisms are rendered innocuous by vigorous and prolonged boiling of the solution before use; still it is preferable to use up a once-opened bottle in a short time, thus guaranteeing unimpaired action of the anesthetic. If solutions of different strengths are kept, the stock bottles must be carefully marked, in order to avoid accidents by mistakes in selection.

AMPULES CONTAINING READY-MADE SOLUTIONS VS. TABLETS.

Considerable discussion has arisen as to the most practical method of obtaining a novocain-suprarenin solution. For a large hospital practice with a well-trained staff and a reliable pharmaceutical department, the daily preparation of a novocain solution from the powder, and the addition of the suprarenin to this solution as the cases present, is surely most economic. For private dental practice, ready-made novocain-suprarenin solutions of various strengths are marketed in ampules by various drug firms. The convenient form which seems to recommend these ampules is, however, largely a delusion, as it is not very easy to withdraw the full contents of the ampule with the syringe. Moreover, the price of the ampules is high, their contents are not always sterile, small openings being left in sealing the glass necks, and the stability of the solution in these containers is by no means unlimited. The tablet form, therefore, predominates in favor, and pure novocain and novocain-suprarenin tablets containing an admixture of sodium chlorid to yield an isotonic solution when mixed with a stated quantity of aqua destillata are being marketed by several reliable American drug houses. The price of these tablets is lower than that of ampules, the preparation of the solution from the pure novocain tablets is simpler than if the powder form is used, the operator may vary in the concentration and quantity of solution at his discretion, and if novocain-suprarenin tablets are used, need not trouble about making a correct isotonic solution nor adding the proper amount of suprarenin from a pipet. Besides, suprarenin in tablets is less perishable than in solution, and as after dissolving the tablet in distilled water the solution is boiled, sterility is fully insured. Brown discoloration of the novocain-suprarenin tablets indicates that they are no longer suitable for use, while pure novocain tablets remain unchanged for an unlimited time. In normal adult cases the novocain-suprarenin tablets are undoubtedly the most practical; yet for the sake of variation in the concentration of the novocain and in the admixture of suprarenin, in children, nervous, debilitated, and convalescent persons, in arterio-sclerotics and the aged, pure novocain tablets and suprarenin solution should be kept in stock.

STERILIZATION OF THE SOLUTION.

The amount of aqua destillata to be used for dissolving a tablet is measured in a graduate that has previously, for the sake of sterilization, been boiled in plain water and rinsed in a 3 per cent. solution of boric acid to counteract any alkali from the water or the glass. The solution is then boiled in an ordinary sterile test tube which has been rinsed in a one-tenth dilute solution of hydrochloric acid to compensate for the alkalinity of the glass. The sealed end of the test tube is held in the flame by the aid of a tightly folded strip of sterilized gauze wound around the upper portion of the tube. The most practical means, however, for boiling the solution and drawing it into the syringe, which is not so easy when a test tube is used for the boiling, consists of a small silver beaker, gold-plated and graduated inside, as designed by Dr. Muehlhaeusler, and manufactured by the Hoechst Farbwerke. This beaker is set in a suitable wire frame with handle, so that the solution can be sterilized, and the contents of the beaker withdrawn to the last drop without the fingers coming in contact with the vessel or the solution. As soon as the solution has cooled to about blood temperature it is drawn into the syringe and injected. It is readily appreciated that this is the optimum temperature for painless injection, quick penetration, and non-irritating effect of the solution.

INSTRUMENTARIUM.

While Fischer has designed and compiled an almost ideally complete instrumentarium, this is by no means a *sine qua non* for success, and the selection of an outfit can be left to the operator's discretion as long as the demands of serviceableness and asepsis are fully complied with. The syringe selected must, of course, be so constructed as to allow of sterilization by boiling after each use; the piston must be tightly fitting, so as to render regurgitation of the solution under pressure impossible, and the form and weight must be such as to permit of easy and delicate manipulation. Fischer's glass-and-metal syringe combines all these advantages with the controllability of the quantity of solution contained in the graduated glass barrel. Still, an Imperial syringe or Parke, Davis & Co.'s Dental Hypodermic syringe, both of which are all-metal and bear graduation marks on the piston, are fully satisfactory. It is best to keep several syringes ready for use, so that for every injection an absolutely sterile needle and syringe are on hand, and the operator is not handicapped by waiting for the re-sterilization of his only syringe if contaminated accidentally, as by being dropped, etc. The Schimmel steel needles seem to enjoy general favor, and their low price permits of using a new one for each case. Pure platinum needles are too soft, and those of iridio-platinum soon lose the sharpness of the point. Any needle that is used more than once must be carefully sterilized by boiling, preferably in a 2 per cent. lysol solution, dried with hot air, and preserved in a sterile glass bottle or in alcohol.

Straight hubs, for both long and short needles, will be required most frequently; for posterior teeth, however, a bayonet-shaped hub may prove very serviceable.

The syringes, with hub and needle attached, are best kept suspended in an upright glass jar filled with absolute alcohol and fitted with a German silver stand to prevent dulling of the needle point by resting on the bottom of the vessel. Such a stand can be shaped-up and soldered quickly by any mechanic. The jar is covered with a flat glass cover with ground edge, which is vaselined, and this cover is kept tightly on the jar over night by binding it down with strips of adhesive plaster to prevent evaporation of the alcohol. The flat cover is preferable to a ground glass stopper, which sometimes is very difficult to remove. Alcohol of 70 per cent. has been found more strongly bactericidal than absolute alcohol; still, absolute alcohol may be preferably used as it soon absorbs enough water from the atmosphere to approximate it to that alleged optimum percentage. In the Bardet syringe sterilizer, which is used by some operators, only the needle is kept sterile by immersion in lysol, while the greater portion of the barrel and piston are exposed to undesirable contamination with micro-organisms from the air.

A graduate, a pipet or dropping bottle, a bottle for keeping the needles, preferably one with ground-glass stopper and bell cover, and a large glass tray for the reception of a lysol, cresol, or alcohol solution in which the syringe, a pair of pincers, a wrench for the syringe, and hubs, all previously sterilized by boiling, can be kept temporarily, complete the outfit. The Evans (of San Francisco) syringe tray seems the most practical.

STERILIZATION OF INSTRUMENTARIUM.

The syringe and the rest of the instrumentarium must be boiled after each use in water without soda, better still in distilled water, and kept sterile until its next using. On removing the syringe from its alcohol bath, some of the alcohol is drawn through the needle and barrel, pressed out and burnt off by passing through a flame.

After the alcohol is burnt off, hot water is drawn into the syringe, as any trace of alcohol which is not thus removed would produce anesthesia lasting several days, as is appreciated by anyone familiar with the treatment of trifacial neuralgia by alcohol injections. The hot water also heats the syringe, and prevents the anesthetic solution from cooling below blood temperature. A Koch's steamer, or an S. S. White electric sterilizer is excellently suited for sterilizing the entire instrumentarium, which should be boiled for an hour or more to destroy all spores.

TECHNIQUE OF INJECTION.

It would lead too far to go into the details of the technique of injection, which may be made in four ways:

First: We may inhibit the function of the peripheral sensory nerves in a circumscribed area, viz, apply terminal, or mucous, or subperiosteal anesthesia for rendering one or several teeth and their surrounding tissues insensitive to pain. For this form of anesthesia an intimate knowledge of the greatest vulnerability of the alveolar bone, viz, the distribution of cancellated areas, which allow a rapid penetration and diffusion of the injected liquid, is imperative. The distribution of these places of preference is very well shown by Fischer's anatomic specimens illustrating the structures of the osseous frame of the maxillæ and alveolar process.

Second: We may anesthetize a whole group of teeth by blocking the conductivity of the sensory nerve trunks supplying these teeth at their exits from their respective foramina, thus inducing conductive or perineurial anesthesia, the technique of which has been greatly perfected by Braun, Fischer, and Friteau.

Third: Single roots of teeth, or those affected with pyorrhea, may be conveniently and quickly anesthetized by injecting directly into the peridental membrane—peridental anesthesia, as described by Prinz in the January, February, and April issues of the *Dental Summary*, 1912.

Fourth: In order to hasten the diffusion of the anesthetic, Otté, in 1896, recommended opening into the superficially anesthetized gingival tissue, and the bone on the buccal side, with a fine spear-shaped or Gates-Glidden drill, and inserting a suitable hypodermic needle into this opening, thereby rapidly producing anesthesia by intra-osseous injection. This method, which has its evident disadvantages, is fully described by B. H. Masselink in the August 1910 issue of the DENTAL COSMOS.

PREPARING THE FIELD OF OPERATION.

Before making an injection in the mucous membrane, the mouth must be put into sanitary condition by removing any tartar present from all the teeth, or at least from those in the vicinity of the field of operation. A mouth-wash of neutral or slightly acid reaction is then given. The area around the prospective point or points of insertion of the needle is swabbed vigorously with a mild solution of iodin and aconite by means of cotton wrapped around a sterile glass rod, wooden tooth-pick, or skewer, thus cleansing the mucosa and binding all bacteria. Instead of iodin-aconite, the application of one drop of carbolic acid is recommended in persons subject to iodism. Both the iodin and the carbolic acid mark the point of insertion by discoloration, and the anesthetizing action of both drugs renders the first insertion of the needle, which is feared the most by patients, absolutely painless.

A FEW PRECAUTIONS.

If all requirements of asepsis in connection with the anesthetic solution, the instrumentarium, and the field of operation have been satisfied, no untoward sequelæ of any kind will follow the injection, if it has been made into healthy tissue. Injection in close proximity to a purulent center must be avoided in all cases, since virulent bacteria may be carried into deeper layers. In case of severe inflammation or abscess, conductive anesthesia must be resorted to. In terminal or subperiosteal anesthesia the needle should be very gradually advanced through the soft tissue, slowly discharging minute quantities of the solution as the needle proceeds, and, after the bone has been reached by the shortest route, the needle is kept in close contact with the bone, thereby avoiding puncture of a bloodvessel and so producing a hematoma, which, especially if occurring on the floor of the mouth, is painful and may cause complications should putrefaction set in. This danger is fortunately a remote one, as the bloodvessels are hard to puncture and have a tendency to avoid the needle. After the contents of the syringe have been discharged at the desired spot, the needle is withdrawn and the area of injection gently massaged with a finger in order to facilitate the diffusion of the anesthetic. Sufficient time must be allowed for the establishment of complete anesthesia, which can be ascertained by the whiteness of the area injected, and numbness upon touch, or by slow institution of the initial steps of the operation. The establishment of complete anesthesia varies in time in different individuals and according to the method of injection employed, the extremes in either direction lying between one and twenty minutes. If two injections are made in close sequence, *i.e.* labially and lingually, the same needle should not be used for both injections, as the first needle may have become contaminated by streptococci from the saliva. Breaking of the needle is not to be anticipated, but, if it does occur, is not dangerous. The needle should be immediately extracted under local anesthesia, and, if not found, left to be taken care of by nature, and encysted, which will occur if the needle has been sterile.

The presence of a third person, viz, an assistant or office girl in the operating room is a precautionary measure which should never be disregarded for social reasons, if for no others.

PROPHYLACTIC TREATMENT OF PATIENTS.

To insure uniformly successful results even in timid, nervous, or obstinate patients and in children, one or two tablets of bromural should be given internally from twenty to thirty minutes before injection. Bromural, which is alphabromisovaleryl-urea, is manufactured in tablet form by Knoll & Co., and is being largely used in Germany in preparing patients for local or general anesthesia. It has a slight odor of valerian, readily disintegrates in water, and is tolerated even in very large doses without any unfavorable reaction. Its agreeable sedative and hypnotic effect is greatly appreciated by the timid in everyday dental operations, even though these may involve nothing more than nervous strain. (See DENTAL COSMOS, July 1909, p. 844, and May 1910, p. 602.) In combination with aspirin, pyramidon, or trigemin, bromural is very useful in headache, of which male patients are wont to complain after overindulgence in alcoholics, and in after-pain. Bromural is more easily tolerated and absolutely harmless as compared with quinin, chloral hydrate or morphin-hyoscin, as recommended by Fischer for prophylactic sedative treatment. The twilight slumber which frequently follows the internal administration of bromural greatly enhances the ease with which our injections can be made.

Scopolamin, to be administered hypodermically by a Pravaz syringe, also has a place in our medicinal equipment, and is especially serviceable in preparing alcoholics for local anesthesia. Very stubborn or neurasthenic patients, or those in whom deep general anesthesia is absolutely contra-indicated, may be induced to submit to local anesthesia by being given a few inhalations of ethyl bromid or nitrous oxid and oxygen, if available, the mask being held at a distance from the face until superficial twilight slumber has set in.

In all such cases the operator's reassuring personality, individual discrimination, and a certain amount of personal hypnotism which can be acquired by training of the will power, is a valuable asset which may prove more effective than even drugs.

CONTRA-INDICATIONS AND SEQUELÆ.

Local anesthesia by novocain-suprarenin solution is contra-indicated in patients who absolutely refuse to submit to an injection on account of sad experiences they have had previously with cocain injections, and in ill-behaved children who are likely to gesticulate, also in ankylosis, extended phlegmonous conditions, in the status lymphaticus, grave anemia, tuberculosis, and infectious or metabolic diseases through which the power of resistance of the tissues has been lowered. In such cases edema may result without the dentist's fault, owing to tissue reactions that are as yet unexplained.

Cases of idiosyncrasy must be watched for, by taking an accurate history of the patient, in the use of novocain as well as in that of cocain. A few cases of idiosyncratic sequelæ following novocain injection have been reported, yet they are less numerous than with cocain, and the symptoms are considerably less severe and alarming. Even these seem to be on a fair way to be done away with entirely by the employment of mixtures of Byla's peptone and novocain, with which Fichot and Billard have made extensive experiments.*

In order to counteract shock or collapse in their light forms, such as palpitation, rapid pulse, pallor, cold perspiration and trembling, a decoction of strong black coffee, which should be kept in stock, or from five to seven drops of camphorated validol in a little water, are given internally, and placing the patient's head in a recumbent position. In more serious affections the heart is stimulated by the inhalation of a few drops of amyl nitrite applied on a napkin, by cold cloths applied to the chest, or a hypodermic injection of oil of camphor. If the patient's individual case has been duly considered in regard to concentration and quantity of solution injected, and all aseptic precautions have been taken in the preparation of the solution and the instrumentarium, no after-pain will set in. Pain from secondary infection, due to faulty oral hygiene, must not be charged against local anesthesia.

* [See COSMOS, January 1913, p. 105.]

PRESSURE ANESTHESIA FOR PULP EXTIRPATION.

For pressure anesthesia, small rods, containing 0.01 gm. novocain and 0.0002 gm. suprarenin are in the market. These rods are applied in the same way as the cocain rods sold for this purpose. The anemia produced by the suprarenin allows of a cleaner operation with less danger of subsequent discoloration of the tooth, and is especially appreciated in children's teeth with large apical foramina. These rods produce perfect results even in advanced stages of pulpitis and in cases of pulp-stones, in which the familiar procedure may have to be repeated once or twice. The great advantage of these novocain-suprarenin rods over cocain or arsenous oxid lies in the absence of pericementitis following pulp extirpation.

RANGE OF USEFULNESS OF NOVOCAIN-SUPRARENIN.

In all operations of a surgical nature in the oral cavity, in the now so popular resection of diseased root apices, extraction of teeth, removal of roots, bone fragments, impacted teeth, cyst operations, resections or scarification of the maxillæ, etc., the methods of local anesthesia indicated are of inestimable value. Numerous minor operations, such as the grinding down of sound teeth, and the preparation of roots for bridges, the separating of teeth, or the wiring of fractured jaws, can be made painless and comfortable for both patient and operator by judiciously applied anesthesia. Scheff, after careful experimentation, has found that in all these cases the injection of novocain-suprarenin in no wise affects the vitality of the anesthetized tooth or its neighbors, if the pulps have been healthy before the injection. By rubbing a pellet of novocain-suprarenin into sensitive dentin with a moistened ball burnisher, excavation can be rendered tolerable, and the gums can be desensitized by rubbing the anesthetic tablet into them with an instrument or the finger, or by painting on them a solution of 20 to 30 per cent., for the fitting and adjusting of crowns, bridges, and orthodontia appliances, and similar painful procedures. It should, however, always be remembered that pain is very often the dentist's most valuable assistant in obtaining a correct diagnosis, especially in the treatment of pulpal and pericemental conditions.

CONCLUSIONS.

Local anesthesia by novocain-suprarenin injection surely deserves a thorough trial by every dentist, and it will prove a boon if the precautions mentioned are observed and the technique of injection is mastered. Considering the present state of perfection of local anesthesia, its possibility should always be first considered before resorting to general anesthesia—not *vice versa*, as unfortunately is still the case with many dentists. In ambulatory dental practices, or in districts where no nitrous oxid and oxygen tanks, no hospital or skilled anesthetist, are easily available, local anesthesia alone is practicable in the office as well as in the patient's home. The production of general anesthesia under difficult conditions or in unsuitable surroundings involves infinite disadvantages and risks, and its final success against such odds is altogether too dearly bought when we know that for dental operations local novocain anesthesia can be obtained so satisfactorily. Medico-legally, also, the application of local anesthesia gives the operator the advantage. To cite a medico-legal authority (Kupfer): "After extensive observations I do not hesitate to maintain that general anesthesia, with the few exceptions enumerated, is unnecessary in operations in the oral cavity, and that, as a medico-legal expert, I should be unable to protect an operator from indictment in case of fatal accident from general anesthesia." Dental colleges would surely raise the efficiency of their graduates, and more forcibly instil into them the necessity of aseptic methods of operating, and the importance of an intimate knowledge of the anatomy of the head, by including a short practical course in local anesthesia in their curriculum. General surgery is rapidly adopting local anesthesia for a great many major operations, and it behooves the dental profession, whose special field by its very nature calls for local intervention, not to lag behind, but unhesitatingly to keep abreast of the foremost modern and efficient methods available.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

HINTS FOR READERS OF DENTAL SOCIETY PAPERS.

By FRANK W. SAGE, D.D.S., Cincinnati, Ohio.

HAVE the typist double-space your paper, so that you may more easily keep your place while reading. Many readers bend their faces forward over their paper, evidently fearful of losing the lines, thus cramping themselves so that they have no ease in speaking. Wider spacing allows one to hold the paper down and the chin up, while facing the audience, the voice thus being allowed to pass over the paper, instead of being muffled behind it.

MANAGEMENT OF THE VOICE.

The management of the voice, however, is the important thing. It often happens that the acoustic properties of the hall are poor, so that unpracticed speakers fail to reach with their voices those even forty or fifty feet distant. At the meeting of the Ohio State Dental Society, in Cincinnati, in December 1912, several readers of papers, as well as those discussing them, spoke in tones so feeble that they were heard only by those near the stage. So it often is in dental meetings.

The dentist may easily learn to expand and project his voice. A few minutes' practicing, before reading, will be found to help wonderfully. A United States senator gives the following instructions to speakers about to ascend the platform: "Stand with the weight resting easily on one leg, the other being slightly advanced, if you prefer. Fill the lungs to their utmost tension, repeatedly, until you feel exhilarated. *Work the abdominal muscles* while exercising your voice, drawing it, as it were, from the depths of the stomach," etc.

Three or four minutes thus spent before reading will help the weakest-voiced speaker surprisingly. Try it, especially the working of the abdominal muscles. Also try projecting your voice as if over an audience. Speak from the throat, not from the roof of your mouth.

A touch of catarrh often hinders the free use of the voice. Public speakers and vocalists sometimes have a rhinologist blow out the nasal passages some hours before ascending the stage. You may do this very well yourself, using some cleansing throat-wash or gargle.

Often, while waiting to be called upon to read or speak, one may, while seated, silently practice the deep breathing and the abdominal exercising. The importance of the latter is hardly to be overestimated. A brisk walk before speaking tones up the voice, especially if accompanied with deep breathing.

STAGE TIMIDITY.

Frequently the young speaker finds his voice cramped and constricted through sheer nervousness. To overcome this timidity, as soon as you mount the stage raise your eyes, and boldly and calmly look your audience over. Don't be in a hurry; glance here and there, to the limits of your audience. You may be surprised at the sudden return of confidence this gives you. You have a feeling of having mastered your audience in the start, instead of being mastered and awed by it. This is a simple, effective trick. Try it next time.

If dentists would pay more attention to the manner of presenting their thoughts to an assembly, our dental meetings would be greatly improved.

ON DISCUSSING PAPERS.

Another matter. Years ago we had more offhand discussions of papers than today. Speakers were not afraid of making "bad breaks," but went ahead, regardless of stumbling; got up after a tumble, and pushed ahead. Some of us older men think the old way the best. I would make this suggestion: Let the debater prepare his paper, then lay it aside, depending on his familiarity with the subject, through his having written it up. A few notes held in the hand should suffice to keep him on the track. If then he finds himself dissatisfied with his extemporaneous effort, he may ask the stenographer to cross off his verbatim report, and use his manuscript instead. Take this, however, from the writer, who has reported in many dental meetings: The offhand speech, if halfway good, will attract more readers in the dental journal than the written one. If not letter-perfect, the reporter who understands his job should be able to dress it up acceptably. That is what he is for, and that is what he does even for United States senators' (probably United States presidents') speeches!

It has become customary for discussors of papers to present written discussions as long as the paper itself. A second and even a third written discussion may follow, the several papers occupying often three hours' time. This dampens interest, and drives scores of wearied members out to entertain themselves examining exhibits. Moreover, happening usually on the opening day of the convention, it has a depressing effect on the later discussions. Few care to sit three hours listening to papers.

By all means let us return to the former way! Members will stay and listen to men talking offhand, because usually there is real enthusiasm such as pertains not to reading. And what they like best to hear on the floor of a dental convention, they like best to read in the dental journal.

CORRESPONDENCE.

THE N. D. A. RELIEF FUND:

An Open Letter to the Dental Profession of America.

[THE following appeal by the N. D. A. Relief Fund Committee has been received for publication, and is cordially commended to all our readers. (See Editorial in our December 1911 issue, vol. liii, p. 1450, "A Dental Benevolent Fund.")—ED. COSMOS.]

An Open Letter to the Dental Profession of America.

Dear Doctor,—Are you acquainted with the effort of the National Dental Association to establish a fund for the relief of its aged and unfortunate members?

Are you in full sympathy with that movement?

If familiar with the scheme thus far, you are aware that the first step was the endeavor during the present year to carry out the plan indorsed by the National Dental Association at Cleveland in 1911. That plan was to ask each state society to increase its annual dues one dollar per member, and set aside the sum thus obtained for the Relief Fund. The committee appointed at Cleveland endeavored to get the question before all the state societies at their last annual meetings, but, coming at the same time that we were asking them to increase their dues for the purpose of entering the National Dental Association under the reorganization, we met with much opposition.

The question was not put to a vote in a number of instances because it was feared we would hinder the reorganization movement. We were received with words of encouragement everywhere, but thus far we have only two states committed to our plan; namely, Tennessee and Colorado. Several of the other states are almost persuaded, and we hope they will vote the measure at their next meetings; therefore we shall keep up our efforts to carry out the original plan. We have been assured that this plan will not carry in some states, for various and sundry reasons, and many opposed to it have asked to be allowed to make voluntary annual contributions instead. Some few noble spirits have already set the example by sending on to the committee their first assessment. This encourages us to come to you, and we ask you to join this generous few, and agree to give annually a small sum to the Relief Fund. This is not to be something "thrown away, never to be heard of again," but it is going to create a fund to insure our members against want in sickness and old age. You may yourself become a beneficiary, or may live to see it help some dear professional friend in time of distress.

Will you, then, send us your name and the sum you are willing to contribute? or will you not save time and correspondence by inclosing your check at once for the first annual payment?

Make your check payable to H. B. McFadden of Philadelphia, treasurer of the National Dental Association. You may rest assured that the distribution of the Relief Fund will be in the hands of those who will thoroughly investigate all applications for help. Every precaution will be taken to guard the funds and utilize them for no other purpose than the relief of worthy dentists.

Will you not ask your professional friends to join you in this movement? Will you not lend us your aid and influence to get our original plan adopted by your state society? Will you not call upon the members of the profession to contribute what they can? Will you not advise us, giving names of those you call upon who feel they cannot contribute—saving us further correspondence and them future annoyance?

Fraternally yours,

L. G. Noel,
Edward S. Gaylord,
W. T. Chambers,
National Relief Committee.

Proceedings of Societies.

NATIONAL DENTAL ASSOCIATION.

Sixteenth Annual Meeting, held at Washington, D. C., September 10 to 13, 1912.

SECTION I: Prostheticic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

Chairman—WESTON A. PRICE, Cleveland, Ohio.
Vice-chairman—HARRY E. KELSEY, Baltimore, Md.
Secretary—MARCUS L. WARD, Ann Arbor, Mich.

(Continued from page 66.)

WEDNESDAY—*Afternoon Session.*

(Continued.)

The next order of business was the reading of a paper by Dr. L. S. MEDALIA, Boston, Mass., entitled "Chronic Alveolar Osteomyelitis (Pyorrhea Alveolaris—Its Causes, and Treatment with Vaccines: With a Bacteriological Study and Report of 115 Cases."

[The first portion of this paper was printed at page 24 of the January issue of the COSMOS; the second part will be found at page 150 of the present issue.]

The next paper was one by Dr. GEORGE B. HARRIS, Detroit, Mich., entitled "Pyorrhea: Its Treatment by Bacterial Vaccines and Results of Animal Experimentation," which was read following Dr. Medalia's paper, the two papers being discussed together.

Discussion of the papers of Dr. Medalia and Dr. Harris.

Dr. G. D. LAYMON, Indianapolis, Ind. I wish to congratulate the essayists upon their most excellent papers. Each of them has thoroughly covered his subject. From practical experience, I know some of the possibilities of vaccine therapy, which I have employed for almost three years in the treatment of dental diseases.

Vaccine therapy has had a great struggle, like every other great issue, but justice and right must prevail. The victory is being won, the curtain of ignorance, prejudice, narrowness, and personal selfishness is being cast aside, and the truth is being laid bare. While I believe that vaccine therapy is still in its infancy, yet sufficient proofs of its merits as a therapeutic agent have been furnished to warrant its judicious use.

Vaccine therapy is not a new mode of treatment, as the principles involved have been applied to disease for centuries. It has gradually grown with the development of bacteriology. Before the application of bacterial vaccines as a therapeutic agent in the treatment of disease, bacteriology was of little or no use to the surgeon. The procedure was just the same, regardless of the kind of organisms present. The mode of treatment was designated by symptoms, and not by bacteriological examinations.

Vaccine therapy has done more than

all else in medicine to make it an exact science. Every year the field of application broadens; its possibilities are unlimited. Pasteur said: "It is possible to eradicate every infectious disease from the face of the earth." Since the marvelous development of vaccine therapy this statement is being realized; there is much yet to learn, but the horizon is gradually being cleared of fear and ignorance.

I am certainly glad to see the dental profession entering this field of experimental medicine. Dentists have come into disrepute in the minds of many intelligent persons simply because they were able to do but little for the common diseases of the mouth, such as pyorrhea alveolaris. I believe that vaccine therapy affords us one of the most powerful weapons with which to combat this dreaded disease.

The study of nature's immunizing apparatus teaches us how to take advantage of this process and produce artificial immunity by the use of immune sera or vaccines. When an immune serum is used, we inject under the skin a highly immunized serum, which contains immune substances to aid the individual in overcoming infection. This is known as a passive artificial immunity. When a vaccine is employed, we inject beneath the skin the dead carcases of previously sterilized pathogenic bacteria suspended in a normal salt solution. The immunity thus produced is known as an active artificial immunity.

A great stride was made when an antidiphtheria serum was introduced as a therapeutic agent in the treatment of diphtheria. Investigation with immune serum in other infections has not as yet yielded satisfactory results. The attention and endeavor of investigators have therefore been turned toward the channel of active immunization. Now we possess a vaccine for a great number of infections.

At first, it was thought that a specific organism was necessary in order to combat disease by this method. Early investigations were made mostly with smallpox and tuberculosis; these diseases were treated by a specific organism, and brilliant results have been reported.

It is best to use a specific vaccine in the treatment of disease where a specific micro-organism can be demonstrated. However, there are a great many infections in which a specific organism has not been demonstrated, some of which are furunculosis, carbunculosis, abscesses, infected wounds, empyema of the chest, antrum, etc., middle-ear disease, pharyngitis, bronchitis, tonsillitis, appendicitis, white swelling, scrofula, some cases of consumption, and chronic alveolar osteomyelitis.

The principal organisms of these infections belong either to the staphylococcus or streptococcus group, and these infections may be combated successfully with an autogenous vaccine composed of these organisms. This statement is true, according to the reports of medical men.

Pyorrhea alveolaris to my mind is caused chiefly by the staphylococcus, this being the principal organism found in almost every case.

My investigations have been directed not so much toward the isolation of a specific organism in this infection, as to the employment of certain vaccines in its treatment. While I am certain that there are a great many bacteria present in pyorrhea cases, I believe that the majority of them are merely harmless saprophytes. The same pus-producing organisms are found in pyorrhea cases as you will find in suppurating lesions in other parts of the body.

The mouth is rendered immune principally by the process of phagocytosis. However, there are two other factors which are active in producing this immunity.

The normal functional activity of the mouth causes desquamation of the epithelial cells with adherent bacteria, and these are destroyed by the gastric juice. The epithelial cells of the oral cavity are constantly being replaced, this desquamation being especially active during active mastication. Although the epithelial cells do not possess phagocytic properties, nevertheless they are lined on the surface and also to a certain extent penetrated by scattered bacteria. The result is that the cells are dislodged by the saliva, and carried away to the stomach to be destroyed.

Another factor to be considered in connection with the immunity of the oral cavity to infection may be antagonism of organisms to one another, the organisms not common to the mouth succumbing to those normally present.

The experiment carried out by Miller on himself throws light on this question. He thoroughly rinsed his mouth with a bouillon culture of bacillus prodigiosus containing over 2,000,000,000 bacilli. The number of bacilli in a loop of his saliva was ascertained at the beginning of the experiment. His mouth at the end of three hours was practically free from the organisms.*

The treatment of pyorrhea by vaccine therapy does not interfere in the least with other modes of treatment. Vaccines are not a panacea for mouth infections, but, if used judiciously, they will prove to be an invaluable aid in the treatment of pyorrhea cases.

In regard to animal experimentation, I have had very little personal experience, but wish to give some reports of prominent investigators.

Geo. T. Carpenter, in a paper read before the American Medical Association, mentioned some very interesting experiments. By infecting a fresh wound in the gums of rabbits with pyorrhea and other pus, he found the parts would remain infected only from two to five days. In other rabbits, a rubber band was placed around the teeth and pressed under the gums until an inflammation resulted. When the parts were infected with pyorrhea and the pus from a chronic ulcer, a pus infection resulted. Like experiments were made in the human mouth on gums which had been neglected, as well as on healthy gums, with similar results. These experiments tend to show that, when animals and man are healthy, the tissues resist infection, but when they are diseased, infection results.

Eugene S. Talbot has carried on a number of experiments in dogs. A dog was provided from a veterinary hospital whose gums and outer alveolar process were almost entirely absorbed, with pus exudate. Forty-six street dogs were selected for inoculation. They were of all breeds and conditions; some were well fed, others very thin. No dog was used whose gums and alveolar process had become infected, or whose tissues were absorbed. Thirty-nine cases which were inoculated by pyorrhea pus healed in eight days. In these, the gum tissues were healthy. The pus had no effect, and the wounds healed as rapidly as any wounds possibly could. In seven, the gums were inflamed, and infection occurred. Suppuration was slight in four, and considerable in three.

The pathogenic findings in these cases were not unlike inflammation and infection in other tissues. All experiments point to the fact that no one organism is responsible for pyorrhea, but, as I have said before, this infection is due to the common pus-producing organisms found in other suppurative lesions of the body.

I have made a microscopical examination of a great number of pyorrhea cases. Slides were smeared with the pus taken from the pus pockets and stained with Jenner's blood stain. Cultures were made by inoculating nutrient agar-agar and glycerin agar-agar. This was accomplished in the following manner: The mouth was sprayed with a mild antiseptic. A suitable pus pocket was selected, preferably on the upper gum, because this portion is freest from saliva. The pus pockets were washed out with sterile warm water, then massaged so as to get pus from the deepest portion. With a previously sterilized platinum loop wire, a small portion of pus was obtained and smeared over the surface of the culture media previously mentioned. These cultures were incubated until a sufficient growth was obtained to be plated; isolation was then made in the ordinary way. These organisms were carefully examined culturally and microscopically. I wish to report the following results, mentioning only the pathogenic organisms: Micrococcus catarrhalis, found in ten cases; streptococcus

* Quoted from J. F. Colyer, "Dental Surgery and Pathology," page 674.

brevis, found in twenty cases; streptococcus longus, found in fifteen cases; staphylococcus aureus, found in five cases; staphylococcus albus, found in every case; pneumococcus, found in twelve cases; bacillus fusiformis, invariably present.

As you see, the bacteriology of pyorrhea is not confined to any one group of bacteria, yet my experience has been that the principal pathogenic organism present belongs to the staphylococcus family, either the albus or a modification of the aureus and albus. These organisms give a characteristic growth upon nutrient agar-agar, having the appearance of a number of small beads. The cell wall is very tough, and the clumps are very difficult to emulsify. The cultural characteristics are very much unlike the growth of staphylococcus taken from other suppurative lesions of the body. I feel that we could safely name this organism staphylococcus pyogenes pyorrhea. I have treated over one hundred and fifty cases of pyorrhea by vaccine therapy—all with autogenous vaccine. The results have been invariably positive, so much so as to warrant the use of vaccine in dentistry.

I believe that vaccine therapy is not practical for the general practitioner, but belongs to the specialist, just as much as orthodontia, extracting, or anesthesia. I am certain that results are being obtained in pyorrhea by men in our profession who are not practicing vaccine therapy, as is shown by their many reports, but surely the course of treatment of this disease can be greatly shortened, and immunity greatly prolonged, by the judicious employment of an autogenous vaccine. This treatment should, however, be administered only by a thoroughly qualified operator.

I wish to add a few remarks concerning the dangers of the improper use of vaccine. When Koch announced his discovery of the tubercle bacillus, and tuberculin was placed upon the market as a therapeutic agent to be used in the treatment of tuberculosis, a great many physicians went wild over the possibilities of this agent. Dr. X knew of a patient who was suffering from tuberculosis, and he immediately decided to give Mrs. Jones an injection of tuberculin, without knowing the dangers of its improper use. The early administration of tuberculin by ignorant and inexperienced physicians did more harm than good. The result was that the use of tuberculin came into disrepute, and its employment for a time was discarded. Its use is being revived, however, and with a broader knowledge of its application in connection with autogenous vaccines. It has been found to be best to treat such cases first with an autogenous vaccine composed of the common pus-producing organisms, thus producing an immunity against these bacteria, and then follow this treatment with tuberculin. By the employment of such methods, vaccine therapy has been given a new life.

The fear of the use of vaccine in dentistry may be attributed, I think, to a lack of training in this particular field. Vaccine therapy has been given a black-eye, owing to the same experiences which I have previously mentioned in connection with tuberculin. The proper administration of vaccines is no more to be dreaded than the use of many drugs found in our materia medica.

Incidentally I may say that there are two kinds of vaccines, stock vaccines and autogenous vaccines.

Stock vaccines are prepared and placed upon the market by certain drug manufacturers. These vaccines are composed of sterilized bacteria which have been artificially cultivated, and are kept by constant replantation and inoculation of different culture media.

Autogenous vaccines are made from the pus taken directly from each individual case to be treated.

The relative value of these vaccines is apparent. Autogenous vaccines contain the organism or organisms in their respective number and virulence. This is a decided advantage, owing to the fact that, in one case, a certain organism may cause swelling, inflammation, and purulency, while the same organism microscopically and culturally in another case may not even be noticed. In one infection the staphylococcus aureus, in another the staphylococcus albus, may be the predominating organism.

Stock vaccines do not presuppose any definite knowledge of their manufacture —anyone using them depends upon the directions printed upon the label. In my opinion, an operator would be far more competent to employ vaccine therapy if he prepared his own vaccine. There is no excuse for the employment of stock vaccines in the treatment of diseases which are met by dentists.

Dr. M. C. SMITH, Lynn, Mass. My experience with vaccines extends over a period of three and a half years, during which my results have been so uniformly successful that I am more thoroughly convinced today of the benefits to be derived from vaccines than ever before.

My experience has been a little different from that of Dr. Laymon, and the more I use vaccines the more I am in favor of stock vaccines. In my opinion we can depend on good stock vaccines made by reliable manufacturers. In some cases, however, I prefer the autogenous vaccines, when I have time to have the vaccines made without endangering the patient.

The question of the use of vaccines in dentistry seems to me a quite important one, since we have a very wide field for their application outside of pyorrhea. I would use vaccines in cases of necrosis of the facial bones, as the beneficial results are very marked. In comminuted fractures of the face or jaws, even before washing out the cavity of the mouth, I invariably administer a large dose of vaccine. I generally use stock vaccines in these cases, giving five minims of pneumococci and two of streptococci vaccines. I depend more on the pneumococci than any other. If the patient is doing well, I may wait four days, and then make another administration. Cervical adenitis is another disease in which markedly good results can be obtained with vaccines. In cases of alveolar abscess extending under the superficial fascia of the neck and discharging a very foul-smelling pus, it is surprising what one or two injections of vaccines will do in cleaning out and drying up the abscess. In all cases with a marked discharge of pus I would advise the use of vaccines. If upon examination of the urine, a large amount of sugar is found, the patient has to be deprived of the ordinary foods and placed on a strict diet. For a time such patients may get on nicely, but then have a relapse, from no apparent cause. I had a case of this kind not long ago, and after a close examination of the systemic condition of the patient, I found that he was not getting sufficient nourishment because he had been forbidden to take carbohydrate foods. As soon as he began to feel better, he began to overwork himself. The systemic condition of the patient, therefore, must be closely watched while giving vaccine treatment.

Dr. T. B. HARTZELL, Minneapolis, Minn. I am very greatly interested in Dr. Medalia's work, which I have been observing for some years by reading his results in various journals, and endeavoring to correlate his work with my experiences in my own special field.

I do not wish to discuss vaccine therapy, but will say that the estimation of the opsonic index is falling into disuse here in the United States, because it is possible to get any sort of an index, if one counts often enough. The Germans, especially, no longer depend upon it. This means that the men who first began to estimate the opsonic index in order to determine the relative value or importance of bacteria found in certain pathological conditions have given up this method, which is no longer being used to the same extent as it was two years ago, although it may be of great value.

In regard to the use of vaccines in cases of pyorrhea or other mouth infections, a search of the literature shows that there are almost as many different opinions about bacterial vaccines for oral cases as there are writers. Dr. Leary, with whom Dr. Medalia was associated for a time, in the DENTAL COSMOS for January 1910 advances the opinion that the fusiform bacillus is the organism we must oppose. Dr. Medalia recommends vaccines containing both staphylococci and diplococci, and others are experimenting with still other bacteria—which would seem to show that, if we are to depend on vaccines for the betterment of these pathological conditions, we will have to employ a good many different kinds of vaccines. The method of the injection of shotgun prescriptions of dead bacteria does not appeal to me as being rational in the average case, though I do not wish to discourage vaccine investigation. Dentists are skilful technicians, and there is doubtless not one here who is not sufficiently skilful in the surgical treatment of the roots of teeth to gain excellent results. Therefore, what is the use of treating patients with vaccines if we can obtain good results without them?

I have used stock as well as autogenous vaccines prepared by Dr. Ulrich of Minneapolis, and I must say that my successes have been fewer than my failures. If the root-treatment that Dr. Medalia referred to in his paper, and which he says should be carried out along with the vaccine treatment, were eliminated, his successes with vaccines would be fewer. Of course, from a combination of good surgical work and the use of vaccines, it is logical to expect good results. Let us use vaccine sparingly and with a certain amount of good horse sense, and only in those cases where we feel that it will be an aid to the surgical treatment.

Dr. T. Sydney Smith, Palo Alto, Cal. I am before you under unfavorable circumstances. It is the close of the day, you are very tired, and the time allotted me is not sufficient to do justice to such an important subject.

Our attitude in the past toward so-called pyorrhea alveolaris has been one of shameful neglect, and many of the methods we employed in treating it could not help being followed by failure. We have lifted the mystery which surrounded this disease, and we are now using rational, scientific methods. These not only prevent and cure pyorrhea, but also prevent at least ninety-five per cent. of cavities, so that our patients can retain their teeth to extreme old age. To emphasize this thought, I shall divide the evolution of dentistry into four eras: First, that of primitive dentistry, the removal of teeth; second, the mechanical era, the invention of artificial substitutes; third, operative dentistry, the repair of teeth, and fourth, that of today, preventive dentistry. And it is from this last viewpoint that the subject deserves most consideration.

Let us first consider the laws which govern healing, that we may apply them correctly to pyorrheal pockets. To use an illustration: If the bifurcation of two fingers were extended through the palm of the hand and the parts kept separate, each surface would heal; then, no matter how they were sterilized and bound together, they could not reunite until both surfaces were surgically freshened and held together in surgical rest.

In applying these principles of healing to pyorrheal pockets, we must first correct the teaching regarding denuded cementum. Our eminent men have believed it to be dead. Even Dr. G. V. Black* told us about a year ago that the vitality of denuded cementum must be brief. As time will not permit me to go deeply into this matter, I will simply state that it cannot die while supported by a vital pulp and dentin. This makes it imperative to keep the pulp vital if possible. We must, therefore, not only remove all deposits from the cementum, but also expose the minute living cells by light, judicious scraping. How unreasonable, then, seems the old practice of applying severe germicides, acids, and pumice, which actually kill the cell life of these newly-exposed wound surfaces. Judicious scraping leaves the fresh blood in the wound to sterilize it and to form the matrix which connects the tissues. This blood-clot method is called "healing by first intention."

This brings us to the point where we must consider the septic condition of pyorrheal pockets, and view the vaccine treatment in a proper light.

Cultures made from exudates of these pockets reveal the fact that they do not

* *Items of Interest*, June 1911.

always contain micro-organisms of the same group. We may find in the same pocket such pathogenic organisms as streptococci, staphylococci, pneumococci, besides the more harmless flora of the mouth. But we must remember that these organisms have lived for months and years in close contact with an abundant blood and lymph supply; their presence has stimulated the blood into the production of such bacteriolysins, precipitins, agglutinins, etc., as would fortify it against them. There can be no better proof of this than the fact that such pathogenic organisms as streptococci have been held in check for years. Again, if we employ this new method of surgical treatment, these pockets heal readily when left to nature's forces, showing thereby conclusively that anti-bodies are present, sufficient in kind and number to destroy the remnant of infection which our surgical work may not remove.

There is no doubt that autogenous vaccines do produce an increase of these specific anti-bodies, but in the treatment of pyorrheal pockets the tissues cannot reunite without the aid of the surgery which we have described, even if the anti-bodies were increased one hundredfold; and since, without the aid of vaccines, we find them in sufficient strength to permit a rapid healing, I ask why we should employ these vaccines.

We cannot intelligently use stock vaccines, because pyorrheal pockets do not always contain the same group of pathogenic organisms. And if we could include all organisms in any given case, such a vaccine would not be suited to their specific degree of virulence. We will understand more clearly the extreme specificity that is required of anti-bodies if we study hemolysis occurring from the infusion of the erythrocytes of one animal's blood into the veins of one of another species.

If we should take some of the normal serum of a rabbit and introduce the erythrocytes of a horse, it would have but little injurious effect upon the cells of the horse. But should we infuse some of the horse's erythrocytes into the veins of the rabbit, there would soon be a substance developed in the serum of the rabbit which would destroy the erythrocytes of the horse. The rabbit's serum would then contain an hemolysin which would quickly dissolve the hemoglobin from the stroma of the horse's erythrocytes. The specificity of this hemolysin is so pronounced that it would have no effect upon the erythrocytes of another species of animal so far removed from the horse as a dog, but it would have some effect upon the erythrocytes of the zebra or mule. This specificity is so accurate that the test would show the biological relation of these animals to the horse.

The rabbit's serum could contain several specific hemolysins at the same time, if it were stimulated by the erythrocytes of different species of animals.

This makes it very clear that if we use vaccines at all, they must be autogenous; only those prepared from the patient's own infection would be likely to include all of the organisms and to meet their particular degree of virulence. We can also see that the bactericidal agents developed within the body are beyond the power of man to imitate, and are the only bactericidal agents which do not interfere with the reconstructive properties of the blood, for they are normal to it.

Dr. Medalia (closing the discussion). I do not think it will be of any use for me to attempt to discuss in detail the statements that have been made by the various speakers. A great many of these statements would have been anticipated, had I been allowed the time to read my paper in full. The published paper will therefore explain several of the points here raised.

The fact that Dr. Laymon found staphylococcus aureus in five cases, and staphylococcus albus in all the other cases of pyorrhea does not, in my mind, justify him in considering the staphylococcus as the one and only organism responsible for pyorrhea, because we all know how harmless an organism the staphylococcus albus is, and how frequently it is present as a contaminating bacterium. Again, the fact that he obtained good results in those cases with autogenous vaccine does not mean that the results were due to the staphylococcus vaccine only, since he told me that he did not isolate the staphylococcus in making up the autogenous vaccine, but made use of all the bacteria found in the cultures.

In reply to Dr. Hartzell, if I had time to read my paper to the end, I would have said, so far as the opsonic index is concerned, that owing to the difficulties encountered in making this test it had to be abandoned as a test for clinical purposes. It is used, however, as an index of immunity in laboratory work on animals. The results obtained with vaccine treatment in bacterial infections is recognized today to be entirely independent of the opsonic index. With regard to his claim that the vaccine treatment is not feasible because of the difference of opinion among bacteriologists as to the real causative bacterial agent of this disease, I will simply say that, if Dr. Hartzell were more familiar with vaccine treatment and the preparation of vaccines, he would know that it makes little difference whether certain bacteria found culturally in this disease are called by one man a streptococcus and by another a pneumococcus in chains, since the autogenous vaccines used include whatever organisms are found culturally. Call them what you may, the name will not alter the contents of the vaccine nor its results.

With regard to the fusiform bacillus and the spirochæta dentium mentioned by Dr. Hartzell: The latter is an organism cultivated under great difficulties, and has been ignored by almost all investigators. The successful results obtained with vaccines not containing this organism is, in my mind, another criterion showing that the spirochæta dentium is not a causative factor in this disease.

The whole subject sums itself up in the simple question whether dentists, "who are pre-eminently technicians," as Dr. Hartzell says, are willing to remain tooth artizans and mechanics, or whether they wish to be dental surgeons and dental physicians. If they would be dental surgeons and physicians, they must do everything for the patient that will help him, and not limit themselves to mechanical treatment.

Dr. Hartzell says that he has treated successfully this disease by local measures alone. If that is the case, why, pray, is pyorrhea the "bugbear" of the dental profession? I would like to ask Dr. Hartzell to make a record of every case and follow it to a successful issue, and then present the results before us. If he already has such records, I could not discover them in the articles published by him.

In answer to the point raised by Dr. M. C. Smith with regard to the use of stock vaccine, I will say that I found the autogenous vaccine mixed with stock vaccine to yield the better results. Stock vaccines have to be used in incipient cases where there is no pus present and the cultures are found sterile. The stock vaccine, however, should be made up from bacteria isolated from cases suffering with alveolar osteomyelitis—pyorrhea—if good results are to be obtained, and not merely from cultures obtained indiscriminately from any source. Autogenous vaccine is preferred by all other investigators.

For a more explicit and comprehensive explanation to all the questions raised by the various men who took part in the discussion I shall have to refer you to my paper, which will be published *in toto*.

The chairman appointed the following committee on the question of the study of amalgams, pursuant to the motion made by Dr. Lundy at a previous session: Dr. T. P. Hinman, Dr. W. A. Price, and Dr. C. M. McCauley.

There being no further business before the section, Dr. Price, the chairman, declared Section I adjourned *sine die*.

(To be continued.)

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held October 22, 1912.

The regular monthly meeting of the Academy of Stomatology of Philadelphia was called to order by the president, Dr. Otto E. Inglis, in the lecture hall of the College of Physicians and Surgeons, Tuesday evening, October 22, 1912, at 8.30 o'clock.

After the transaction of some routine business, the President announced as the first paper for the evening that by Dr. R. H. Riethmüller, Philadelphia, entitled "Local Anesthesia in Dentistry, with Special Consideration of Novocain."

[This paper is printed in full at page 169 of the present issue of the Cosmos.]

The President announced that, as the next paper was also on the subject of anesthesia, it would be now read, and the two papers would be discussed together—the next paper being one by Dr. T. D. Casto, Philadelphia, entitled "Accessories of Nitrous Oxid and Oxygen."

[This paper is printed in full at page 166 of the present issue of the Cosmos.]

After the reading of the papers, Dr. E. R. Sausser gave a practical demonstration of the use of novocain, and explained in detail the technique to be followed in the injection of this anesthetic. Dr. A. E. Bassett also gave a practical demonstration of the method of producing analgesia by means of nitrous oxid and oxygen, in a patient with extremely sensitive dentin. The demonstration proved very successful, and while the patient was under the influence of the anesthetic, cavities in two teeth were excavated.

Discussion.

Dr. Edward C. Kirk. I think pretty nearly everything has been said that should be said in discussion of the subject, but while listening to these papers, particularly that regarding the phase of anesthesia now called analgesia, my mind has gone back a number of years to a period when on one occasion a young man, a clerk in a pharmacy in our neighborhood, came into the office of my stepfather—who was a surgeon—and asked if something could be done for a felon on his finger. After looking at his finger the surgeon said there was only one thing to do, and that was to lance it thoroughly. The young man replied that he could not stand that, but something had to be done. Whereupon the surgeon said: "If you will follow my directions, I can give you ether in such a way that it will not destroy consciousness but you will not feel the pain from the operation." He then directed the young man to inhale small quantities of ether, and then told him to test for himself the reaction to the irritation of rubbing his fingers together until the sensation had gone from his finger. After tapping his finger on the table for a few moments with increasing vigor, he said, "I do not feel it very much now, so I guess you can cut it," and then turned his hand over to the surgeon, who made an incision to the bone and immediately asked the boy if it hurt him. He answered, "No, it did not hurt, but I heard it crack." He had heard the peculiar sound that cutting of the flesh under these conditions makes, and the patient's condition I suppose was what is now called analgesia. I have seen ether administered in many cases in that way, and it is possible with any anesthetic. The question of the anesthetic zone in nitrous oxid administration has long been generally recognized. Dr. J. D.

Thomas published a paper on that point in the DENTAL COSMOS.*

There are some things that are new about the subject, or rather they are being brought more definitely to our attention; first, the general recognition being accorded to the scientific fact that the condition of peripheral anesthesia can be practically utilized, and the other, the perfection of the technique for achieving this very valuable stage of anesthesia. It is not analgesia, but peripheral anesthesia without loss of consciousness. The recognition of the availability of that phase of anesthesia for such practical work as we are doing in dentistry is a very interesting aspect of the matter, and there is no reason why there should not be, with improved technique, an extension of this blessing of anesthesia for the mitigation of the type of human suffering we have been causing by our dental operations, and in the enduring of which we have produced a tremendous wear and tear on the nervous systems of our patients, simply because we have not availed ourselves of this possibility that we can now utilize without difficulty.

Dr. J. D. THOMAS. Unquestionably, as Dr. Kirk says, the analgesic condition produced by nitrous oxid and oxygen has been known for a long time. We have recognized it, I know, in our practice. We establish a certain stage of analgesia or peripheral anesthesia, so that a knife can be drawn across the patient's hand without his feeling it, as in the case described by Dr. Kirk. The first effect of nitrous oxid anesthesia is peripheral paralysis, while cerebral paralysis occurs last. Vision and hearing are the last senses that are paralyzed in the progress of progressive anesthesia, consequently, before the stage of unconsciousness arrives, a numbness can be observed in the peripheral nerve-endings all over the body, and yet the patient is conscious enough to know what is going on. This is an effect that can be readily utilized, and should become a matter of great value in dentistry in various ways.

The principal drawback in nitrous oxid anesthesia is the accompanying asphyxia. I think in years past we have been asphyxiating the patients, and many of them were no doubt operated on under conditions of asphyxia. Some patients are asphyxiated more readily than they are anesthetized. I remember the first major operation which to my knowledge was performed with nitrous oxid. It was an operation performed at the Pennsylvania Hospital by Dr. Morton, who amputated a leg at the thigh. I administered the anesthetic, and the patient was kept under it for twelve minutes. In this case ether was very much contra-indicated, and Dr. Morton was asked to try nitrous oxid. In the first stages of the administration, there was a rapid approach to asphyxia, so I simply raised the facepiece, and allowed the patient to get a little air, which relieved the condition. The patient recovered consciousness a couple of minutes after the administration. That was the first recogniton of the ideal condition of nitrous oxid anesthesia. After that it became more or less general to obtain relief from asphyxial condition by raising the mouthpiece and allowing air to get in. In this way a perfectly good color can be maintained during the anesthesia, which is a very important feature in prolonged operations where profound anesthesia is desirable. In an operation, however, such as has been shown us tonight, in which profound anesthesia is not necessary, there is no reason why a condition of peripheral anesthesia should not be kept up indefinitely, if regulated properly, without carrying the patient to profound anesthesia. I see no objection to this method of procedure; in fact, I think, it will prove of great benefit to the patient as well as to the dentist in excavating sensitive dentin and extirpating pulps.

Dr. W. A. BORDEN. I am very much pleased to have seen this demonstration tonight. I have been using oxygen in combination with gas in operations for five years, and I have derived

* See COSMOS for June 1893, vol. xxxv, p. 442.

great benefit therefrom. I began using nitrous oxid in 1886. The first person I ever saw administer gas was Dr. Darby, in a clinic given at the University of Pennsylvania, and the patient happened to be a classmate of mine—now Professor Goodspeed, of the University of Pennsylvania. Dr Darby extracted several teeth for him, which would have been a painful operation without the use of an anesthetic. Knowing Goodspeed very well, I questioned him about the operation afterward, and he said that he did not feel anything at all, but was having a fine time. I was graduated soon after that, and began making a specialty of extracting with nitrous oxid, at Columbia, Pa., after Dr. Darby's example, viz, giving it without the admission of atmospheric air. The benefit of atmospheric air was not thought of at that time, the object being to keep the air out as much as possible. After a while, operators began to allow the patient to inhale a little air, and they obtained about the same results as with oxygen, except in the case of certain people—as those with deficiency in quantity or quality of the blood, anemic persons, alcoholics and persons addicted to smoking cigarets to excess—as they would become asphyxiated before they were anesthetized. With oxygen, however, we do away with that effect, and produce anesthesia more effectively.

I have a gasometer to furnish the pressure, and by keeping the temperature of the room at seventy degrees, I always have an even temperature of the oxygen and nitrous oxid, and get about the same result as we have seen here. The nosepiece and the mouthpiece I use are different from that which has been shown here, which I think is an improvement over mine. If I were using the analgesia method with every patient, I would use the apparatus shown. For my purposes, viz, extracting, I should not like to have an apparatus of this kind in view (I believe the seeing it would make timid patients more nervous), and inasmuch as I do not use nitrous oxid and oxygen in all cases, and for prolonged anesthesia only in special cases. I think the method shown tonight is a great benefit to patients who have extremely sensitive cavities to be excavated, and who need to have pulps extracted without pain.

Dr. J. H. Gaskill. I do not wish to discuss the papers particularly, but I have one or two questions to ask.

The earlier writers who used nitrous oxid speak of the possibility of kidney troubles following the administration of nitrous oxid, and Dr. Casto spoke of a case in which there was an increase of albumin after its use. I would like to ask if he can state whether or not it was caused by the nitrous oxid, or whether it was a coincidence. I have not seen any further reports on this subject, and I have been wondering whether or not, by keeping the patient under the influence of nitrous oxid for such a length of time as has been demonstrated, the effect which some of the earlier writers spoke of as following the use of nitrous oxid and oxygen would be produced.

I would also like to ask if, by bringing novocain in contact with the pericementum, there is danger of causing necrosis by interference with the normal conditions in the region of the bone.

Dr. Kirk. We have used novocain in the dental clinic at the University of Pennsylvania quite extensively, and it has come to us through two sources; first, the insistence of Dr. Prinz upon its use as an anesthetic, and the large number of students who come to us from Europe and have been quite accustomed to use novocain in the hospitals in Europe, have insisted upon using it in our clinic in preference to cocain. Our experience with it bears out the reports of Dr. Riethmüller on the European experience with it. The very diminished toxicity of novocain as compared with that of cocain is probably true—at least we have found it to be true in our experience; the features, too, of no aftereffects and the facility with which it can be sterilized by heat—all are definitely in its favor. While it is not as rapid in its anesthetic effect as cocain, if given a little time it will produce an anesthesia quite as profound and lasting or a little more so than cocain. We have come to regard it as a very great step in advance in the means for producing local anesthesia.

The question which Dr. Gaskill raised as to whether there is danger of necrosis is an important one. I do not apprehend on general principles that there would be any danger of producing necrosis of bony tissue with sloughing of the soft tissues by injections of novocain, providing the operation is done aseptically. That is to say, the toxicity of the drug is relatively so slight that I do not apprehend any serious necrotic effect from the poisonous character of the drug itself, and by using isotomic solutions any danger from the difference in specific gravity is eliminated. Statistics of operations thus far done, which cover now a record of half a million cases, as Dr. Riethmüller has cited, seem to indicate that we have in novocain a safe and reliable means of producing local anesthesia, and one which very certainly eliminates a number of the disadvantages of local anesthesia with cocain, especially the very great uncertainty as to what is the minimum safe physiological dose of cocain. We know the idiosyncratic relation of people to that drug, and that many will be almost alarmingly affected by a fair average dose. I do not mean psychologically alone, but that a definite physiological disturbance is produced in the circulation of such patients by even a minute dose of cocain, and that tricky quality does not seem to attach itself to novocain.

Dr. Gaskill. What prompted my question was a practical case which proved that the evidence of necrosis is sometimes slow in showing itself. This was a case in which the pulp of a right central incisor had been extirpated some twelve years previously, and the tooth crowned. A few weeks ago the patient presented complaining of pain in the region of the incisors. I applied all the well-known tests to the left central, in which there was a vital pulp, and I received no response from it other than normal. I tried local treatment, but could give the patient no relief. Finally I suspected pulp nodules, and extirpated the pulp of the left incisor under pressure anesthesia, without affording relief. I dismissed the patient, thinking that in the course of two or three days the pain would disappear, although there was some swelling about the tooth; but she failed to get relief. When I finally extracted the tooth, pus issued from the alveolus. I requested the patient to return in two or three days, thinking she would have relief, but on presentation she reported that there had been continual pain. I then used an explorer and found that a small spiculum of necrosed bone was being thrown off, and which undoubtedly came from the apical region of the right central incisor, on which a crown had been for twelve years, while the root of this tooth was apparently as solid as it ever had been.

Dr. Riethmüller (closing the discussion of his paper). There is very little danger from necrosis if, as Fischer has clearly pointed out, absolute asepsis is observed. I have only recently read a report by Professor Williger of Berlin on six cases of infection, in which novocain had been used carelessly in a public dental clinic by young operators. These cases were, however, immediately diagnosed by the X ray, and treated in time to prevent any really serious necrotic conditions.

In regard to the price of novocain, I have been informed by the director of a municipal public dental clinic of one of our largest cities that the annual item for nitrous oxid and oxygen has been very considerable, while if novocain had been used instead, the expense would be almost negligible, and not only as good but better results would be obtained, because nitrous oxid and oxygen analgesia, though it is suitable for the excavating of sensitive dentin, cannot be employed for the extirpation of dental pulps, as some of the gentlemen who discussed Dr. Casto's paper seem to believe. The nitrous oxid and oxygen analgesia is not sufficiently deep for this more radical operation, and the operator, if he wishes to employ nitrous oxid and oxygen for pulp extirpation has to produce general anesthesia, which, as I have said, in every case, no matter what anesthetic is used, means a general intoxication of the central nervous system. This, of course, can be overcome by patients enjoying full health, but, for practical and pathological reasons, I think the results obtained with novocain all over Europe and in the South American and English colonial countries, where local anesthesia seems to have been appreciated a great deal more, and where local anesthetics have been used for years, not only in the form of novocain but cocain, are more favorable. Whether this is due to greater care in sterilizing, or to racial and climatic conditions, I cannot say, but these factors have no doubt something to do with the uniformly favorable results obtained in local anesthesia by our foreign *confrères*. There is no doubt in my mind that racial and climatic conditions have to be reckoned with in the administration of both local and general anesthetics, because, as you know, it is certainly safer in Europe to administer chloroform than it is in this country, and to this day a great many minor operations are performed there under chloroform.

For practical reasons, novocain should at least be given a fair test by every operator, and he will find that he will save a great deal of time, expense, and anxiety, and incidentally will improve the esthetic appearance of his office. Bulky tanks, in my opinion, do not look confidence-inspiring to patients, and the noises produced by the escaping gases and the inhaler are not conducive to a nervous person's mental comfort. Give local anesthesia with novocain-suprarenin a fair trial, and it will be interesting to hear your reports of the results obtained.

Dr. HUGGINS. I have been requested to ask the difference in technique in the use of novocain and cocain in pressure anesthesia?

Dr. RIETHMÜLLER. The technique with novocain is practically the same as that in pressure anesthesia with cocain. For this purpose it is not necessary to have the novocain tablets combined with suprarenin or adrenalin. Pure novocain can be obtained in tablet form, and works as well as cocain, though perhaps not so rapidly, as Dr. Kirk has suggested. On the other hand, if you wish to make an immediate root-canal filling as practiced in Europe and often condemned in America, the astringent action of the suprarenin is useful; there is no hemorrhage, and no pericemental irritation, as is so frequently observed after pressure anesthesia with cocain.

In regard to the injection method, I would say that for terminal anesthesia of a small number of teeth anyone familiar with the injection of cocain can certainly be successful with novocain anesthesia, and he will always be on the safe side.

Dr. CASTO (closing the discussion of his paper). The paper which I read was a *résumé* of the accessories I consider necessary in nitrous oxid and oxygen analgesia and anesthesia. A great deal has been written in the last three years by surgeons and anesthetists of this country regarding the great benefits accruing from the use of nitrous oxid and oxygen as a general anesthetic. Operations lasting from thirty minutes to two hours and even longer have been performed under this anesthetic. Many men are conducting researches and tests concerning albuminuria, acidosis, the effect on blood pressure, the problem of rebreathing, etc., and a review of all of their practices and observations would surely prove to be interesting, although each man comes to a different conclusion. It is for this reason that I appeal to you tonight. If there are twenty men in Philadelphia interested in this practice, they should perfect it to the utmost, and determine the principles governing it. If albuminuria can possibly result from this method of anesthesia, and there are people laboring under the effects of it, we should know it. No one man can find that out. I have now a case of this kind under observation, but how many days may pass before I find another such case! If we had twenty men who could make observations on fifteen or twenty cases during a year, and report on them, we could reach valuable conclusions.

I am not here to compare the value of this method with that of other methods. That question is for the individual operator to consider. Dr. Gatch, in a review of the fatalities due to this anesthetic, reports only one fatal case in fifty thousand administrations, which shows that nitrous oxid and oxygen anesthesia must be comparatively safe. I appeal to those interested to labor together with me earnestly in this field of research, so that we may present useful results to our *confrères* in a not far distant future.

Motion was made and carried to extend a rising vote of thanks to the essayists for their interesting papers.

Motion was made and carried to adjourn until the next regular monthly meeting.

"F. D. I."

INTERNATIONAL DENTAL FEDERATION.

Summary of the Proceedings at the Annual Meeting held at Stockholm, August 28 and 29, 1912.

[Report furnished to the Dental Cosmos per courtesy of the *British Dental Journal.*]

(Continued from page 97.)

Executive Council.

Wednesday Afternoon.

(Continued.)

The Miller Prize.

The Council then considered the question of the award of the Miller Memorial prize, the President announcing that he was prepared to receive nominations of candidates.

Dr. Brophy said that when in Dresden the previous week he was visited by Dr. Jenkins, who asked him to present to the Council some books and papers on behalf of the candidature of Professor Carl Röse. He consented to do so, and one of his chief reasons was that when the last award was made to Dr. G. V. Black, the name of Dr. Röse received the second highest number of votes. He presented to the Council six volumes and a list of ninety-three publications representing the labors of Dr. Röse for the profession.

Dr. Aguilar seconded the nomination of Dr. Röse.

M. Roy said he was requested by the Fédération Dentaire Nationale of France to submit the candidature of their *confrère,* Dr. Godon.

Dr. Rosenthal seconded the nomination of Dr. Godon.

The President announced that he had received two other suggestions for the prize, but as the names were not proposed at the meeting, they would not be voted upon.

Dr. Brophy asked whether as a jury they were limited under the rules of the award to a candidate's literary and scientific contributions to dentistry.

The President said that the Executive Council was in no way limited, and, acting as a jury, would award the prize to the person who, in the terms of Article 2 (e), 3, "had rendered the most eminent services to dentistry."

A vote by ballot was then taken, and resulted in favor of Dr. Godon. On a show of hands the Council then made the vote unanimous, and amid applause the President declared the honor to have fallen to Dr. Godon.

M. Roy returned thanks for Dr. Godon, and said that France would be touched by the honor paid by the F. D. I. to one of its most eminent dental surgeons.

Dr. Aguilar presented the report of the "International Miller Prize Fund" Committee, and also the accounts, as follows:

Gentlemen,—Your Secretary begs to report as follows: At the presentation of my last report to you on August 1, 1911, the capital of the "International Miller Prize Fund" was represented by 49,626 francs. Since then we have received as new subscriptions from the United States 11,200 francs, collected by the American Committee through the initiative of our *confrère,* Dr. Brophy, who brought this sum to our last meeting in a cheque for £448 2s. 10d. Besides this sum the fund has received, as you will see by the appended balance sheet, from interest on its stocks, some 2389 francs, which brings the actual capital of the Miller Prize Fund to nearly 63,000 francs.

As decided at the last meeting of the board, and after previously taking the advice of two bankers, in the month of September last, 25,000 francs of the cash at the bank was invested in the purchase of Argentine bonds 6 per cent. Cédulas Hipotecarias, a safe stock that pays a good interest. Considering that we have still some 18,000 francs in current account at the bank without drawing interest, I would call your attention to the advisability of investing that sum in some securities, and would suggest the convenience of purchasing Japanese State 4½ per cent. bonds, or some other stock that would return 4 or 4½ per cent. interest.

This committee at the present meeting should also decide as to what sum of money shall be given in cash to the recipient of the Miller prize that is to be awarded this year, which sum, together with the expenses of the diploma and medal to Dr. G. V. Black for last year, should be deducted from our account of capital.

Your Treasurer's account for the last year—August 1, 1911, to August 1, 1912—is as follows:

Treasurer's Account—International "Miller Prize" Fund.

Dr.		*Fr.*	*Cr.*	*Fr.*
April 1.	Cash in Current Account at the Deutsche Bank, Mks. 22,334,50	27,917,50	Purchase of $11,000 nominal value of 6% Argentine State Cédulas Hipotecarias	24,466,40
" 1.	Cash in hand	2,546,28	To the Deutsche Bank, for safe keeping of Bonds	7,25
" 2.	Received from Dr. T. W. Brophy from subscriptions collected in the United States, a check for £448 2s. 10d.	11,200,00	Cash at the Deutsche Bank in Marks, 4,239,95	5.300,03
	Credited by the Deutsche Bank, Berlin, for collection of coupons of German State Bonds and Argentine Cédulas Hipotecarias, dates from November 14th to June 24th (Mks. 1,911,25)	2,389,78	Cash at the Deutsche Bank in Francs	14,279,88
	Fr.	44.053.56	Fr.	44,053,56

INVENTORY OF CAPITAL—INTERNATIONAL "MILLER PRIZE" FUND.

Our account of Capital at the Bank is as follows:

1912.		Fr.
August 1.	Value of 15,000 Marks nominal of German State 4% Bonds	19,162,50
	Value of $11,000 pesos nominal Argentine State—Cédulas Hipotecarias	24,216,40
	Deposited in Current Account in Marks, 4,239,95	5,300,05
	" " " " " Francs	14,279,88
	Fr.	62,958,83

FLORESTAN AGUILAR, *Hon. Secretary.*

The meeting of the Miller Prize Fund Trustees took place August 28th. Present, Dr. Brophy and Dr. Aguilar.

The minutes of the previous meeting were read and approved, and letters of Drs. Weiser, Godon, and Mummery were read, regretting their non-participation, owing to their inability to come to Stockholm.

The following business was transacted:

(1) The Secretary read the report published above.

(2) The report was accepted.

(3) It was decided that the remaining sum of money standing in current account at the bank be invested in some reliable state securities, preferably in U. S. A. bonds.

(4) It was decided that in consideration of the expenses involved in preparing and producing the first "Miller medal," awarded to Dr. Black in 1910, expenses which amount to about 5000 francs, this Board of Trustees will place at the disposal of the Executive Council of the F. D. I. the sum of 1500 francs for the expenses and medal of the Miller prize for 1912.

(5) After careful consideration it was decided that in conformity with the wishes expressed by different members of the F. D. I. at the meetings of 1910, 1911, and 1912, this Board of Trustees advises an alteration of the present regulations for the awarding of the Miller prize in the sense that the standing order to be added shall comprise the following points:

(*a*) That nominations of candidates for the prize may be made by any member of the F. D. I. or by any dental institution, society, university, or corporation invited to do so.

(*b*) That the nominations of candidates shall be presented in writing, stating the merits of the candidate and accompanied by copies of the books or writings of the candidate in any of the official languages of the Federation.

(*c*) That nominations are to be presented before January 1st, in the year of the award in the following August.

(*d*) That notice of the awarding of the prize and invitations to present nominations be sent to all members of the F. D. I. and to any professors, associations, universities, or corporations that the Council may approve.

FLORESTAN AGUILAR, *Sec'y,*
Internat. Miller Fund Committee.

Dr. SCHAEFFER-STUCKERT proposed that a duplicate of the Miller prize medal in bronze be provided for the new Dental Institute in Berlin, to be opened in October 1912.

Dr. AGUILAR suggested that a duplicate also be sent to the T. W. Evans Institute, to be opened in Philadelphia in October 1913.

Dr. BROPHY seconded both propositions, which were carried.

Dr. BROPHY, as a supplementary report, stated that America had not finished its contributions to the Miller Fund. Further, Dr. Reid, editor of the *Dental Journal* of Toronto, was getting the co-operation of Canadians, and he (Dr. Brophy) heard that they had raised over 1000 dollars, which would soon be forwarded to the Treasurer. As to the award of the prize, he regretted his misconception as to the rules. Dr. Godon was one of the best friends he had in the world, and though he (Dr. Brophy) had proposed another candidate, he was in no sense opposed to Dr. Godon's candidature. Indeed, he was in full accord with the decision, and he congratulated Dr. Godon, and also the F. D. I. on recognizing the eminent services of a great Frenchman.

The PRESIDENT thanked Dr. Brophy for his efforts in adding to the capital of the Miller Prize Fund, and stated that he would telegraph to Dr. Godon the Council's decision.

The session then concluded.

Hygiene Commission.

This Commission met on Thursday morning, August 29th.

The President (Prof. E. JESSEN), delivered the following address:

President's Address.

I heartily welcome you in the name of the Commission, in the hope that the session in Stockholm may bring success to our endeavors and lead us nearer to our aims. Our secretary, Mr. Lenhardtson, will give you full particulars of the activity of our national committees during the last year, and what has been attained. I have been charged by the Managing Committee to lay before you suggestions for approval, and to make some proposals.

The International Commission for Mouth Hygiene, with a general board of directors, is composed of committees from twenty different countries, whose names appear in section 4, pages 3 to 5, of the *Internationalen Archiv für Mundhygiene.* The commission is under the protection of his Majesty King Gustaf V of Sweden, and since its reorganization at the International Dental Congress in Berlin, 1909, through its national committees it has established a National Association for Mouth Hygiene in the following countries: Denmark, Sweden, Finland, Norway, Holland, Belgium, France, Switzerland, Italy, Austria, and Russia, as reported in the four numbers of the *Archiv.*

The German Central Committee for the care of teeth in the schools was formed in Berlin in 1909, independent of the International Hygiene Commission. Up to the present, through its efforts and the assistance of the preparatory work which had been done by the German dentists, 120 dental clinics have been established for the public schools in Germany. The governments of several countries take the greatest interest in these efforts to benefit the rising generation.

The greater the number of those who devote themselves to striving for the public welfare, the more successful will be our work. I therefore ask you to obtain still more new members, pointing out at the same time that, according to our statutes, we are not only able but we are under obligation to receive men and women of any profession who are interested in our cause—as thereby our commission will be enlarged, and, more and more extended, will continue to win new countries for the sphere of its endeavors, and be enabled to set before itself higher and higher aims. To its aims I desire to refer briefly.

All know that we want to spread among the people the knowledge of the importance of a sound and healthy mouth. We want to popularize dental hygiene by introducing it into all schools, the army, the navy, hospitals, and infirmaries, and by providing dental assistance for all those families which are in urgent need of such help, but are not in a position to pay for it.

It is to the interest of all governments and municipal administrations to advance such efforts even for purely material reasons; for, as I have had already the honor of stating to you in the opening session, great pecuniary gains are made in the national wealth by the systematic introduction of dental hygiene.

It is true that we have started successfully on the way toward a systematic introduction of dental hygiene, but we are still very far from the ultimate object. The influence of our commission is still relatively inconsiderable. We are not yet independent enough in a pecuniary sense to give to our exertions that weight which is necessary for the assertion of our claims within a sphere of action which extends over all the civilized world. To that end we are not only in need of sympathy, but more so of material help, as much on the part of political and municipal administrations as on that of rich philanthropists.

We need money to procure dental assistance and means for dental hygiene free of cost to the poor in all countries, to establish dental surgeries for school children everywhere, and to lend them expert and material help. For such a far-extending scheme, a central station is needed from which the work could be systematically conducted in all countries. Some philanthropic institution might enable us, here in Stockholm, our high Protector's capital city, to erect a building in which would be performed everything within the department of dental hygiene, and the results of which would then have to be carried out in general practice.

We are yet very far from achieving all these final aims, but if we look back upon the long distance we have already covered, it will be seen that we have pushed ahead in spite of everything, and then the conviction will grow in us that we shall continue to progress.

Secretary's Report.

Mr. ALBIN LENHARDTSON presented his report on the progress of public dental hygiene during the past year. He said that since the last meeting in London in 1911, the dental hygiene movement had taken more definite forms in several of the countries represented in the Hygiene Commission of the F. D. I. The number of new school dental clinics had increased, though perhaps not in the same proportion as during the previous period. The most important thing, however, was that the value of mouth hygiene for the nation was being increasingly recognized by public authorities, from the highest to the lowest. He thought it was perhaps advisable not to "force the pace" too much before they were able to obtain the requisite data from practical experience of working these clinics. Several difficulties had already appeared. In some countries, for instance, the municipal authorities had not given sufficient consideration to the question of salary; in other countries, unsuitable methods of treatment were adopted. "In Sweden we have tried to deal with the problem in a radical way. The Swedish National Association for the Promotion of Mouth Hygiene, and the Swedish Dental Federation, have applied to his Majesty for the nomination of experts to consider the best method of regulating the public dental service. This is the most noteworthy proposal yet made in any country, and the Swedish press have strongly supported it. The only objection has been made, strangely enough, by the Royal Board of Medicine. However, according to the latest information, there is every prospect that the government will appoint such a royal commission in the autumn; a more striking testimony as to what a strong position we have already gained in Sweden cannot be found."

As to progress in other countries he could not give a complete account, because he had received reports from only about ten countries represented in the Hygiene Commission.

In Germany there are now about 120 school clinics. In Bavaria an association for the promotion of dental hygiene in schools has been started, chiefly owing to the energetic work of Professor Walkhoff, who has educated public opinion by pamphlets and papers.

In the United States of America, efforts have been mainly concentrated upon the education of the public. The interest manifested by life insurance companies in mouth hygiene is also of importance. Professor Wallin published the results of his careful examination of the Marion school children, proving that children are seriously retarded in school work by dental disease and unclean mouths.

In Great Britain, steady progress is being made. Some large towns like Bradford, Norwich, Cambridge, and Sheffield have whole-time school dentists; other local authorities appoint dentists for part-time service, the fee for this being £1 per half-day of about three hours. (In Sweden, the Swedish Dental Federation has fixed a normal salary of 5s. 6d. per hour.) London has now seven school dental clinics in operation. In some rural districts, dental clinics are started by private generosity. The Birmingham Education Committee recently decided to appoint five dental surgeons for their scheme of school dental treatment. In his annual report, Sir George Newman (chief medical officer to the Board of Education) put great stress upon preventive dentistry. He laid down four general principles which should govern school dentistry in England, as follows: (1) All arrangements for each area should be under the supervision of the school medical officer, as the school dentist should be definitely and organically connected with the school medical service; (2) The inspection and selection of all cases should be carried out by the school dentist himself; (3) Conservative dentistry, both for inspection and treatment, should concentrate on a definite age period, namely, six to eight years; (4) Dental treatment should always be followed up by regular re-examination, and, if necessary, renewed treatment. It is gratifying to note that school dentistry has the sympathy of the medical authorities of the Board of Education in England.

Mr. Lenhardtson, referring to New Zealand, drew attention to Professor Pickerill's valuable book on the "Prevention of Dental Caries and Oral Sepsis," this being the Cartwright prize essay of the Royal College of Surgeons of England. A chapter in it was devoted to Public Dental Hygiene, and gave an able presentation of the subject. In Australia, the government of Queensland has already appointed a dental inspector for state schools, and intends to appoint two more.

Full information would be given by Dr. Gabriel Wolf, secretary of the Austrian Association for School Dentistry (which has received grants of £126 from the Vienna municipality, and £84 from the state), in his paper dealing with progress in Austria. Dr. Zilz had written a scientific work on "Tuberculosis and the Oral Cavity."

Dr. Bon, secretary of the Belgian Association, reported that the mouth hygiene movement was being organized.

In Denmark, King Christian has given his patronage to the Danish Association, which publishes a journal. School clinics are established in three towns, and systematic examination and treatment has been introduced in two educational institutions.

In Finland, the political situation handicapped the movement. The Finnish Association, however, was working chiefly in educating the people.

The French National Committee is engaged in organization, and aims at obtaining semestral examinations of school children's teeth.

In Holland, the Dutch Society is devoting attention to propaganda work for establishing school dental clinics.

In Italy, our colleague Dr. Guerini has done admirable work. Besides writing in the daily press with his well-known enthusiasm, he read an excellent paper before the International Anti-Tuberculosis Congress in Rome (April 1912), on "The Importance of Oral Hygiene in Combating Tuberculosis," which has been reproduced in over a hundred papers. School dentistry has been introduced in Rome, Milan, Genoa, and Turin, the latter town having one clinic for each of five districts.

The Norwegian Association has received contributions of 1000 kroner from the state and 500 from the Christiania municipality. The sums are not large, but they indicate official approval of our aims. A good idea of this association is to enter municipalities as members; in this way their interest in dental hygiene is maintained. A school dental clinic has been established in Bergen, a town of 75,000 inhabitants, which has made an annual grant of 17,000 kroner. Norway has six dental clinics in towns, and one in the rural district.

From Switzerland a report has been received as to the school dental clinic in Lucerne.

The Swedish Association has constituted three provincial branches, with the governors as presidents. Application has been made to the government for a grant toward publishing a popular pamphlet of 100,000 circulation. In eight or ten towns, schemes are in hand for starting school clinics. Sweden, with five and a half millions of people, has now twenty-five school clinics. The association proposes to publish a journal of its own in the autumn. The royal commission already mentioned will probably begin its work this autumn and will consider the regulation of the dental service in relation to schools, the army, hospitals, sanatoria, asylums, and prisons; state railway, post-office and customs services; government grant for public lectures in dental hygiene; appointment of a dental surgeon to the Royal Board of Medicine and the army medical administration. Eventually it is hoped to obtain a government subvention for studying the etiology of dental caries, but this is perhaps too theoretical a question to be pressed at present.

Mr. Lenhardtson announced that Dr. Steffen (of Cuxhaven), who had promised to read a paper on "Care of the Teeth of Soldiers and Sailors," was unable to be present.

The President read the following cablegram from Dr. Williams Donnally (Washington, U. S. A.): "Please greet Federation, and announce new law providing sixty commissioned naval dental officers with status and compensation identical with first-grade medical officers. The present authorized annual compensation of American army and navy dental surgeons approximates half a million dollars."

A letter was read from Dr. Jenkins (Dresden), who regretted he could not attend, and thanked the Hygiene Commission for electing him as honorary president. He added: "Please accept congratulations upon the progress already made and express my steadfast conviction that the Hygiene Commission of the F. D. I. is destined to be one of the most efficient factors in the great modern movement for the physical regeneration of the world."

The Russian National Committee, through its Moscow representative, sent greetings, and stated that they would do everything possible to promote the dental hygiene movement in Russia.

M. Decker, of Luxemburg, also wrote stating that he could not attend.

M. Roy, commenting on the Secretary's report, said the habits of childhood influenced the whole life, and once well begun, the care of the teeth was continued automatically. In France they had asked for dental inspection of school children by dental specialists to be included in the new law. The responsible minister was convinced of the necessity of this, but it was a question of money. At present, medical inspection cost two million francs and when reorganized it would cost eight millions. They must, however, insist on the economic benefits of school clinics for society as a whole, as demonstrated by Professor Jessen.

Dr. Wolf said the support of the state for school dentistry was becoming stronger in Austria. It was very necessary to impress the importance of mouth hygiene upon professors, specialists, and public health authorities. He proposed that the F. D. I. approach the different governments with the request to be officially recognized.

The minutes of the H. C. F. D. I. were read by Dr. Van der Hoeven.

The honorary members and national committees, therein named, were recommended for appointment, as follows:

Hon. Members and National Committees.

Honorary president—Dr. Elof Förberg, Stockholm.

Honorary members—Ministerial Director, Prof. Dr. Kirchner, Berlin; Dr. Paul Ritter, Berlin; Dr. S. C. Benson, Helsingfors.

Member of Committee—Excellency Lingner, Dresden.

Danish National Committee—Army Dentist Viggo Randböll, Copenhagen.

German National Committee—Dr. Pursche, Berlin.

Austrian National Committee—Professor Dr. Scheff, Prof. Dr. Weiser, Dr. Karolyi, and Dr. Gabriel Wolf, Vienna; Prof. Dr. Bönnecken, Prague.

Swiss National Committee—Dr. Eltner, Basle.

Finnish National Committee—Pehr Gadd and Gunnar Siven, Helsingfors.

Russian National Committee—Prof. Dr. Fr. Zwierschorsky and M. Minker, St. Petersburg; J. Otantschikoff and P. Dauge, Moscow; Dr. Rakowsky, Charkoff; Dr. A. Redalien, Odessa.

Philippines National Committee—Dr. L. Ottofy, J. L. Arbiza, and B. Arevalo, Manila.

Japanese National Committee—Dr. M. Chiwaki (director of the Dental School, Tokyo), Dr. S. I. Enomoto (president of the Japanese Dental Society), Dr. S. Shimura and Dr. T. Shmamine, of Tokyo.

It was proposed to alter the Rules by adding to Article 10: "The Executive Council shall be formed not only by fifty regularly nominated members, but also by adding the presidents and secretaries of the different commissions."

Referred to the Executive Council.

It was agreed, subject to the approval of the Executive Council, that "Copies of the *Internationalen Archiv für Mundhygiene* shall be at the disposal of each national committee in one of the four official languages, the expenses to be paid by the F. D. I."

It was agreed that Professor Walkhoff's brochure on Dental Hygiene be recommended to the national committees.

It was agreed to recommend the national committees to ask the school authorities to issue every half-year the statistics on mouth hygiene, according to the general scheme of Strassburg, with the alterations deemed necessary in each country.

The PRESIDENT proposed that the accounts of the Hygiene Commission should be revised annually by Dr. Rosenthal, the Treasurer of the F. D. I.

On the proposition of Professor Christensen, it was agreed to send telegrams of thanks and congratulations to the Queen Mother of Holland and the King of Denmark. The telegrams were signed: "Paterson, Jessen, Van der Hoeven."

PAPERS, ETC.

Dental Treatment for Private and Higher School Children.

Professor CHRISTENSEN then read his paper, entitled "Proposal for Systematic Treatment of Children in Higher-Grade Schools by Private Dentists," as follows:

In our earnest endeavors to promote dental hygiene among the children in "provided" (board) schools, we must not lose sight of the fact that in private schools there are a large number of children who also need our care and attention to a high degree. While we exert ourselves to provide rational dental treatment for the very poor, it would be absurd were we not at the same time to give a thought to the children of that class of the community who, in spite of their often limited incomes, manifest an honest desire to pay their way, and do not on every occasion make an appeal to public charity.

Most children attending private schools have very bad teeth, for which various factors are responsible. Few of the children have such well-to-do parents but that the dreaded dentist's account keeps them away as long as possible from seeking help from him, and the indulgent bringing-up and mode of life, the enervating absorption of all possible studies, society functions and diversions—all this contributes not alone to weaken the organism, and as a consequence the teeth, but renders it very difficult for them to find time for the care of the teeth or the visit to the dentist—unless hard necessity, in the guise of toothache absolutely forces them to it.

One could, if one would, make this a charge against parents of this type (it might, perhaps, be of advantage to do so), but this does not do away with the fact that the teeth of children in our private schools are bad, and are not properly looked after, and this is what we ought to find a remedy for.

Two years ago I had an opportunity in Strassburg of inspecting the results of Professor Jessen's work among children in "provided" schools, and as a result of the discipline in dental treatment which had been carried through, found children with clean mouths and healthy teeth everywhere, from the little ones in the "Kleinkinderschule" (infant school) upward. The thought struck me when I considered the defective state of the teeth among children in better positions in life whom I knew in private schools, how unreasonable it was not to attempt to bring about also an efficient, regular inspection of these children's teeth. It should certainly be feasible, by means of a sensible economic system, to get over the financial difficulty, which is otherwise the greatest obstacle we have to contend with.

The crux of the matter in the economic principle respecting dental clinics for school children is that the inspection of the teeth should take place so frequently that the disease is discovered in good time, and is therefore not permitted to spread so far that the treatment thereby becomes difficult and lengthy, *i.e.* EXPENSIVE.

Every dentist would therefore easily be able, without any pecuniary loss to himself, to establish comparatively cheap treatment of school children's teeth, if only an arrangement could be come to whereby parents were sufficiently trained to let their children attend at stated times. But, as every dentist who has had any experience knows, it is, generally speaking, impossible to maintain the rule as regards attendance, unless the arrangement can be backed up by special measures which will act as a hold upon the parents.

It is of no use whatever to work only by means of admonition and the indicating of reasons why it should be. We human beings are only human—with but few exceptions. But we can tempt parents by the suggestion of pecuniary advantage. Therefore cheap treatment on annual terms, but with payment in advance, is the best expedient: people are seldom willing to lose what they have once paid for.

In my own practice, I have personally tried to realize a plan of this sort, but insufficient time at my disposal has constrained me to abandon the idea, so that I am unable to communicate anything as to the outcome of my own experience in the working of such a scheme. But a Copenhagen colleague, Jörgen Höyer, who for several years has treated children's teeth upon yearly terms, has kindly informed me that he is very well satisfied with the experience he has had. But he only receives children upon an agreement extending over four years at least, and his fee of 10 kroner (11s.) annually has to be paid in advance. Under another form, Knud Lyngen, of Copenhagen, has recently endeavored to reach the same goal; he has established a special clinic for private schools, and here also payment is made in advance.

This payment in advance, with the loss of the right to receive further treatment if the times of attendance are not kept —without there being a reasonable excuse for such omission—is the most effective means for insuring accuracy in the keeping of the necessary appointments.

After a time there will probably be established more dental clinics upon this principle, but it cannot be regarded as sufficient that here and there should be found dentists who singly, each in his own sphere, seek to insure the care of the teeth among private school children. This matter must be taken up as a matter for the community, just as dental hygiene among children in provided schools has been. As the most natural and rational means of attaining this object I suggest the formation of "dental sick clubs for children," with free choice of dentist. Hereby would be most easily secured the pecuniary advantage for the parents and the necessary discipline for the children.

Here is a task for the heads of private schools to support the scheme by making it obligatory for the children attending schools to submit to regular treatment at the hands of a dentist.

I do not intend to place before you at present any ready-made scheme for the establishment of such "dental clubs." It would be useless to waste time upon it, as an idea must always have time to sink into the minds of people before we can cherish the hope of its being comprehended and adopted. I will therefore confine myself to sending forth the idea, whilst earnestly recommending it to the careful consideration of the Hygiene Commission.

Dr. Cunningham said that Professor Christensen had touched upon a subject of great importance, but which, however, was more theoretical than practical. He believed that Dr. Rosenthal had carried out a scheme for pupils of higher and private schools. But they wanted to know the results of experience on such matters, and he suggested the postponement of the discussion.

This was agreed to.

Care of the Teeth of School Children in Austria.

Dr. Gabriel Wolf (Vienna) then read a paper on "The Care of the Teeth of School Children in Austria."

He said that Dr. Hillischer directed attention to the subject at the International Hygiene Congress in 1887. In 1903 the Austrian Minister-president made an official pronouncement on the importance of public enlightenment as to the dangers of dental caries. Reports on school dental inspections increased, and state medical officers took cognizance of the matter. With the appointment of school doctors in teachers' training colleges, dental inspection became compulsory. Professors at the gymnasiums showed interest and induced parents and scholars to seek dental treatment; for example, the director of the state gymnasium at Linz within six years increased the proportion of pupils dentally treated from 28 to 93 per cent. The problem of finance hindered progress for some years toward the only practical means of combating caries—treatment in clinics. In 1907 the city of Brünn arranged with private dentists to treat poor children, but this was soon given up owing to the cost. Prague also arranged with private dentists to treat the children for an annual lump sum, but this system did not succeed, and a school dental clinic would this year take its place. In Vienna, private dentists had treated the children in the municipal orphan asylums since 1906. The university dental institutes in Graz and Innsbruck made certain provision for poor children. The Berlin International Dental Congress gave fresh impetus to the movement. At Berndorf, a town near Vienna, the first school dental clinic in Austria was established in 1909 through the initiative of Herr Krupp. A further advance was the formation of an Austrian Society for the Care of School Children's Teeth in March 1911. The public authorities manifested their interest by making grants, and many subscriptions were received. The society considered its chief task to provide for the 100,000 children in Vienna, and would next carry its propaganda into the provinces and form branches. The first result of the society's activity was the opening of the first Vienna school dental clinic in the autumn of 1911. The efforts of the society were also directed to awakening the interest of the teachers and securing the co-operation of the state. He was gratified to report that two state school dental clinics would shortly be opened in Vienna, and the city had provided for another clinic in a large school now being constructed. In the provinces a clinic was to be established at Baden, as also at Brünn and Prague. The support of the government's Health Department was assured by the fact that the society had its chief, Hofrat Dr. von Haberler, as president. In May 1912 the Austrian National Committee of the Hygiene Commission was constituted, and Regierungsrat Prof. Dr. Scheff was elected president. In conclusion, Dr. Wolf alluded to the difficulties yet to be solved—above all, the financial problem for state and municipal budgets. Yet while they admired the achievements in Sweden and Germany, they were satisfied to be able to point to good results obtained in Austria in a comparatively short time.

Swedish National Bread and its Value in Oral Health.

Prof. G. Lagerheim, of Stockholm, gave an address on "Swedish National Bread and its Value in Oral Health."

After an introduction to the subject of the dietetic value of starch as food in the animal economy, considered from the chemical and physiological points of view, the lecturer proceeded to discuss the preparation of bread. He said that from olden times there had always been baked in Sweden a sort of rye bread, called "Spisbrod," which was indispensable to the nation and was praised by foreigners. This bread was made of coarse unsifted rye meal, spices, and yeast, and was dried hard in large round flats. Owing to its hardness and brittleness, one was compelled to chew it thoroughly, which was of great importance for keeping good teeth. Through the quantity of saliva formed in chewing this bread, the digestion of the starch was furthered. In Sweden common experience taught that such bread was of great use as food for children, because it formed strong jaw-bones and healthy, white teeth.

The lecturer exhibited a variety of specimens of different Swedish breads, which members were invited to inspect and taste.

Raw Carrots as an Important Factor in Dental Hygiene.

Professor Christensen (Copenhagen) spoke on this subject, as follows:

Long experience has taught me that in the raw carrot we possess a food which is splendidly adapted to teach the rising generation the almost obsolete *art of chewing*. I think I am right in believing that I am not alone in having observed this, but as up to the present I have not seen that the subject has received the attention it merits, I have thought it opportune to bring the matter forward here. If the chewing of carrots were introduced in a systematic manner, it would constitute an important factor in the fight against the increasing degeneration of the masticatory organs of the people of civilized countries.

It is excellent teaching we dentists advocate—that children during their growing years shall learn to masticate thoroughly, so as to develop their organs of mastication; but it has unfortunately proved most difficult to carry this out in practice, as in our days there are but few articles of food which are suitable for thorough chewing while being at the same time of such a character that the tenderly nurtured children of our days find *pleasure* in doing so.

Tender meat, soft bread, chopped food or porridge simply require a kneading process which only by courtesy can be called *chewing*. And it does not assist our purpose much to prescribe for children, as a rule, thick, coarse bread with hard crusts. Especially is this so in the case of such children as require help most—those with weak teeth, undeveloped jaws and relaxed muscles; such children positively cannot endure chewing the "pedagogic" crusts, so they swallow them in a more or less unmasticated state.

If one would make any progress with children in the matter of thorough mastication, it is at the same time necessary to indicate to them a food which they will *enjoy* chewing, and in this connection I would remark that it would, therefore, be of the utmost importance for investigators who, like Röse and Kunert, are working to bring about a reform in the making of our bread, to lay stress upon the fact that the bread of the future should be pleasant to chew, or else it will only be the small eclectic or pedantic minority who will reap any benefit from the reform in question.

The raw carrot possesses just the characteristic that it gives the child a desire to use his chewing organs. It is pleasant to chew, sufficiently hard while being at the same time brittle enough, so that the child is anxious to overcome the resistance, and he soon learns to masticate it as he should, because his natural instinct induces him to chew it as small as possible, for by this means he obtains the fresh and juicy taste of the carrot to the full.

The same applies also to a few other fruits, *e.g.* apples, but many children cannot chew apples, because the subacid juice sets their teeth on edge, and at any rate in the countries of the north it is not everybody who can afford the comparatively dear apples as daily food for the children. Therefore, I recommend carrots as first and foremost. Let the children chew a raw carrot every day, and the benefit will soon be apparent. That is my advice.

But there is one drawback to the carrot: it is too plebeian in its origin. In the sybaritic days in which we live our school children would never dream of including such an ordinary and simple thing as a carrot among luxuries such as the "tuck shop" tempts them with. It will be difficult for the carrot to compete with sweets, toffee, caramels, liquorice, and the rest, which are bad things for the teeth, unless we can induce public opinion to take into favor the healthy delicacy which a sweet, juicy, raw carrot really is.

Dr. Cunningham's Cinematograph Demonstration.

This took place in a biograph theater in Stockholm, before a large audience, on August 29th.

Mr. Paterson briefly introduced Dr. Cunningham as the pioneer of the new movement for educating the public by cinematographic lectures in the important matter of the care of the teeth.

Dr. Cunningham stated that this movement originated in Sweden, for Stockholm was the first place where he spoke about children's teeth. The film he was going to show was, unfortunately, not complete, but it was prepared for educating those who were going to administer the laws of health, as well as for all intelligent people who were ready to do something for the children. It was only through the children they could save the coming race. It was very difficult to project a film like that, but he wished them to understand it as only a first trial, and as a Britisher he was proud to be able to attempt it for the first time. Giving a summary of five years' work at the Cambridge Children's Dental Institute, he said that in 1907 only 3 per cent. of the children had sound permanent teeth, but in 1912 over 70 per cent. had sound permanent teeth, and a clean mouth. What Cambridge had done, every other town, great or small, could do, and ought to do, and so they would really save the nation's teeth.

The film was divided into stages. In the first stage the anatomical appearances of the jaws and teeth were displayed. The eruption of the first molars was ingeniously shown. Caries of a tooth occupied another stage. The remainder of the film illustrated the treatment of children attending the Cambridge Borough Dental Institute.

Address by Mr. Horace Fletcher—"An Appreciation of the Dental Profession."

Before the Hygiene Commission on the afternoon of August 29th, Mr. Horace Fletcher (New York), president of the American Mouth Hygiene Association, delivered an address, entitled "An Appreciation of the Dental Profession."

He said he would speak as a business man in appreciation of dentistry.

Statistics showed that in America at least 90 per cent. of people required some amount of dental treatment. Mouth diseases were essentially diseases of civilization, with its hurry, rush, and excitement. In the last twelve or fifteen years he had been gradually convinced, as he studied the subject from the practical side, that the mouth was the gateway to health. He learned that at West Point military academy, 98 per cent. of the young men, who must be considered the flower of American manhood, came there with more or less defective mouths. He had visited the experimental school in Cleveland, where Dr. Ebersole demonstrated that children were improved 25 to 50 per cent. from a mental and moral standpoint after dental treatment and instruction as to thorough mastication. Abundant evidence could be gathered from all countries to show that a large percentage of mankind was more or less in an unfit condition owing to unsanitary mouths. This was both a cause and an effect, because insufficient mastication and insalivation brought about indigestion and a whole cycle of diseases springing from malnutrition. That being the case, it was not too much to say that the competent dentist was the man of the moment in preventive medicine. The Forsyth Brothers, Boston, had given two million dollars, and would give more if necessary, to found a dental infirmary for children between six to sixteen years, and to carry on a thorough campaign for the clean mouth. That was a business man's appreciation of dental science.

His own appreciation had been a growing one. Fifteen years ago he found himself in a condition of shattered health, and he knew it was the result of malnutrition. At that time he was able to retire from business, and realized that the most important thing was to put himself into a fit condition, for the insurance officers had refused to accept his life, and he knew their condemnation was true. He began to study the subject for himself, but found that the textbooks devoted only a few paragraphs to the first three inches of the alimentary canal, but some thousands of pages to guessing about what happened in the rest of it. The medical writers simply jumped from the vestibule of the subject into the dark. He investigated the question, and showed in his books that if people realized the potency of saliva, and paid attention to the treatment of food in the first three inches of the alimentary canal, the diseases on account of which he was condemned faded away. Within three months he was in better health than for twenty years, and on his fiftieth birthday he rode over thirty miles on his bicycle. That was thirteen years ago, and since then his course had been one of steady recuperation, so that he was better at sixty-three than at fifty, nor had he yet arrived at the summit of recuperation. He had probably had more dentists at work on his mouth than any man living. In his travels all over the world he had fifty dentists experimenting on his mouth, and he considered it quite as much a duty to pay frequent visits to a competent dentist as it was to take his food. He believed it to be the mission of what was known in America as "Fletcherism," to advocate the hygienic or clean mouth quite as much as proper mastication after it had been made clean. Just as a factory needed a repair shop for its tools, one was equally required for the mouths of the workers, and he had put this before large employers as a profitable business investment. If he had the care of competitors for the Olympic games, dental treatment would be the first thing.

At the meeting of the National Dental Association of the United States, he was elected president of the Mouth Hygiene Association, which had an executive committee composed of members of the dental profession. He was leaving that day to attend the first annual meeting, and he hoped to assist in the advocacy of mouth hygiene as a measure of preventive medicine.

In his contact with dentists, he had found them to be an exceedingly unselfish set of men, for he knew men, whose time was worth 12 to 20 dollars an hour, give up a day or half a day a week for attending the poor in the dental infirmaries. Though the profession was not well paid, that showed it had caliber of superior quality. For that reason, if he had time and strength, he had decided to become their advertiser, and in this way express to the world his high appreciation of dentistry.

Executive Council.

THURSDAY MORNING.

At the meeting on the morning of Thursday, August 29th, Mr. Paterson, president, was in the chair.

The PRESIDENT announced apologies for absence received from Dr. Godon (Paris), Dr. Kirk (Philadelphia), Dr. Daubry (St. Petersburg), and Dr. Weiser (Vienna); Dr. Rojo (Mexico); Messrs. G. G. Campion (Manchester) and J. H. Mummery (London).

Report of the Hygiene Commission.

Certain honorary members were elected, and Dr. Förberg was elected an honorary president of the Commission; Dr. Guido Fischer (Marburg) was elected a member of the F. D. I.

The Council considered the proposal from the Hygiene Commission to use as the official journal of the F. D. I. the *Internationalen Archiv für Mundhygiene.*

Dr. AGUILAR (Madrid) proposed that the question be postponed until the next meeting.

Dr. ROSENTHAL seconded.

Dr. VAN DER HOEVEN (Hague) said there were three reasons against adopting the proposal of the Hygiene Commission. First, he thought it was illogical for the Transactions of the F. D. I. to be published, not by itself but by one of its subcommittees. Secondly, the *Internationalen Archiv* was not seen by many dentists as yet. Thirdly, the Hygiene Commission did not explain how to get the money for publishing the Transactions in four languages. He did not know of any other way of getting the money except by his own proposal, namely, of contributions from all national dental associations.

M. ROY (Paris) supported Dr. Van der Hoeven's observations.

Dr. VAN DER HOEVEN explained that he was giving his personal opinion, and not speaking as honorary secretary of the Hygiene Commission.

Dr. ROSENTHAL (Brussels) said the first thing was to know how much it would cost to publish the Transactions in four languages. When that question was settled, they could then discuss how much money they should ask from each national association. He thought it would cost a great deal of money.

The PRESIDENT thought that, after the views expressed by the present and past treasurers of the F. D. I., the question should be adjourned for further consideration.

This was agreed to.

Dr. VAN DER HOEVEN proposed—

(1) That the national dental associations of the various countries represented in the F. D. I. should contribute an annual subscription to the funds of the F. D. I. proportionate to their membership.

(2) That in the event of an official organ of the F. D. I. being established, free copies be sent to such national dental associations in numbers proportionate to their membership.

He said his object was to arrive at the publishing of an official journal of the F. D. I. in its four languages, and to make its work more known throughout the world by sending a free copy of the Transactions to every member of a national dental association contributing to the F. D. I. The proposal of the Hygiene Commission concerning the *Internationalen Archiv* did not meet the requirements, and he therefore opposed it. He knew no way of getting the money for publishing the Transactions except by inviting the different national associations to give an annual subscription to the F. D. I. funds. He did not think the contribution need be very high, because there were a great many associations which would be glad to pay something when they secured copies of the Transactions for their members. As their work was for the benefit of dentistry throughout the world, every reputable dentist ought to know about it. They were only a consultative body, and their whole power lay in getting their ideas impregnated in the minds of *confrères,* and their work made more popular among dentists all over the world.

The PRESIDENT said the proposer's aims were admirable, and asked if he had formed any idea as to how much the national dental association would be likely to contribute?

Dr. Van der Hoeven replied that it was impossible to say until a committee had inquired.

Dr. Schaeffer-Stuckert (Frankfort) said they could not expect any money from Germany, where dentists already supported thirty-five societies.

M. Roy (Paris) thought the views of Dr. Van der Hoeven were very logical, but the money difficulty was great. He proposed that the F. D. I. make inquiries.

Professor Dieck (Berlin) differed from Dr. Schaeffer-Stuckert, and thought the Central-Verein, which has 1100 members, or the Vereinsbund, would contribute.

Dr. Aguilar pointed out that the F. D. I. already received from some countries a contribution for the fees of its Council's representatives. He thought that the first proposition was not practicable, and besides it was not necessary, because they should have a surplus next year to hand over to the organizers of the International Dental Congress of 1914. For the present, therefore, they did not need money. As to the second proposition, it would be too expensive to publish the Transactions in four languages. He thought their president merited a most enthusiastic vote of thanks for his efforts in publishing the 1911 Transactions in such an excellent and economical way. He moved that he and the assistant secretary, Dr. Guy, be asked to continue this work.

The President suggested that the matter be left to the general secretary, the treasurer, Dr. Guy, and himself. They would endeavor to supply as economically as possible copies of Transactions, not only to every member, but also to affiliated societies of the F. D. I.

Dr. Van der Hoeven said he appreciated very much what had been done, and agreed to the President's suggestion. He accordingly withdrew his proposals.

Dr. Aguilar moved a vote of thanks to the president, Dr. Schaeffer-Stuckert, and Dr. Guy for the pains and skill with which they had carried out the publication of the Transactions of 1911.

Dr. Van der Hoeven seconded the motion, and it was cordially passed.

Thursday Afternoon.

The Executive Council met on Thursday afternoon, August 29th, to receive reports and to adopt resolutions. Mr. Paterson (president) was in the chair.

Dr. Van der Hoeven submitted the recommendations of the Hygiene Commission, including names of honorary members, and the minutes.

M. Roy proposed, and Dr. Rosenthal seconded, that Dr. Förberg be elected honorary president of the Hygiene Commission. This was passed unanimously.

Dr. Rosenthal proposed the election of Mr. Sedley Taylor, Fellow of Trinity College, Cambridge, and Mr. Brooks, editor of the *Cambridge Daily News,* as honorary members of the Hygiene Commission. He added that he thought it important that all those belonging to the Hygiene Commission who were dentists should be members of the F. D. I. and pay their dues as such. Of course, lay members would not be asked to pay.

Dr. Schaeffer-Stuckert said he would advise the enforcement of their resolution, that for the future in the election of dentists to the Hygiene Commission, only those whom they were assured would accept membership of the F. D. I. should be elected.

Dr. Van der Hoeven then proposed the election of the gentlemen mentioned in the Hygiene Commission's list to be members of the F. D. I. as well as of the Hygiene Commission.

The elections of honorary members and ordinary members of the Hygiene Commission were agreed to.

Dr. Van der Hoeven said he would put on the table, for consideration next year, a proposal to alter Article 10 (*a*) so as to include, among members of the Executive Council, the presidents and honorary secretaries of the different commissions.

The President pointed out that the Articles of the F. D. I. could not be altered until the next Congress in 1914.

Dr. GUY said there was a great advantage in the membership of the Executive Council being fixed at fifty. As a matter of fact, most of the presidents and honorary secretaries of the commissions had been and always would be chosen to be members of the Executive Council. At the last Congress they were only empowered to add one member to the Executive Council for a fresh adherent country. It was much better to have a definite number.

The PRESIDENT said it was always possible for the presidents and honorary secretaries of commissions to be consulted by the Executive Council on their own or the Council's initiative. In such consultation work, of course, they would have no vote, otherwise the proportional balance of national representation would be upset.

Dr. VAN DER HOEVEN, after consulting Drs. Jessen and Lenhardtson, said that he would withdraw the proposition.

The proposal to recommend Professor Walkhoff's brochure to the national committees was next considered.

Professor WALKHOFF explained that the pamphlet was written at the request of an association of physicians with 20,000 members. It was really intended for the information of doctors and professors who were interested in dental hygiene.

Dr. SCHAEFFER-STUCKERT said he would recommend every country to issue a similar booklet, or have Professor Walkhoff's translated. He proposed that the motion be adopted.

Dr. ROSENTHAL seconded, and it was carried.

The PRESIDENT hoped that in Great Britain the brochure would receive favorable notices in the medical press, and so be recommended to doctors generally.

Dr. VAN DER HOEVEN then proposed that the Council adopt the statutes of the International Hygiene Commission, as published in No. 3 of *Internationalen Archiv für Mundhygiene,* with the alterations approved in Berlin.

Dr. ROSENTHAL said this was a sequel to the important discussion at the last meeting in London, when the proposal that the F. D. I. should undertake indirectly the sale of tooth-powder and brushes was rejected. Consequently, new regulations were framed for the Hygiene Commission, in which the F. D. I. would not be mentioned.

Dr. JESSEN said the new statutes would only apply to certain countries like Germany, Denmark, and Holland, whose national committees agreed with his method of raising funds.

Dr. SCHAEFFER-STUCKERT said the change of statutes would enable the International Hygiene Commission to do what it chose on its own responsibility.

The PRESIDENT said he could not see any reason why one commission, because it was made a permanent commission by special resolution of the last congress, should be supplied with fresh statutes and regulations any more than other commissions—*e.g.* Education, Bibliography, etc.

Professor JESSEN replied that the Hygiene Commission had quite different duties. Its sphere was more practical and less theoretical.

The PRESIDENT hoped their commissions might be trusted to do what was right and ethical, whether their duties were practical or theoretical, without special regulations and statutes to that end.

Dr. VAN DER HOEVEN thought, as a result of the discussion in London, it was necessary to have special statutes.

M. ROY said the London Meeting left the question to be decided by each national committee in its own country.

Mr. LENHARDTSON said the Hygiene Commission wished certain stipulations made so that no trouble should arise. They were working practically, and on different lines from other commissions.

Dr. ROSENTHAL objected to the proposed regulations because they were in direct contradiction to what was passed in London.

Dr. GUY observed that it was impossible to come to any conclusion, as the new regulations were printed only in German.

Professor JESSEN withdrew the proposition, and undertook to issue the proposed regulations in English, French, and German, to members of the Council, before the next meeting.

This was agreed to.

The Council approved the recommendation to national committees to request the school authorities to issue every half-year their statistics on mouth hygiene, according to the general scheme of Strassburg, with the alterations deemed necessary in each country.

Governments' Recognition of the F. D. I.

The recommendation, "That the F. D. I. be officially recognized by the governments of the different states," was next considered.

The President said such official recognition was doubtless very desirable, and he thought the best way to gain it was through the merits and character of their public work becoming known. In Sweden, the King was impressed by the value of the work of the F. D. I., as some of those present had witnessed at the royal reception on the preceding day, and that was without any request having been made for official recognition on their part; and so it would be with other governments.

Dr. Van der Hoeven agreed, but thought that when the F. D. I. made recommendations to governments, official recognition would assist.

Dr. Schaeffer-Stuckert explained that until the International Dental Congress of 1909 they had not seen official representatives of governments at their meetings, but they hoped to see them from all states in the Congress of 1914.

Dr. Rosenthal thought the Transactions of the F. D. I. should be sent officially by each national committee to the government of its country.

M. Roy considered it would be well to endeavor always to obtain the attendance of government delegates at F. D. I. meetings.

Dr. Guy agreed with Dr. Rosenthal's suggestion, but thought the F. D. I. gradually established relations with governments in their different countries where they met. In addition, they might request national committees to do their best to get in touch with ministers and governments, and when possible, induce them to extend official recognition to their meetings.

On the motion of M. Roy, seconded by Dr. Rosenthal, it was agreed to forward copies of Transactions to governments, and urge members to endeavor to obtain from their respective countries an official delegation to the F. D. I.

A letter in Spanish was read from Dr. Rojo of Mexico, stating that a permanent Mexican National Committee had been formed in union with the F. D. I. He sent fraternal greetings and regrets for absence owing to the great distance.

The Accounts.

The auditors reported that the accounts were in order. They suggested that a balance-sheet be published and sent with the program of the meeting to the members of the Executive Council.

M. Roy, speaking as one of the auditors, proposed a hearty vote of thanks to Dr. Rosenthal, the treasurer, and acknowledged his kindness in bearing the expense of changing checks from different countries.

Mr. Harrison, speaking also as an auditor, seconded, and said the accounts were very clearly and accurately kept.

The accounts were passed.

MILLER PRIZE FUND ACCOUNTS.

Dr. Aguilar presented the accounts, and said the income was estimated at £100 to £150 per annum. They expected to be able to award every two years a prize of £200, or 5000 francs. As instructed, the trustees had completed their suggested new regulations, as given above in the minutes. They had considered the recommendations by Professor Walkhoff and Dr. Kirk, and these would be compared with the conditions for the Nobel prize. The regulations would be printed in English, French, and German, and come before the Council next year.

The President said they were very

much indebted to Dr. Aguilar and Dr. Brophy for their valuable report. He anticipated that the total funds of 63,-000 francs would be still further increased as a result of Dr. Aguilar's forthcoming visit to America.

On the motion of Dr. ROSENTHAL, seconded by M. Roy, a cordial vote of thanks was passed to Dr. Aguilar for his services as honorary secretary to the Miller Prize Fund Commission.

M. ROY suggested that the Miller medal and diploma should be presented ceremonially at the opening session of the F. D. I.

Dr. GUERINI said statistics showed that dentists were short-lived, and to award the Miller prize every two years was not often enough. They should award it annually, like the Nobel prize.

The PRESIDENT pointed out that the rules could not be altered until the next Congress.

Place of Meeting for 1913.

The PRESIDENT said the last item on the agenda was the decision to be taken as to the place of meeting of the F. D. I. in 1913. He had promised Dr. Brophy, who had left to attend a meeting in Washington, to submit to the Council the invitation from the American National Dental Association.

Dr. AGUILAR said he was authorized by his colleagues to invite the F. D. I. to meet in Spain. At the same time he had promised Dr. Brophy that he would vote for going to America.

Dr. ROSENTHAL proposed that the F. D. I. go to America, as he understood was tacitly agreed in London last year.

Dr. SCHAEFFER-STUCKERT suggested The Hague for 1913, and America for 1915.

Dr. VAN DER HOEVEN promised to do his best to make the meeting a success if they came to Holland, but he thought they could hardly reject a second invitation from America.

Professor DIECK pointed out that there were 40,000 dentists in America, and since the Berlin Congress the relations of the F. D. I. with America had become very good. He favored accepting the American invitation.

Dr. GUY said the discussion was important in view of the holding of the next International Dental Congress in London. An enormous amount of work would have to be done. The most important work of the next meeting should be the organization of the London Congress, but if they met in America possibly only one or but few British representatives could attend. He moved that they accept the invitation from Spain.

Professor WALKHOFF suggested holding a special meeting to complete arrangements six months before the 1914 Congress in London.

The PRESIDENT considered that would be too late.

M. ROY thought they must consider the highest interests of the F. D. I. It would be a serious matter if American members abstained from taking part in the congress.

The PRESIDENT said he was sorry to introduce a personal note, but neither he nor the general secretary, Dr. Schaeffer-Stuckert, nor the assistant secretary, Dr. Guy, would be able to go to America, and he was afraid that only a small number of the F. D. I. generally would attend. Under such circumstances, would America be more disappointed at receiving a small number of F. D. I. visitors, than at having its invitation declined until after the congress in London?

A ballot was taken, and resulted as follows: America, 9 votes; Holland, 3; Spain, 2.

Dr. AGUILAR suggested that the F. D. I. should meet in America in connection with the National Dental Association's meeting.

Mr. PATERSON said the Executive could arrange that. He gathered from the observations made that members favored a meeting-place on the Atlantic coast, and the month of August as a convenient time. And as Dr. Aguilar was going immediately to Washington to attend the meeting of the American National Dental Association, he would ask him to explain the situation to their American *confrères.*

At the conclusion, Professor LECHE proposed a hearty vote of thanks to the President, and this was carried with cheers.

SOCIAL FUNCTIONS.

Royal Reception.

His Majesty King Gustaf held a special *levée* at the Palace, at 2.30 P.M. on Wednesday, August 28th, when the following members of the Federation were commanded to attend: The president, Dr. Förberg, Professor Walkhoff, Dr. Schaeffer-Stuckert, Dr. Rosenthal, Professor Jessen, Dr. Cunningham, Dr. Brophy, Dr. Aguilar, Dr. Guy, M. Roy, and Mr. Lenhardtson.

His Majesty conversed with all, and expressed his hope for a successful meeting.

The Annual Banquet.

The annual banquet of the F. D. I. was held on August 28th, in the beautiful dining-hall at Hasselbacken, a fashionable pleasure resort of Stockholm, and it was a brilliant and successful function.

Mr. Paterson presided, and was supported by Mr. Hultgren (president of the Swedish Dental Society), Dr. Förberg, Professor Sonnberg, and Mr. Dahlen (president of the Swedish Dental Federation).

After the loyal toast, Dr. Förberg communicated a gracious message from his Majesty, who assured the members of his great interest in the work and aims of the Federation. His Majesty was pleased to be Protector of the Hygiene Commission of the F. D. I. and sent his greetings and best wishes for a successful meeting.

Dr. SCHAEFFER-STUCKERT proposed the toast of "Swedish colleagues," acknowledging their hearty welcome and generous hospitality. He made special reference to the valuable services of Dr. Förberg and Mr. Lenhardtson in making such successful arrangements.

Mr. HULTGREN replied, and said that many strangers had recently visited Stockholm to take part in the Olympic games and strive in physical competition to win honor and glory for their native countries. Members of the F. D. I. did not, however, meet to compete against each other, as it was a matter of indifference which country reached first the goal set before them and accomplished the task of successfully combating a great evil. They could all vie with one another in friendly rivalry to attain results which should contribute to forming the laurel wreath of victory to be worn some day by the F. D. I. He proposed with all cordiality the toast of "The F. D. I.," which was drunk with appropriate Swedish honors.

Dr. AGUILAR, replying, recalled his visit to Stockholm ten years before, and said he was proud to be among them again, because Sweden, apart from possessing the oldest dental society in Europe, could be looked upon as a model of good ethics, and its practitioners were men of the highest moral standard. He knew the interest King Gustaf took in the work of the F. D. I., thus acting upon the Latin maxim: *Salus populi suprema lex.* He wished all success to the Swedish societies, and with all his heart said "Skol!"

Dr. W. GUY proposed the toast of "The Miller Prizeman." He said he did not know what greater honor the dental profession offered to its votaries than the Miller prize. Some of them were wearing decorations—well earned, he doubted not—and for many of them he believed there were decorations in store. What might be called the blue ribbon of the profession, the Miller prize, had been bestowed upon Dr. Charles Godon, who was known to all of them as the "Father of the F. D. I." Dr. Godon had watched over the development of the F. D. I. from its earliest days, and no trouble was ever too great for him so long as it helped to forward what they all had at heart—the welfare of the F. D. I. The work which Dr. Godon had done, not only for the F. D. I., but also for national dental associations in France, and for the cause of dental education, would be long remembered. But that which, above all things, would confer the laurel of immortality upon their friend was the fact that he had been chosen by the most eminent jury of his *confrères,* the Executive Council of the F. D. I., to receive the Miller prize. They sympathized with him in the great affliction which had lately befallen him. Of Dr. Godon's good qualities it could be said, in brief, that he exemplified every virtue for which his country was distinguished. They congratulated Dr. Godon on receiving this signal honor.

Dr. GUERINI proposed "The ladies," in a happy and humorous speech.

During the banquet the Miller prize medal was handed round for inspection. The inscription on one side was "*Præmium Milleri*—G. V. Black, 1910—*Pro meritis excelsis doctissimo,*" and on the other, "W. D. Miller, 1853—1907."

The evening concluded with music and dancing.

Banquet at the Grand Hotel Royal.

Dr. and Mrs. Förberg had invited the members and ladies to an evening yachting excursion to the Villa Förberg at Djhursholm on August 29th, but, owing to the uncertain weather, they decided instead to give a dinner at the Grand Hotel Royal, where their splendid hospitality provided a memorable evening's enjoyment.

There were brief and witty speeches, and at intervals a party of male glee-singers contributed delightful vocal harmony.

Dr. Godon sent the following telegram: "Thank my colleagues for their manifestations of sympathy in my bereavement, which keeps me away from the meeting, and assure them of my constant devotion to our dear F. D. I."

Professor JESSEN said they were happy to be guests of Dr. Förberg, who took a leading part in founding the Hygiene Commission at Stockholm ten years ago, and whose name was honored in the dental world for his zeal in the cause of school children. He announced that Dr. Förberg had that day been elected honorary president of the Hygiene Commission, and they hoped to have his help and support for many years to come. Dr. Jessen also referred to the presence of Dr. C. S. Bensow, the veteran Stockholm dentist, who started the great Scandinavian Dental Society for Sweden, Norway, Denmark, and Finland, which meets every four years.

Dr. FÖRBERG acknowledged the distinction conferred upon him, and then proposed the toast of "Absent friends."

Mr. PATERSON, following Swedish custom, returned thanks for "meat and drink," and expressed the warm thanks of the guests to Dr. and Mrs. Förberg for their brilliant hospitality. His speech was indorsed by loud cheers and musical honors.

Swedish Dental Societies' Banquet.

On the evening of August 30th, members of the F. D. I. were the guests of the Swedish Dental Society and Federation at the Grand Restaurant, Saltsjöbaden, a seaside resort and yachting center near Stockholm. Mr. Hultgren presided, and among the large company were several Swedish lady dentists. Among the guests were the Minister of Education and Professor Leche.

The MINISTER proposed the toast of "The Swedish dental societies," and expressed, on behalf of the government, its best wishes for the success of their meeting, and also the assurance of its high esteem for their services to the public health.

Mr. DAHLEN replied.

Mr. HULTGREN, speaking in French, eulogized the work of the F. D. I., and said they were proud that the King of Sweden was High Protector of the Hygiene Commission. He hoped the members would have pleasant recollections of their visit.

The PRESIDENT of the F. D. I., in reply, made a happy speech in Swedish.

At the request of the President, Dr. GUY said that, in furtherance of F. D. I. work, the President and himself had visited many countries and traveled thousands of miles. They would not have undertaken those journeys if they had not been inspired by the thought that in years to come that work would prove fruitful, and would help materially in the progress of humanity to a better life. The realization of those ideals would be their best reward. They would never forget the signal honor conferred by his Majesty King Gustaf in receiving them in audience. They had a sense of great gratitude, too, in the knowledge that the work of the F. D. I. received the appreciation and recognition of the government.

Mr. Lenhardtson proposed the healths of Professor Leche and Dr. C. S. Bensow, which were honored with enthusiasm.

M. Roy recalled the old friendship between France and Sweden, remarking that he was proud to know there was French blood in the veins of the first sovereign who had publicly recognized the F. D. I.

Mr. Boström and others also spoke before the conclusion of a very convivial gathering.

Commission on Education.

Report of the President of the Commission for 1912.

To the Officers and Members of the Education Commission of the International Dental Federation:

Honored Colleagues,—The deliberations of the Education Commission at its London meeting in August of last year were crystallized in the substance of three resolutions, two of which embodied the conclusions of the commission with regard to two fundamental pedagogical questions in dental education.

The first resolution deals with the gradual disappearance of the preceptorial system, *i.e.* private pupilage as a recognized method of preparation for dental practice, and places the commission definitely on record as favoring the general adoption of the technical method, *i.e.* dental school mechanical training.

The second resolution expresses the belief of the Education Commission that the technical method, *i.e.* dental school mechanical training, can be utilized so as to develop the artistic sense as well as the manipulative skill, and that it is the duty of the dental school authorities to endeavor to arrange and elaborate their method of instruction in such a manner as to secure this end.

The third resolution provides for the creation of a subcommittee on Pedagogical Methods to undertake detailed consideration of teaching methods in vogue in the several countries, to consider the proportionate degree of didactic teaching which should be associated with the technical method of training, and to report thereon at a subsequent meeting.

In furtherance of the third resolution, M. George Villain, Paris; Mr. Wm. Guy, Edinburgh; Mr. W. H. Gilmour, Liverpool, and Dr. Wm. Bebb, California, were constituted the subcommittee on Pedagogical Methods, with the president of the commission as chairman.

As set forth in my report at the London meeting, the development of the work of the Education Commission had brought us to the point where, at the Brussels meeting in 1908, it was possible to adopt the report of the subcommittee upon the maximum and minimum program of studies, and to definitely recommend the proposed program as the curriculum for students by the dental schools.

As the logical sequence of the adoption of the report of the Committee on Curriculum at Brussels, dealing with the nature and extent of the curriculum, the underlying question of how to most efficiently train dental students in the subjects of the curriculum came prominently to the front for consideration. In short, the pedagogical aspect of the question as a factor inseparably connected with the extent and character of the curriculum was definitely presented for settlement, or, as stated by the president, Dr. Sauvez, in his opening address at the Brussels meeting, it became necessary for the commission to express its views upon "the value of various methods of training."

In furtherance of that purpose, I had

the honor to invite your attention to the consideration of two questions which were deliberated by your honorable body at the meeting last year in London; the first question being the relative value of the preceptorial system of private pupilage as compared with the system of training students in regularly organized dental schools by professors and instructors who are assumably trained specialists in dental educational methods.

The result of your deliberations upon that question are embodied in the first resolution which I have quoted, and in which the commission records its opinion as favorable to the gradual abandonment of the plan of teaching by private pupilage, and the relegation of dental education to the care of those who are specialists in the teaching of dental professional subjects in regularly organized dental schools.

The second proposition that the commission was invited to consider is the possibility of utilizing the manual training or objective method of laboratory teaching for the development not only of manual dexterity, but for the education of the artistic sense as well; and by its second resolution the commission has also recorded its opinion affirmatively on that proposition. For the further development of our knowledge, and the recording of our views upon the pedagogical phase of the standard curriculum which we have recommended, the subcommittee on Pedagogical Methods was appointed.

It is with deep regret that I am compelled, through force of circumstances, not only to be unable to attend the present meeting, but to report indifferent progress in the work for which the committee was assigned—unusual conditions having since the last meeting arisen which have rendered it physically impossible for your chairman to give the consecutive attention to the collection of the mass of data required, or the time needed for the proper collaboration and digestion of the data obtained. I am, therefore, compelled to ask your indulgence, and request further time for the preparation and presentation of a more detailed report on the work of the committee.

From a study of the report of the deliberation of this commission upon the fundamental questions propounded in my report at the London meeting, it is quite evident that any attempt at the unification of pedagogical methods in the training of dental students must necessarily meet with criticism, not to say objection, arising from the variety of opinions and experiences of those engaged in dental educational work in its various phases. For example, in England, where the preceptorial method still holds a recognized status as an educational method, it would hardly be possible to arrange for the immediate abolition of the preceptorial system and to substitute wholly therefor the system of training exclusively in the dental schools. On the other hand, in America, where the manual training or laboratory method of instruction has in some respects been developed and applied to an extreme degree, there is an evident demand for return in somewhat larger measure to the plan of didactic instruction; this tendency arising from an increased recognition of the importance of inculcating into the minds of students a more comprehensive understanding of the underlying scientific principles of his work. So that when we come to consider the application of pedagogical methods to the standard maximum and minimum curricula which as a commission we have recommended to all schools, we are confronted with the fundamental difficulty arising out of the indeterminate proportions which the purely didactic work ought to bear to the technical or laboratory aspects of our standard curricula; and still further difficulty arises from our lack of a specific definition of the meaning of didactic instruction in contradistinction to laboratory or technical instruction.

If we mean by didactic instruction only such instruction as is presented in a formal lecture, and if we include in our definition of laboratory or technical instruction all of the explanatory teaching that should properly accompany the demonstrative teaching of the laboratory, then for the sake of convenience we may apply the term didactic teaching only to such formal exposition of underlying scientific principles, or historic presentation of the subject-matter of the course, as may be given in the usual formal discourse from the lecture platform of the school. Such a division of the teaching work of the curriculum must, however, be purely an arbitrary division, rather for convenience of description than for the practical education of the student; for in the larger conception of what has been actually designated as the manual training method, the central idea suggested by the phrase manual training, that it is a system of hand-training exclusively, has been altogether overshadowed by the recognition of the fact that the manual training idea in its essence is primarily a system of mind training through the medium of the hand as a perceptive organ, and that in the larger and more general understanding of the principles which it involves, manual training is an objective system of education which utilizes all of the perceptive faculties in the educating of the mind.

In such a view the didactic system and the laboratory, or objective, system become correlative and interdependent; for while on the one hand no method of laboratory training can be of practical value unless accompanied by intelligent didactic explanation by the instructor in charge, so also didactic instruction by the formal lecture in any department of physical or biological science requires the material aid of objective demonstrations to enhance its teaching value by direct appeal to the other perceptive faculties in addition to that of hearing. Therefore, as I have said, the distinction between didactic instruction and laboratory technique training must remain an arbitrary division, and the principles which apply to education as a whole must be brought to bear in the laboratory as well as upon the lecture platform for the attainment of the best educational results.

The whole question then resolves itself into a study and application of the problems of pedagogy as related to the needs of dental education; and at the basis of pedagogy lies that young but vigorously growing science, psychology.

It may be conceded that there are occasional instances where teachers, like poets, are born, not made, yet on the whole, in view of the problems which the great field of education presents, it is scarcely more hopeful for us to depend for our supply of efficient teachers in dentistry, or in any other department of biological science, upon those occasional, sporadic, special pedagogical creations than it would be for the world to depend upon the same source of supply for its needed quota of skilled chemists, engineers, or astronomers, etc.

The demand for good teachers so far exceeds the supply of those naturally born to the work, that the supply must be created, and like any other high efficiency product, must not be created empirically or in a haphazard way, but through skilful and intelligently directed methods of training. Dentistry has thus far depended for its teachers upon a more or less self-selected body of men whose tastes, inclinations, or ambitions have led them to adopt teaching as an avocation, a side issue as it were to their vocation as practitioners of dentistry; but a very small proportion of our teachers have elected to devote themselves exclusively to teaching work and have specially prepared themselves for their work by training in the pedagogical principles which are fundamental to all educational methods.

The increasing demand for skilled practitioners of dentistry arising out of the rapidly growing demand for dental service as a public necessity is bringing us rapidly to the point where it will be necessary for us as a profession to give more earnest consideration to the thorough training of men for the special life-work of dental teaching, in order that the general level of education of the coming generation of dental practitioners may be brought up to the standard which a reasonable public expectation clearly demands. In order to achieve such an object as is here suggested, it will be necessary that the training of dental teachers shall become a part of the recognized business of dental education, either ultimately by the establishment of separate schools of dental pedagogy or by the inauguration of courses within already established dental schools for the definite purpose of training men in the science and art of dental teaching. The creation of courses in dental pedagogy within already established dental schools and the admission of selected qualified men to such courses would tend not only to focus the attention of existing dental teachers upon the scientific principles which are at the foundation of dental teaching, but would dignify the calling of the dental teacher to a degree that would attract good men to the teaching profession, and above all would tend to improve our teaching methods in such a way as to eliminate largely the empirical and haphazard methods now in vogue, and put our educational system upon a more rational and scientific basis.

It is my opinion that this commission should give serious consideration to the matter of harmonizing our teaching methods upon the basis of the pedagogical principles which are fundamental to all educational methods, and use its influence in the stimulation of the study of dental teaching as a professional specialty before undertaking to discuss in detail the best methods of teaching to the student the countless technical procedures which constitute the various subjects of study in the dental curriculum.

The operative and mechanical procedures which constitute the material data of our craft are constantly changing, new ones are arising, and older methods are becoming obsolete. The variation in manual dexterity required to perform these varied operations is a dexterity which when acquired through experience in a limited variety of operations is readily applicable to all, but the power to impart the intelligent conception of the underlying principles, the directing power that will enable the student to best utilize his manipulative skill and successfully apply it to the varying conditions necessitated by new operations, is a function of the teacher.

In the consideration of our educational problem in dentistry, it would seem that we have laid too much stress upon the data of the curriculum, and not enough stress upon the teaching of the teacher to teach. I propose, therefore, for your consideration, the desirability of recommending that each school of dentistry, as a part of its educational work, take steps toward the preparation of a course of instruction in dental pedagogy for the benefit of its own corps of instructors, and to afford facilities and opportunity for those interested who wish to prepare themselves for the vocation of dental teacher as a life-work.

I request that this may be accepted as a report of progress, and that the commission will, under the circumstances, grant a further period of time, in order that the subcommittee on Pedagogical Methods may submit a more detailed report upon the subjects which your honorable body has referred to it.

Respectfully submitted,
EDWARD C. KIRK,
President Committee on Education.

Commission on Bibliography and Documentation.

As stated in the last report, presented in London, the commission asked every society affiliated to the F. D. I. to collect books, treatises, dissertations, etc., for the Federation Library. The results did not answer our expectations. However, we have the pleasure to thank Dr. Sebastian Carrasquillo of Bogotá, Republic of Colombia; Dr. Manuel Arteza of Bogotá; Prof. T. Cancela of San Paulo, Brazil; Albert Patino, director of *Odontología Columbiana;* Dr. Aguilar of Madrid; Alfred Lichtwitz of Güben (Germany); the Dental Faculty of Bogotá; The S. S. White Co., and also some anonymous donors.

Recognizing the influence of the press, the commission this year sent to the 108 dental publications of which the address was known, a notice as follows:

Dear Sir,—I would feel obliged if you would insert the following communication in your paper. I beg also to call your attention to the advantage and importance of sending your publication to the Commission of Bibliography and Documentation of the "Fédération Dentaire Internationale." A complete collection of all that has been published finds its place there, and could be consulted by the dentists of the whole world.

This commission of the F. D. I. is established at 3*bis* Rue de la Régence, Brussels, Belgium (Palais des Beaux Arts), and all books, newspapers, pamphlets, catalogs, engravings, or photographs relative to the dental art should be sent to this address.

Many papers inserted this communication, and the thirty-two following journals undertook at once to send copies regularly to the library:

Archiv für Zahnheilkunde (Dresden) *Deutsche Zahnärztliche Zeitung* (Berlin), *Deutsche Zahnärztliche Wochenschrift* (Berlin), *Journal für Zahnheilkunde und Zahntechnik* (Berlin), *Zahnärztliche Rundschau* (Berlin), *Zeitschrift für Zahnärztliche Orthopedie* (Berlin), *Internationalen Archiv für offentliche Mundhygiene* (Strassburg), *Odontologische Revue* (Prague).

Dental Cosmos (Philadelphia), *Items of Interest* (New York), *Dental Digest* (New York), *Dental Review* (Chicago), *Dental Summary* (Toledo, Ohio), *Oral Hygiene* (Pittsburgh).

British Dental Journal (London), *Dental Record* (London), *Dental Surgeon* (London), *Edinburgh Dental Student* (Edinburgh).

Journal Odontologique de France (Paris), *Le Laboratoire et le Progrès dentaire* (Paris), *Le Monde dentaire* (Paris), *L'Odontologie* (Paris), *Revue générale d'Art dentaire et Revue odontologique* (Paris).

La Odontología (Madrid).

Le Journal Dentaire Belge (Brussels), *Le Progrès Médical Belge* (Brussels).

Tydschrift voor Tandheelkunde (Amsterdam).

Revista Italiana de Odontojatria (Naples).

Praktijeskoe Zubowratschennais (Odessa).

Boletin mensual de la Sociedad Odontologica del Uruguay (Montevideo).

La Odontología Colombiana (Bogotá).

Revista Dental (Havana).

Besides the *Archiv für Zahnheilkunde*, of Dresden, the *Internationalen Archiv für offentliche Mundhygiene*, of Strassburg, sent us a complete set of their publications, and the *Revista Italiana di Odontojatria*, of Naples, has promised the same. Consequently our library is from this moment well furnished with periodicals, and the F. D. I. may congratulate itself upon this brilliant *début*. In its name I heartily thank the editors of these publications. These collections will offer to us an always increasing interest, for you know how difficult it is to obtain complete sets after some years.

The commission intends to make another appeal to the press, and will keep itself informed of new periodicals, and thus hope to be able to furnish next year a complete return as to dental journals issued in the whole world.

The commission has associated itself with the Commission Centrale de l'Union des Associations Internationales, to which 132 organizations belong. It has been shown necessary to centralize the international movement and so endeavor by every means to extend the relations and common action between all associations which represent this movement, each in its own sphere. Its first duty is to discover means to bring about co-operation and agreement on questions of unification and standardization in nomenclature, terminology, and documentation, and also in international publications.

In order to extend its services the commission asked the official representatives of the F. D. I. to appoint in each country a member to participate in its work. Messrs. E. C. Kirk (Philadelphia), J.

Ottesen (Christiania), C. van der Hoeven (The Hague), and Elof Förberg (Stockholm) have kindly offered their assistance, and we are personally grateful to them. We beg to propose as members of the Bibliographical and Documentary Commission of the F. D. I.:

Harald Ramberg, Arsenalsgatan, 8B, Stockholm, recommended by Elof Förberg.

L. Frank, Stationsweg 35, Rotterdam, recommended by C. van der Hoeven.

A. Joachim, 17 Rue de Dublin, Brussels, recommended by E. Huet.

Sigurd Henrichsen, Lillehammer (Norway), recommended by E. Ottesen.

R. H. Riethmüller, Lock Box 1615, Philadelphia, recommended by E. C. Kirk.

We await the answers of the following countries: Argentine, Australia, Brazil, Canada, Chile, Colombia, Cuba, Denmark, England, Finland, Italy, Japan, Mexico, Russia, Spain, Switzerland, Uruguay.

Emile Huet,
Pres. Commission on Bibliography and Documentation.

EDITORIAL DEPARTMENT.

DENTISTRY AS A DEPARTMENT OF THE PUBLIC HEALTH SERVICE.

WE have received through reliable sources information that the Board of Aldermen of New York City has recently taken official action placing dental service directly in line with the various other public health activities of the great metropolis. We are informed that—

> On recommendation of Dr. E. J. Lederle, Health Commissioner of New York City, the Board of Estimate and Apportionment has appropriated the necessary funds to employ ten (10) dentists by the Department of Health in the division of Child Hygiene, and one (1) dentist in the division of Communicable Diseases. The Board of Aldermen has also passed this and it has been approved by Mayor Gaynor.
>
> In the division of Child Hygiene, nine (9) of the dentists will receive $1200 and one (1) will receive $1500. The one in the division of Communicable Diseases is to be attached to the Otisville Home for Tubercular Diseases, which is under the management of the New York City Department of Health, and will receive $1200.

There was asked for supplies $12,000, and it is probable that this sum has been appropriated, but as the appropriations are made in such a way that some of the items go together in the division of Child Hygiene, the experts who are going over the budget are as yet unable to make a report as to whether this is the exact sum or not.

The appointments have been made from a civil service list, the same as is done in the case of the appointment of physicians for the Department of Health.

This action on the part of the health authorities of New York City marks another and decided step toward what we believe must ultimately be the disposition of the relationship of dentistry to the public health service, viz, by making dentistry a regular and official factor in the work of municipal and state departments of public health. In its pioneer stages the public health service of dentistry necessarily depended upon volunteer organizations of dental practitioners to carry on the work, but each instance of the official recognition of the importance of dental treatment in the public health service becomes a valuable precedent which greatly simplifies the matter of extending such service until all health boards shall have practically included dentistry as a part of their legitimate work.

Philadelphia, we believe, was the first municipality of importance to take the step. The work inaugurated in that city in 1908 has, under the fostering care of the municipal health department, constantly grown, until there are now, besides the central City Hall clinic, three branch clinics held at various localities in the city, utilizing the services of twelve salaried operators, with an increasing demand for the further extension of the free dental service. Wherever the city authorities have established a municipal dental service the demand for its extension has naturally followed. Dependence upon voluntary effort for the efficient maintenance of public dental clinics must always constitute a factor of uncertainty. The only guarantee of permanence is the incorporation of dentistry as a part of the organized health service.

Moreover, the official recognition of the value of dental service which is clearly implied in its connection with the organized health work of the municipality and state tends to give to dental service its proper status as a health measure, and to its representatives a professional standing to which, by the very nature of their work, they are justly entitled, but which has previously failed of recognition for the simple reason that its importance has not been either generally understood or recognized by the medical profession as a whole. That such recognition has now been achieved is made evident by the action which we here report upon the part of the New York board of aldermen, and that by the United States government in the passage of the laws creating a commissioned dental service in both army and navy, and by the general demand for skilled dental service growing out of a popular knowledge of the fact that the human mouth is a breeding-ground of pathogenic germs and that it is the principal avenue for the infection of the body.

THE NATIONAL RELIEF FUND.

We call attention to the circular letter of the Relief Committee of the National Dental Association which appears at page 183, this issue. Doubtless individuals can be found—doubtless will be found—who will object to the plan, the methods, even the objects, of the committee's activities. Such are to be found in connection with any suggestion or movement which has not ingrafted itself firmly as a part of the social order. Nevertheless we doubt not that the dental profession as a whole will approve of the purpose which the committee has in hand. Its object is to give needed relief to worthy practitioners of dentistry who are lacking the means to help themselves at a time and under circumstances when their ability to help themselves is a rapidly vanishing quantity.

It is all very well and comparatively easy for any of us to take the ground that had these unfortunate members of our profession been more frugal, or had they not wasted their substance in various ways which those who are wiser may deem foolish, their lot would not have been so unfortunate. On the other hand, we are dealing with a condition, not a theory in such cases, and a theory will not provide clothing, food, or shelter in the same practical way that the necessary current coin of the nation will produce. It is naturally difficult to realize that the need of the needy is of very much importance when we do not happen to have a personal acquaintance with the needy ones. When, however, we view the question from the standpoint of the individual involved, or when we have him at very close range, he is a different-looking proposition. He then constitutes not only a direct appeal to our sympathy and generosity, but in a very definite sense his relief becomes a professional duty.

It might be interesting for the dental profession as a whole to consider what an imposing bulk of sustenance would be represented by one, five, or ten per cent. of the money value of the food annually consumed at professional banquets, having little other usefulness than the securing of a so-called "good time" to the participants. If ten per cent. of the total amount annually expended by the dental profession in America for food thus consumed, and the necessary expenses incident thereto, were diverted to the sustenance fund of the National Relief Committee whose appeal we have here referred to, it would probably take care of all of the indigent and superannuated members of our profession for the balance of their lives. A few per cents. of well-selected self-sacrifice upon the part of the major portion of the dental profession, who can well afford to make it, is all that is necessary to eliminate the discomforts of the indigent of our profession. Why not do it?

BIBLIOGRAPHICAL.

A MANUAL OF CHEMISTRY. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-book specially adapted for Students of Medicine, Pharmacy, and Dentistry. By W. SIMON, Ph.D., M.D., Professor of Chemistry, Coll. of Physicians and Surgeons, Baltimore, and Baltimore College of Dental Surgery; Emeritus Professor, Maryland College of Pharmacy; and DANIEL BASE, Ph.D., Professor of Chemistry, Univ. Maryland. New (10th) Edition, enlarged and thoroughly revised. Octavo, 774 pages, with 82 engravings and 9 colored plates illustrating 64 chemical tests. Cloth, $3.00, net. Philadelphia and New York: Lea & Febiger, 1912.

On the appearance of the eighth edition of this work, in 1905, we said concerning it that "It is a book for students by a teacher who in his particular field fully measures up to the requirement of that designation. The ground covered is no more than ought to be well traversed by every student of medicine, pharmacy, or dentistry whose knowledge of chemistry is intended to be part of his working professional equipment and not a mere pretense. A careful examination of the work suggests the thought that no one thing or influence could contribute more to the solid advancement of the dental profession than that each of its members should make the contents of this book a part of his intellectual equipment and attain the same facility in the use of its contained information as he makes of his knowledge of technical dentistry. We are of opinion that the crying need of dentistry today is a better and more thorough training in the data and science of chemistry. Simon's book is a means to that end."

Our favorable opinion as above expressed in 1905 is strengthened and further borne out by the improved and revised edition before us. Much interesting, valuable, and important matter has been added to the tenth edition. In a new chapter on the Theory of Electrolytic Dissociation are considered the later developments of thought regarding the philosophy of chemical action, the theory of ionic equilibrium, the ionization of acids, bases and salts, reactions on the ionic basis, activity of acids and bases, hydrolysis of salts, neutralization, electrolysis and Faraday's laws, etc., electrolytic solution, tension of metals, principle of the storage battery and ionic explanation of the action of indicators. Articles also appear upon exothermic and endothermic reactions, reversible reactions and chemical equilibrium, thermo-chemistry, the solution of gases and Henry's law, freezing-points, boiling-points, Raoult's law, and the laws of osmotic pressure.

After a careful and critical examination of the text, we believe that the work has been brought thoroughly up to date and is fully in accord with the latest advancements of chemical science. The authors state it as their object—"to furnish to the student in concise form a clear presentation of the science, an intelligent discussion of those substances which are of interest to him, and a trustworthy guide to his work in the laboratory." We know of no work of the same scope that so fully accomplishes these desirable purposes.

Text-book of Human Physiology, including a Section on Physiologic Apparatus. By Albert P. Brubaker, A.M., M.D. Fourth Edition, revised and enlarged. Price, cloth, $3.00. Philadelphia: P. Blakiston's Son & Co., 1912.

The subject-matter included under the general term Physiology is so extensive in amount and so broad in its relationships that the task of preparing a comprehensive presentation of it for the instruction of students and practitioners of medicine is by no means an easy one. The author of the present work fully recognizes this difficulty, but his long experience as a teacher of the subject has eminently fitted him for producing what he has accomplished in the present work—a practical exposition of physiology from the point of view of the needs of the student and the practitioner of medicine, the kind of physiologic knowledge which, when possessed by the practitioner, enables him to better understand and to more intelligently solve the disease problems with which he is confronted in the regular routine of his practice. Furthermore, the author has succeeded in accomplishing a condensation of the enormous mass of data at his disposal, not merely for the purpose of a concise rendering, but to produce a practically useful work by careful selection of the essential and more important parts of the subject and the elimination of special and more abstruse matters which more fittingly constitute the field of study of the physiological specialist.

The book is an acceptable presentation of its topic that will be appreciated by all who wish to acquire a knowledge of the essentials of physiology.

Hints, Queries, and Comments.

ORTHODONTIC REGULATION IN COMBINATION WITH TREATMENT FOR PYORRHEA ALVEOLARIS.

To the Editor of the Dental Cosmos:

Sir,—I am forwarding some photographs, which are interesting in that they show the results of an operation which may be made to accomplish a double purpose—first, to cure a pyorrheal condition, and second, as an orthodontic measure.

In the case illustrated the upper right central had both extruded and protruded, and the left central and lateral had separated as the result of a pyorrheal inflammation. The relative positions of the teeth referred to are shown previous to operation in Figs. 1 and 2. The left central and lateral were brought in correct alignment with ligatures. The right central was then extracted, the root-socket deepened, and after thorough preparation of the tooth for replantation in the usual way—with the exception that nothing stronger than bathing with normal salt solution was used for antiseptic purposes—the

Fig. 1.

Fig. 2.

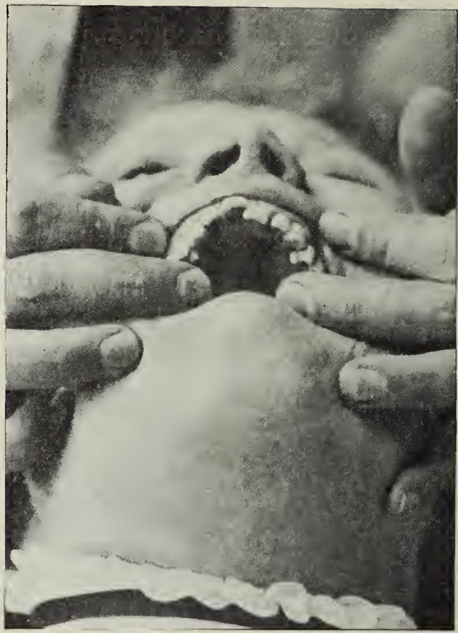

Fig. 3.

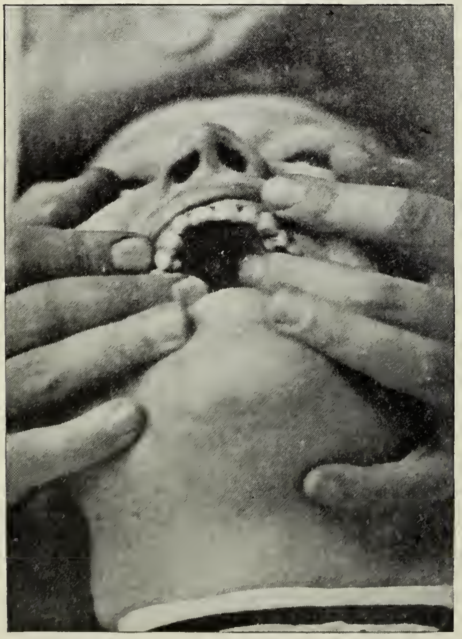

Fig. 4.

tooth was replaced, and retained in position by ligatures until complete fixation ensued as the result of healing of the tissues after the operation. (See Figs. 3 and 4.)

Dr. Emeis, a dentist of Logan, Utah, and son of the patient, informs me now, ten years after the operation, that the tooth is in perfect position and condition. I have done quite a number of these operations successfully.

When, for some reason or other, an incisor begins to extrude and protrude, which frequently occurs when there are no other indications of pyorrhea in the mouth, I feel that it is a better operative procedure to adopt the replantation method than to mutilate sound approximal teeth in an effort to adjust a permanent splint for the purpose of retention.

I thought that possibly the report of this operation, illustrating a practical method of dealing with these annoying cases, might be of interest to the profession at large, for, while I have heard frequently of replantation for the sake of curing pyorrhea, I have seen no records indicating that the operation has been used also as an orthodontic measure.

W. Leon Ellerbeck, D.D.S.

Salt Lake City, Utah.

GUM SECTIONS "HARD ON THE GUM."

One objection to the use of gum sections is the great thickness of the plate under the upper lip, which renders them unsuitable for use in many cases.

By the use of the rigid strengthener behind the six upper anterior teeth as advocated by me in Dental Cosmos for April 1912, in a communication entitled "How to Prevent Fracture of Gum Sections," this objection can be obviated. The six anterior teeth are fitted closely to the gum, that is, without vulcanite behind or over them. Previously, the joint betwen the incisors opened and appeared very unsightly, owing to the warping rubber, and it is with the purpose of preventing this that vulcanite is built up behind and above the facings. But the strengthener attains the same aim, and permits of dispensing with the vulcanite, if desired.

In setting up the teeth the front of the model is cut away or deeply scraped, and when the case is fitted in the mouth, any surplus rubber which has flowed behind the front sections is cut away with burs, and any portion of the plate where the porcelain presses too hard—as can be seen by the blanching of the gums—is relieved by a carborundum stone.

That portion of the strengthener referred to, which is to lie behind the six anterior teeth, is made of No. 11 platinoid wire, thinner wire being soldered to its ends, behind the bicuspids.

The above method is applicable only for upper plates.

J. L. Elphinstone, D.D.S., L.D.S.

Aberdeen, Scotland.

THE USE OF MODELING COMPOUND.

Granted that the operator knows how to soften modeling compound properly, and how to fill the tray therewith, before inserting the filled tray in the mouth, the surface of the softened compound is coated lightly with vaselin. Then the inverted tray is held over an alcohol lamp, moving it quickly about so that the compound does not become blistered from the heat.

This coating of vaselin serves a double purpose: First, it seems to make the surface of the material softer, and second, it prevents the impression from sticking to the teeth and becoming distorted in being removed from the mouth. The best white vaselin should be used for this purpose. It is melted by placing the bottle containing it in warm water, when a few drops of oil of wintergreen or oil of peppermint are added. This will be found to improve the taste of the compound, which the patient will appreciate.

After the impression has been removed from the mouth and thoroughly cooled in cold water it should be washed with soap and water, to remove all traces of mucus and saliva. A round paintbrush will be found useful for getting into all the depressions of the impression.

After washing, the impression should be immersed in a 1:500 solution of mercuric chlorid, for ten minutes. As the compound is contaminated only on the surface, this solution will thoroughly sterilize it, and it may safely be used again. Before pouring the cast the impression is placed in running water for a short time, in order to remove all traces of the mercuric chlorid.

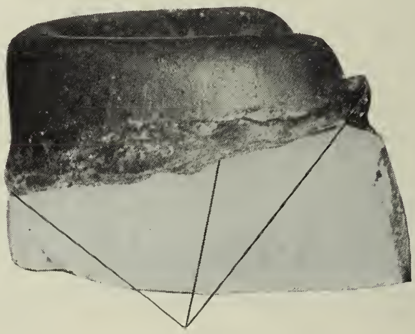
After the poured cast has thoroughly hardened, any compound which may overlap the tray is cut off, and the tray is cooled with cold water. By gently tapping on the handle, the tray can be removed from the impression as clean as before it was used.

We now have the model in the compound impression (Fig. 1), and now is the time to trim the model to the desired form, as there is no danger of damaging the teeth so long as they are covered with the modeling compound. After the model has been trimmed to the desired form (Fig. 2), a groove (Fig. 2, *a*,) is cut under the edge of the impression material. This removes the sharp edge of plaster, which will otherwise break off and mix with the compound when the latter is removed from the model.

We are now ready to separate the model from the impression. The whole is placed in warm water, and when the compound is warmed through, it can be removed from the cast, clean, free from bits of plaster, and sterilized. All that remains to be done is to mold it into cakes for further use. If the operator starts with clean, unscratched trays, all the future polishing necessary can be done with a woolen cloth.

Fig. 1.

Fig. 2.



The operator should study the compound which he is using, note its behavior and the temperature at which it works best, and learn the proper amount to use for a given case. If he does not obtain good results, the compound may be at fault, but the chances are equal that he is himself to blame.

THERMO-STERILIZATION OF ROOT-CANALS. A METHOD OF STERILIZATION WITH SODIUM DIOXID, PERMITTING OF FILLING AT ONE SITTING. By Dr. H. Mainguy, Nantes.

At the French Congress of Stomatology of 1911, Zsigmondy of Vienna described his method of enlarging root-canals with the aid of sodium dioxid, which was reviewed at length in Dental Cosmos, January 1912, p. 126. His procedure was based on the decomposition of sodium dioxid in the presence of water, resulting in the formation of sodium hydrate, which dissolves the organic matter in the dentin around the root-canal.

Mainguy starts from the observation that if hot air is blown upon sodium dioxid powder mixed with glycerin, or if this mixture is touched with a red-hot metal point, it ignites with the production of heat and vapors. He puts the tooth under rubber dam, carefully protects the patient's neck and chest with napkins, and then prepares the tooth so that easy access can be obtained to the root-canal. If in the apical region of the tooth vital pulp fibers are left, they are to be anesthetized with novocain and removed. The instrumentarium for the sterilization of the root-canal consists of a glass or agate slab, a firmly closed dropping bottle, half filled with glycerin, barbed root-canal broaches and reamers, a lead bottle containing the sodium dioxid, a hot-air and a water syringe. A broach dipped in a paste made of glycerin and sodium dioxid is introduced into the root-canal or canals of the tooth, and the root-canal is thus disinfected by a combination of thermal action, dehydration, and the production of nascent oxygen. The canals are then washed with alcohol, dried, and filled by one of the approved methods. If no serious pericemental lesions are produced by this deflagration of sodium dioxid, as we are inclined to believe will occur, this method seems as feasible as the potassium and sodium method of Schreier.

THE PREPARATION OF MANUSCRIPTS FOR PUBLICATION. [Editorial.]

WHY SOME MANUSCRIPTS ARE RETURNED. [Editorial.]

The *Journal's* frank editorial suggestions in regard to authorship and preparation of a paper contain so much truth and valuable information for active and prospective authors that their reprint in a dental journal cannot be but of benefit to authors and publishers alike.

The preparation for publication of the many papers read in annual meetings, not to mention the volunteer contributions, is a more formidable task than many imagine. It is not probable that even authors who are extremely careful in the preparation of their manuscripts realize the amount of editorial work required on them before they are ready for the printer. With a little care and attention to a few simple suggestions, this labor could be greatly lessened, while no more work would be imposed on the writers of papers. It would, of course, require too much space here to mention all the points to which author's may profitably give special care. Attention, however, may be called to two or three points. It is almost needless to say that in this day manuscripts should be typewritten; in fact, nearly all of them are so prepared. But many are written in whole or in part with single spacing—an inexcusable fault, since double or triple spacing, which gives more room for adding subheads, directions to printer, etc., is just as easy. A third matter to which attention should be called concerns references to other papers or authors. It is better to treat bibliographic references as footnotes; and all footnotes, bibliographic or not, should be numbered consecutively in a single series from the beginning to the end of the paper. This may seem trivial, but is really important. If the author wishes to refer, further on in his article, to an author and publication already cited in precisely the same manner, he need not repeat the footnote, but should merely use the reference number already assigned to that particular footnote. In the manuscript the footnotes may be placed at the bottom of the pages or at the end of the paper. Care in following these few simple directions and in reading manuscripts over after they have been copied will earn the undying gratitude of manuscript editors, compositors, and proofreaders, not to mention the "ultimate" readers. It will also repay the author with the consciousness of having produced a creditable piece of work.

The sorrow of an author whose manuscript is returned—deep though it be—cannot be compared to that of the manuscript editor who, without the "justified" enthusiasm of the author, guided merely by the cruel spirit of analysis, stumbles over a "sentence" of this character:

"It is indeed true that in the height of the inflammatory process, during the moist stage Staphylococci are found in the secretion and it is also possible by some trifling traumatism to allow the penetration of Staphylococci into the limp spaces of the cutest and there owing to disintegration of the bacterial body antitoxins are set free."

The article from which the above was quoted also contained the following remarkable examples of orthography: "Persistent skin" (resistent skin); "accatete" (acetate); "a two edge sword"; "antipruric"; "suborrhic"; "a leader" (liter) of water; "Sophlicoccus"; "pussular condition." And yet some authors wonder why their manuscripts are returned!

The foregoing is gratifying evidence that not only dental journals have their trials.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, September 1912.]

THE THERAPY OF PULP DISEASES. By PROFESSOR BOENNECKEN, PRAGUE.

Starting from the opinion that every pulp extirpation is really only a pulp amputation, owing to the fine ramifications of the dental pulp, especially at the apical foramen, as Fischer and others have proved convincingly (see DENTAL COSMOS, June 1912, p. 722), Boennecken demands that every root-canal, after the pulp has been devitalized with a paste of arsenous oxid and cocain equal parts, and eugenol, and extirpated as far as possible with a Donaldson root-canal broach, shall be sealed with a paste which will reliably sterilize and mummify the remnants of infected pulp tissue, which are sure to be present, especially after pulpitis. For removing the necrotic pulp tissue he employs aqua regia in all accessible root-canals, claiming the following advantages for this method: This strong acid decalcifies the microscopically minute lime concrements which are present in every diseased pulp, thus rendering even the buccal canals of upper molars and the mesial canals of lower molars passable for a fine broach—barring abrupt deviation of the root from normal direction, pulp-stones attached to the root-canal wall, and canals entirely blocked by secondary dentin, as found in old age. Aqua regia devitalizes the remnants of vital pulp tissue left at the apical foramen or in very narrow root-canals after attempted total extirpation, and prevents the recurrence of pulpitis after root-canal treatment. Aqua regia in its disinfectant power is surpassed only by thymol. After devitalization, the pulp-chamber is opened with a sharp rosehead bur, the débris is flushed away with warm water, the tooth is put under rubber dam, and all pulp tissue that can be reached is extirpated with Donaldson broaches. A few drops of aqua regia are then introduced into the root-canal in the jaws of fine tweezers, capillary attraction aiding in the introduction in upper teeth, and the aqua regia is pumped to the apex with fine smooth Donaldson broaches, which, in larger canals, may be wrapped with a very small strand of cotton. After all pulp débris has been thus carbonized, and not the slightest sensation is left in the root-canal, sodium hydroxid in powder form is introduced into the canal by means of a moistened smooth broach, thereby neutralizing the two acids in the aqua regia, dissolving the albuminates and saponifying the fats. The canals are then dried with thymol-alcohol, thymol paste is introduced, and the canal filled with paraffin. (See H. Prinz, "Filling Root-canals with an Improved Paraffin Compound," DENTAL COSMOS, October 1912, p. 1081.) The experiments carried out by Boennecken in order to determine the absolute and lasting sterility of a root-canal treated in the manner described are very encouraging, and his method seems to offer the advantages of simplicity and saving in time over other much-recommended methods. In a series of 243 experiments in teeth with gangrenous pulps, thymol proved to be the strongest disinfectant, eugenol the weakest. With concentrated alcoholic solution of thymol it was possible to sterilize within thirty seconds a gangrenous and exceedingly putrid root so completely that a bouillon culture remained clear for eight days, showing that all spores even within the dentinal tubuli had been killed. Aqua regia stands second in disinfecting power, with 40 per cent. formalin next. Putrescent pulps which had been removed in their entirety from extracted teeth were completely sterilized within sixty seconds by thymol, aqua regia, and formalin alike. Far inferior to these three antiseptics are tricresol-formalin and caustic soda, which are about equal in their disinfectant power, and are closely followed by carbolic acid, chloral hydrate, and balsam of Peru, and at a considerable distance by the much weaker eugenol. From all this it appears that thymol and aqua regia deserve a place of preference in the treatment of infections of the pulp.

[*Sud-Est Dentaire*, Marseilles, October 1912.]

INSUFFLATION OF IODIN VAPOR IN DENTAL THERAPEUTICS. BY PAUL BERNARD.

A simple apparatus for the insufflation of medicated vapors, which method has always enjoyed great popularity among our French *confrères*, is described by Bernard as follows: A single-bulb glass tube with two open ends is mounted at one end with a rubber hose of convenient length ending in a rubber bulb, at the other end with one in which a short glass rod is inserted, the point of which can be molded over a Bunsen burner to any desirable shape and fineness of lumen. The bulb is charged with iodin crystals, then heated on a convenient stand over the flame of an alcohol lamp or a Bunsen burner, and as soon as the beautiful violet vapors of the iodin begin to develop, the point of the applicator tube is inserted in the cavity of the tooth to be treated, and the vapors are forced into the cavity by exerting pressure on the rubber bulb at the other end. If the mouth of the applicator tube is stopped up owing to precipitation of the iodin vapors, it can be cleaned by holding it over a flame, or by passing a broach or explorer into it. The writer reports a number of cases in which the pain incident to pericementitis and the sensation of elongation of the tooth disappeared a few hours after this iodin treatment. In deeply carious deciduous teeth and putrescent root-canals, this form of treatment seems to offer great advantages.

SOCIOLOGICAL DENTISTRY. BY S. J. RAUH, D.D.S.

RELATION OF THE CHARITIES AND CORRECTIONS DEPARTMENT TO THE DENTAL MOVEMENT. BY O. P. GEIER, M.D.

RELATION OF EDUCATION TO THE DENTAL MOVEMENT. BY DR. F. B. DYER.

RELATION OF THE SCHOOL TO THE DENTAL MOVEMENT. BY J. S. HAUER.

ATTITUDE OF THE MEDICAL PROFESSION TO THE DENTAL MOVEMENT BY W. D. PORTER, M.D.

RELATION OF THE ANTI-TUBERCULOSIS MOVEMENT TO THE DENTAL MOVEMENT. BY S. IGLAUER, M.D.

RELATION OF THE WAGE-EARNER TO THE DENTAL MOVEMENT. BY M. E. CAMPBELL.

RELATION OF CITY HEALTH TO THE DENTAL MOVEMENT. BY J. H. LANDIS, M.D.

The recognition which the oral hygiene movement has found in the medical, educational, and administrative camps is signally attested by the liberal space allotted by this medical journal to the oral hygiene symposium arranged by the Cincinnati Dental Society on April 26, 1912. The first author, chairman of the meeting, defines the oral hygiene movement as consisting of three main divisions: Educational work such as public lectures, tooth-brush drills, etc.; dental inspections, and the free clinic, which, in his opinion, should be taken over by the municipality, this policy being cheaper in the end than the child's failure of promotion in the public school.

Dr. Geier, director of charities and corrections, expresses himself as fully appreciating the helpfulness and need of dental work in the house of refuge, the first purpose of which is to restore the children to a normal physical condition.

Dr. Dyer, superintendent of public schools, is of the belief that the oral hygiene movement in schools has been the most important one for the profession as well as the children, that has transpired in the history of the dental profession. He reports that, in 1909, nine hundred and twenty children in one of the schools under him were examined, of whom less than ten had had dental attention. An examination in the same school in 1910 showed that 25 per cent., viz, two hundred and fifty children, had received dental treatment, which speaks loudly for the awakening of the people.

Mr. Hauer, school principal, testifies to the effect that the dental work done in his school has proved to be mentally, morally, and physically beneficial to the pupils, whose parents in a four-fifths majority cannot afford to pay for dental work.

Dr. Porter cites the appalling statistics revealed by dental examinations of school children, and comments upon the dispatch with which the dental profession has overcome the initial skepticism of the medical profession toward this movement. He recommends free dental treatment of children even before they have reached school age, and considers that at present there are no philanthropic movements that offer greater opportunities than this plan of looking after the physically deficient children who otherwise would be neglected. It is infinitely better to give these children a fair chance to grow up into useful, independent citizens than to organize charities for them after they have reached a state of partial or entire dependence, as a result of ailments that could have been corrected in childhood. We hear much of the awful danger of race suicide, but instead of weeping over hypothetical children, we will do much better to devote ourselves to the welfare of the actual flesh-and-blood children with which we are surrounded.

Dr. Iglauer, president of the Cincinnati Anti-Tuberculosis League, complains that the dental and anti-tuberculosis movements are greatly handicapped, because both are directed against diseases so widespread throughout the world and so insidious in their onset. The diseases which both movements seek to overcome have been with us so long, and society has become so accustomed to their presence, that by some they are regarded as almost inevitable. Familiarity with disease often breeds contempt for the same, so that preventive dentistry and medicine have to encounter the ignorance, superstition, and inertia of a public unmindful of its own best interests. Propaganda must therefore be made through lectures, the press, public clinics, and above all through the public schools, to enlighten the young and prospective adult generation of citizens and voters, because the solution and control of all movements for the public health must finally rest with the state. The formation of a national bureau of health, so long delayed but now in prospect of consummation, is a great step in the right direction, but the state and the city also have an important part to perform in this great work toward final victory over preventable diseases.

M. Edith Campbell, of the Cincinnati board of education, states that one of the most difficult tasks of her office is to convince the wage-earning girl that her health is her capital. Since all methods of reform, and attempts at class legislation toward producing the efficient, well-developed human being have failed so far, we are forced to the old wearying way—the way of the individual. The individual must be taught that only through the perfect care, conservation, and development of his physical and mental resources can he compel life to disclose its secret richness to him, and can he conquer its exigencies and rise above its sordid struggle. In such a training of the individual the dental work in public schools will be a most potent force.

Dr. Landis, health officer of Cincinnati, emphasizes the untoward influence of unhealthy oral conditions on the entire organism, and points out that defective teeth and unclean mouths mean a great financial loss to a community, because it requires children thus affected at least six months longer to complete the eight common-school grades than it does those without defective teeth. The expense incurred by public dental school clinics, therefore, is a real economy, and the oral hygiene movement will bring about more perfect physical development, greater freedom from preventable disease, a shorter average period in school, and a wider dissemination of information concerning hygiene.

CLASSIFICATION OF DENTAL CARIES. By Dr. B. Nevrezé.

[*Revue Trimestrielle Belge de Stomatologie*, Antwerp, September 1912.]

TOXICO-PATHOGENESIS OF DENTAL CARIES OF TUBERCULOUS ORIGIN. By Dr. B. Nevrezé.

These essays represent painstaking contributions to the classification of dental caries, in which the French dental profession has always taken an active interest. The author's suggestions are as follows:

Dental caries of toxico-systemic origin is due to infantile diseases, viz, to a series of lesions which evolve during two distinct periods: First, a toxic period in which toxins in the blood play the principal rôle. Second, a parasitic period, in which the saprophytic microbes of the mouth complete the destructive process. In the first period, up to the fourteenth year, the tooth is hypocalcified, owing to toxic infections producing symmetrical lacunar lesions in the form of vacuoles in the dentin, standing in fixed and definite relationship to the process of calcification in regard to chronology and topography. Such a lacunar tooth may remain intact in appearance for a long time, if the toxins are eliminated from the organism. Generally, however, the toxins reach the blood circulation, and arrest the secreting functions of the odontoblasts, as well as impair the calcific material already secreted. During the second period, the saprophytic micro-organisms in the mouth determine the destructive process, since the already demineralized tooth falls an easy prey to these micro-organisms.

Following up this theory, dental caries of toxico-systemic origin is defined by the writer as a disease of the tooth characterized by two distinct phases: A first one, in which the toxins diminish the vitality of the odontoblasts, probably by a paralyzing dynamic action upon these cells, perhaps even by actual demineralization, and a second period in which the microbes, having become hypervirulent owing to lack of resistance, destroy the enamel, dentin, and pulp. This definition points out the mode of treatment in caries of tuberculous origin, viz, therapy by tuberculin, which embraces three stages—drainage of the toxins, immunization by tuberculin, and recalcification, thus assigning to the dentist the task of immunization, instead of mere mechanical repair.

REASONS FOR THE DISCOUNTENANCING OF COWPER'S OPERATION IN THE TREATMENT OF CHRONIC EMPYEMA OF THE MAXILLARY ANTRUM. By Dr. Becker, Berlin.

Cowper's operation consists in establishing a communication between the oral cavity and the maxillary antrum through the alveolus, this artificial fistula to be kept open by means of a prosthetic appliance, until healing has been induced by irrigations. Although a great many stomatologists have in recent dental literature expressed themselves as being strongly in favor of this operation, Becker strongly discountenances it, for the following reasons: The establishment of a communication between the oral cavity and the maxillary sinus is impractical, as it is always liable to permit of a reinfection. The small aperture created does not permit of a thorough removal of all granulations. The wearing of a prosthetic appliance is fraught with all sorts of inconvenience and untoward effects upon the oral tissues. Moreover, at least one tooth must be sacrificed, and the treatment is an unduly prolonged one. For these reasons a radical operation is strongly indicated, as it allows of easy examination of the entire antrum, and, if necessary, of the ethmoid bone, which is frequently also affected. The Luc-Caldwell operation offers the best advantages in this respect. Still, radical operations should not be undertaken until medicinal treatment and endo-nasal operation have proved to be failures.

DIATORIC CROWN WITH PIVOT FOR BICUSPIDS. By Dr. J. E. Boitel, Neuchâtel.

The root is prepared, and a platinum ferrule adjusted of one-tenth millimeter thickness and from four to five millimeters height, which is trimmed down on the labial surface. A plaster impression is then taken, and an articulating model poured. A diatoric bicuspid tooth is then ground to an approximate fit upon the root, leaving, however, enough space for a metal base. The tooth is then articulated by grinding its base, tried in the mouth, and invested in plaster together with the ferrule, with its masticating surface down. A platinum base of one-tenth millimeter thickness is then fitted in the ferrule against the base of the tooth, and fastened with wax. Both base and ferrule are removed from the plaster, invested in investment material, and soldered together with pure gold. A hole is then punched in the base, corresponding to the direction of the root-canal, a small platinum tube is adjusted in the hole, the lumen of this tube corresponding to the countersunk aperture in the diatoric tooth, and the tube is soldered to the base with 20-karat gold. Ferrule and tooth are then tried once more on the root, the tooth is removed, and a pivot inserted through the base in the root-canal, fastened to the platinum tube with wax, removed together with the cap, invested and soldered. In this way a ferrule, base, pivot, and tube are obtained in one piece, insuring ample root-protection and stability of the cap as well as the diatoric after both have been cemented in place on the root.

[*Zahnaerztliche Rundschau*, Berlin, Nov. 21, 1912.]

PYORRHEA ALVEOLARIS AMONG THE NATIVES OF EGYPT, AND TREATMENT. By Dr. J. Bauer, Cairo.

The author reports of his experiences extending over ten years among the Arabic, Coptic, and Sudanese population of Egypt, who exhibit a remarkable prevalence of alveolar and gingival diseases. These people are chiefly vegetarians, and eat a great deal of raw vegetables, rarely meat, and then only mutton and poultry, and abstain from alcoholic beverages. Despite this apparently rational mode of life, Bauer has observed pyorrhea alveolaris due to gout or diabetes in 80 per cent. of his adult native patients. The application of pyocyanase* was followed soon by recurrences of the disease, and was therefore given up. Mild cases were treated by scaling off any salivary or serumal calculus present, and introducing aromatic sulfuric acid into the pockets until the flow of pus ceased. In advanced cases the gingiva can be cut, and all necrotic parts removed. This, however, requires subsequent suturing of the gingival flaps, and is impracticable in posterior teeth, especially on the buccal side. A more practical method of treatment is as follows: A fine and long platinum loop is fitted to a galvano-cautery, and inserted under the anesthetized gingiva, until the end of the loop has reached the alveolar process. After a little practice, necrotic portions of the alveolar process are easily recognized by the touch, and the infected portions are cauterized by turning on the current. The pain is insignificant, provided the cauterizing is done at repeated short intervals. If a few days after the cauterization minute globules of pus can still be expressed, the pockets are treated with aromatic sulfuric acid. If the patient pays strict attention to oral hygiene, and all diseased portions of the alveolus have been thoroughly cauterized, a complete cure is effected, provided that, from the very beginning of treatment, all loose teeth have been immobilized.

If, for instance, two teeth are loose, two adjoining teeth on each side are put under the rubber dam with well-waxed silk ligatures applied high up on the cervices. The isolated teeth are then cleansed of fatty adhesions by benzin, dried with cold air, washed with alcohol to make sure that no impurities remain on the teeth, and then dried with hot air. Starting with a firm tooth, the isolated teeth are then carefully and firmly wrapped with from three to five windings of continuous surgical silk ligature, the interproximal space is filled with tightly drawn knots, leaving enough space between the gingival papilla and

---

* For literature on pyocyanase in dentistry, see Dental Cosmos, November 1909, p. 1344; February 1910, p. 243; July 1910, p. 806.

the crown to allow of convenient cleansing of the interproximal space and approximal surfaces, and a strong continuous splint ligature uniting all the isolated teeth is thus obtained. After drying the teeth and the continuous ligature described with hot air once more, the ligatures and teeth are covered with a coat of transparent celluloid dissolved in acetone to a syrup-like consistence, and applied with a pointed orange-wood stick. After from fifteen to twenty minutes this solution is sufficiently hardened to permit of removal of the rubber dam, which is effected by first cutting the cervical silk ligatures and then slitting the rubber dam away from the teeth. These silk-celluloid immobilizing ligatures keep for a very long time, present an esthetic appearance, can be easily repaired, and are very much cheaper than swaged or cast gold splints.

A report of several cases from practice concludes this attractive communication.

PERISCOPE.

Protecting Patient's Cheek in Applying Rubber Dam.—Most patients appreciate having their face protected while the rubber dam is in position by placing small pieces of cottonoid between the holder and the cheek. —G. MUNROE, *Dental Review.*

How to Steady the Engine Handpiece.—About three inches of rubber tubing, such as is used for fountain syringes, is stretched over the handpiece, leaving about one-half inch of space between the tubing and the point where the burs are inserted. This rubber can be cleaned easily with a wet cloth and a little soap.—C. H. WACHTER, *Dental Review.*

Removing a Shell Crown Without Mutilating.—A small hole is drilled bucally just below the occlusal surface of the shell crown, and an old instrument with a slightly curved point is inserted into the hole. By using the surface of the root as a fulcrum, it is surprisingly easy to remove the crown from the root. The hole in the shell crown can easily be repaired.—H. R. S. TAYLOR, *New Zealand Dental Journal.*

Enlarging Narrow and Tortuous Root-canals.—If there is a sharp turn in a root, and a reamer is forced beyond this curve and twisted, it is liable to break. In order to avoid this accident, it is good practice to ream out the first two-thirds of the canal only by means of a Kerr broach, and depend on ordinary barbed or plain broaches for clearing the apical third of the canal. —C. E. FELLMAN, *Dental Digest.*

Pouring Perfect Dies of Melotte's Metal.—In pouring dies of Melotte's metal the metal is often either too hot or too cold, or the bismuth has been burnt from the metal, all these factors producing imperfections in the dies. In order to obtain a sharp die, the metal should be poured into a rubber ring, and just before it hardens pressed on firmly with a glass pestle of about the size of the rubber ring. A die made in this way will be smooth and free from bubbles. —L. C. HOLLAND, *Dental Summary.*

Schiller's Skull.—Professor Froriep, the anatomist, has succeeded in identifying the skull of the poet Schiller among a confused mass of bones in the crowded Weimar Cemetery, principally by means of his teeth, of which he is known to have lost only one, a lower left bicuspid. The flawless strength, beauty, and regularity of the teeth is remarkable, especially so when one remembers that Schiller was "ailing" for the greater part of his life, and that his last years were overcrowded by persistent ill-health.—*Archiv für Zahnheilkunde,* per *Dental Record.*

Oxygen Poisoning.—Bornstein has been experimenting with animals to determine the conditions permitting life in an atmosphere of hydrogen. He knows of only one case of actual oxygen poisoning in man, and this was on himself while he was studying the subject. The oxygen seemed to affect the lungs exclusively in his experiments; the alveoli were filled with effusion. The experiences reported justify the conclusion that man can stand oxygen at a pressure of two atmospheres for twenty or thirty minutes without harm, which is of interest in connection with general anesthesia.—*Deutsche Med. Wochenschrift* per *Journal of Amer. Med. Association.*

Protecting Gum Margins in Crown Work.—To protect the gum margins around a root prepared for a cast Davis crown between sittings, a small piece of gutta-percha is warmed sufficiently to make it plastic. The root is dried thoroughly, and the gutta-percha is molded to place. To insure the permanence of this covering until the next sitting, a very small tack can be used. The tack is warmed in a flame, pressed through the gutta-percha, and inserted in the root-canal, thus holding the gutta-percha firmly in place.—A. E. De Riemer, *Dental Review.*

Care of the Head-rest of Dental Chairs.—The head-rest should be given most careful attention. No patient likes to rest his or her head on a soiled head-rest, or on one that has been used by another person. Clean linen should be placed on the head-rest after each patient. The writer has found the use of hygienic head-rest pads made of paper equally good. These paper pads are made of heavy crepe paper, one hundred sheets making up one pad. If the sheet that has been used is torn off the pad in the patient's presence, a most pleasing impression is made upon the patient.—J. P., *Western Dental Brief.*

Prophylactic Treatment of Hemophiliacs.—The extractor must know what to do when given a history of predisposition to hemorrhage, in order that when he extracts he may feel assured that everything has been done that could have been done. In these cases extraction should be avoided if possible, but if the removal of the tooth be absolutely necessary we must proceed with a prophylactic method of treatment for about seven days prior to the operation.

This should consist of the administration of calcium lactate in doses of 10 to 15 grs. The operation should be performed in the morning, thus giving the whole day for treatment should hemorrhage occur, the wound to be immediately plugged as a preventive, coupled with the administration of some hemostatic such as the continuance of the lactate, for it is obviously easier to prevent hemorrhage occurring than to arrest it when once it has commenced. The subsequent treatment consists in the continuance of the hemostatic.—W. A. S. Hills, *Dental Record.*

Suggestions on Bridge Work.—The clinician's method does not differ from the ordinary procedure until the abutments are made and mounted. Then the space to be bridged is filled with wax; the opposing teeth, which are mounted on the articulator are closed, and the cusps carved up. The Steele's backings and facings are then mounted in proper relation, the investment is removed, the wax boiled out and crystal gold packed in its place. The investment is then dried out carefully, and sufficient solder sweated in to fill the crystal gold, and to secure attachment to the abutments. The bridge is removed from the investment and polished, and the facings are cemented to place.—J. N. Stewart, *Dental Practice.*

Melting Platinum.—Lime has been found the best material for crucibles for melting platinum. It is about the only material that will stand the high heat of the oxyhydrogen blowpipe. Pieces of burned lime are selected as free from fissures and foreign matter as possible; a cavity is cut in a selected piece to hold the platinum, which is melted in the cavity by an oxyhydrogen blowpipe, and then allowed to cool. The button of platinum is hammered until it is thin enough to enter a pair of rolls to be rolled into sheet. Since the general introduction of the electric current the electric arc has been used for melting platinum, a carbon crucible being used. Objection has been made to this method on account of a tendency in the platinum to take up carbon at an intense heat, and thereby become somewhat brittle.—W. H. Trueman, *Dental Brief.*

Iodin in Mouth-washes.—Carles advocates the use of iodin as a mouth-wash, especially in cases of foul breath due to dental caries. One gram of potassium iodid should be added to 20 grams of iodin tincture, and of this mixture from one to three drops should be thrown into a quarter of a glass of warm water. With this solution the mouth should be carefully rinsed. The hotter the water the more drops it will carry. If iodin tincture is used alone, the iodin is separated out by the water, and clinging to the mucous membrane causes a lasting and disagreeable taste. Potassium iodid keeps the iodin in solution, and the taste becomes mild and pleasant. The drug penetrates to all the crevices of the mouth, and acts as a deodorant and an antiseptic. The lotion is to be recommended as a prophylactic to those with sound teeth, and the writer is convinced that by employing it regularly, especially at bedtime, caries can be prevented. The teeth are not permanently stained by the dilution mentioned.—*Gaz. Hebd. des Sciences Méd.* per *British Dental Journal.*

Bar Upper Partial Dentures.—Bar upper partial plates are made of a saddle of vulcanite or metal and joined together by a bar across the roof of the mouth as far back on the hard palate as possible. The bar is placed about the thickness of cardboard from the roof of the mouth, except over hard spots, when it is placed about twice that distance away. The saddles cover the ridge and project far enough down to give the plate good support. If the saddles are made of metal, the bar should be soldered to the saddle, but if vulcanite is used the bar should be flattened and notched or have holes put through it, so that it will be held tightly into the vulcanite.

A good wide clasp is about the best attachment for holding these plates, although any kind of modern attachment, *i.e.* Roach, Gilmore, and Bennet, may be used. The attachments give best service when placed on opposite angles of the case.

I have used a great many of these dentures, and can highly recommend their use whenever it is possible to use them. The patients like them because they leave the roof of the mouth practically free, interfering with neither taste nor speech. If you try them, I am sure you will be more than pleased with the results.—J. A. Bothwell, *Dominion Dental Journal.*

Cysts at the Roots of Teeth, in Origin Tuberculous.—Zilz reports four cases of cysts at the roots of teeth in which bacteriologic investigation revealed the presence of Much's granula, which he defines as the non-acid-fast form of the tuberculosis germ. The findings are profusely illustrated, and the questions discussed why it is so difficult to detect acid-fast, Gram-staining bacilli in the gangrenous pulp, and why primary tuberculosis starting in carious teeth is not of more common occurrence. He regards Much's granula as merely ordinary acid-fast tubercle bacilli which have lost their acid-fast properties; hence the organic fluids are able to disintegrate them, and the vital centers, the granula, escape into the surrounding medium. When conditions become more favorable to the bacilli, they may become impregnated again with acid-fast substance, and the acid-fast form thus develop again, which in turn may break up anew into granula. His plates show the process distinctly, the granula causing no tuberculous changes in the dental cyst. The bacilli probably found their way through the blood into the cyst, and while there remained latent, but regained their virulence when conveyed farther to lymph-nodes or lungs. Inoculation of animals with the granula always gave positive results.—I. Zilz, *Beitrage zur Klinik der Tuberkulose,* per *Journ. of Am. Med. Association.*

The Teeth of Workers in Lead.—Viktor Hinze has made observations on a large number of lead-workers in an accumulator factory. He noticed that the gums and teeth of the men who were suffering from plumbism were in a bad condition. The former were swollen, hyperemic, and infiltrated. Tartar incrusted the edges of the teeth. It occurred to him that the removal of the tartar and active care of the teeth and gums might lead to a limitation of the poison within the body. He therefore started by scraping the teeth and collecting the tartar, which he subjected to a careful chemical examination. In one case, that of a man who showed anemia, atrophy of the extensor muscles of the left hand, etc., 0.329 gram of tartar was removed, which contained 0.48 per cent. of metallic lead. In this case the seventeen teeth which the man still possessed were extracted, and thus both the tartar and the teeth could be examined chemically. The examination of the teeth showed that the crowns contained 0.038 per cent., and the roots 0.033 per cent. of metallic lead. It is therefore evident that a deposit of lead is present which suffices to keep the symptoms of lead intoxication going. On removing the tartar from the teeth of other workers in the factory, he succeeded in curing the hyperemia, tendency to bleeding, cyanosis, and boggy swelling of the gums; and several obstinate cases of gingivitis soon cleared up.—*Berlin. Klin. Woch.* per *British Dental Journal.*

The "New" in Dentistry So Old.—In the cullings from the Dental Cosmos of fifty years ago, many instructive and amusing features may be found; also one is impressed with the fact that in some of our procedures we have not advanced so much as our imagination has led us to believe was the case. Of course, as far as instrumentation is concerned, and the ease to our patients as well as to us, there are radical changes, but not always as regards results.

It is questionable whether today as large a percentage of good gold workers can be found as existed fifty years ago, and notwithstanding all the scientific theories pertaining to occlusion, lines of beauty, etc., existing today, it is doubtful if one can obtain a better-looking, better-fitting, and more artistic and useful plate than our forefathers made; in fact, plates are generally not as good, for two reasons: First, because we make comparatively few, and second, it is almost the universal custom to use plain teeth instead of gum sections.

The papers and discussions published in the volumes mentioned bring out the fact that the so-called Black cavity preparation was advocated before Dr. Black began to practice. Prophylaxis was advocated and was called "prophylactic treatment" the same as today, also was opposed then as it is now. Fee bills were advocated and condemned. The constitutional causes of caries were a favorite topic for discussion, which resulted in as much enlightenment as it does now. The dentists regretted that dental journals published so much trash simply to fill space; the same regret exists today. And last, but not least, there was an organized effort made to reorganize the National Dental Association; the same effort is being feebly made now.—*Western Dental Journal.*

OBITUARY.

DR. WILBUR F. LITCH.

Died, at his home in Ardmore, Pa., December 25, 1912, Wilbur Fisk Litch, D.D.S., M.D., in the seventy-second year of his age.

He had been in poor health following an attack of grippe in the early autumn, later developing symptoms of valvular heart trouble which became critical and alarming, so that grave concern was felt as to the outcome of his malady, but, as he subsequently rallied, hopes were entertained of his ultimate recovery. He, however, suffered a relapse, which terminated fatally on the date above stated.

Wilbur Fisk Litch was born September 18, 1840, in Eastham, Mass., of Scotch-English ancestry, his forebears being among the pioneer settlers in Plymouth colony. His father was Josiah Litch, a minister in the Methodist Episcopal Church. In consequence of the removal of his father and family to Philadelphia, Dr. Litch from early childhood was a resident of that city, and there received his education.

In 1858 he entered as a student the office of his uncle, Dr. J. M. Barstow, a practicing dentist, one of Philadelphia's most expert carvers of porcelain block teeth, under whom he had a thorough training in office and laboratory work. In 1859 he matriculated in the Pennsylvania College of Dental Surgery, from which he was graduated with the degree of D.D.S. in 1861. For three years he was a student in the private anatomical school and dissecting room of the celebrated anatomist and surgeon, Prof. D. Hayes Agnew. After being graduated in dentistry he entered upon the study of medicine in the Jefferson Medical College, and was graduated with the degree of M.D. with the class of 1864–65.

After several years of service in the medical department of the United States army, his last assignment being that of post surgeon at Fort Yuma, Cal., he returned to civil life, and in 1871 entered upon active dental practice in Philadelphia.

In 1878 he was appointed professor of materia medica, therapeutics, and principles of prosthetic dentistry in the Pennsylvania College of Dental Surgery, and in 1899 was made dean of the college. These positions he continued to occupy until the Pennsylvania College of Dental Surgery ceased its educational work at the close of the session of 1909.

Dr. Litch was a member and ex-president of the Pennsylvania State Dental Society, of the Pennsylvania Association of Dental Surgeons, and of the National Association of Dental Faculties; a member of the National Dental Association, and its vice-president for the East in 1907–08, an honorary member of the American Academy of Dental Science, a member of the Philadelphia County Medical Society, and of the American Medical Association, and for over thirty years was dentist to Girard College of Philadelphia.

To dental literature Dr. Litch's chief contribution was the "American System of Dentistry," published in 1887–88 in three volumes. Of this work, which occupied some five years in preparation for the press, he was the editor, and to it he contributed the chapters on "Anesthesia and Anesthetics," "Crown and Bridge Work," and "Metallic Facings for Carious Crowns."

The publication of the "American System of Dentistry" marked a decided epoch in the history of dental literature by gathering together in a single publication the more important developments of dental science and art which had taken place up to that time in all departments. The work was so fundamentally and so thoroughly done that with but slight alteration much of it would be considered standard at the present time. The "American System of Dentistry" produced a distinctly forward impulse toward the more rational practice of dental art, and was productive of that result largely because of the intelligence, foresight, and wisdom of its editor, Dr. Litch, in the selection of his corps of contributors, and in his editorial shaping of the character and quality of their contributions to the text of this monumental work.

In 1881 Dr. Litch read before the Pennsylvania State Dental Society a paper on "Antiseptics in Dentistry," published in the DENTAL COSMOS for February 1882, in which the value of iodin and other of the halogens as disinfectants, dependent upon their power of not only destroying germs but of decomposing putrescent gases in root-canals, was emphasized and, probably for the first time, explained in connection with dental therapeutics.

One of his practical contributions to dentistry was the half-band crown for upper incisors and canines, first employed by him in 1876, prior to the introduction of the Richmond full-band crown, and described and illustrated under the title "The Collar Crown," in the DENTAL COSMOS for September 1883.

In 1899 Dr. Litch became editor of the *Dental Brief*, in which office he continued until his death.

Dr. Litch was a thorough teacher. He possessed that characteristic which, for the lack of a better designation, is called the teaching instinct—a quality based upon keen insight into the needs and difficulties of the student mind, and the adaptation of his mode of teaching to meet those conditions in his teaching work. He was a man of high professional ideals, one who consistently lived his professional life upon the high plane that he sought to impress upon those about him, and particularly those in his educational charge. In his bearing toward his patients, his colleagues, his students, indeed toward everyone, he was always the dignified and kindly gentleman. Those who knew him but superficially often mistook his dignity and reserve of manner as evidence of a certain austerity of character, whereas, on the contrary, those who really knew and understood him were well aware of the gentleness and kindliness of his disposition, the simplicity of his character, the warmth of his regard for his friends, and his keen appreciation of all that is good and noble in life. He was markedly artistic in his tastes and temperament, a great lover of music and an intelligent musical critic, particularly in its interpretative aspects. To attend a high-class musical presentation with Dr. Litch and to listen to his comments upon the performance was not only a delight, but a real education in itself.

Measured by the best standards, the professional life of Wilbur F. Litch was a conspicuous success. It is impossible to estimate the value and importance to the profession in which he was so prominent a figure, of the effect of his direct teaching and the equally important impression which the example of his own professional life exerted upon it. There can be no difference of opinion among the very large number of men who have benefited by his influence as to the fact that the status of dentistry has been elevated to a higher plane of usefulness and a broader and more intelligent scope of activity through the career of Wilbur F. Litch. His most enduring monument will always be the continuing influence of his professional life-work.

Dr. Litch leaves a childless widow.

The funeral services were held at his home in Ardmore, Pa., on December 28th, and were largely attended by his friends and colleagues of the dental profession. The interment was private.

Brief Necrology.

Dr. I. T. MORFORD of Spencer, W. Va., on November 2, 1912, of typhoid fever, in his fifty-sixth year.

Dr. CHARLES J. COOPER of Brooklyn, N. Y., on November 18, 1912, of typhoid fever, in his sixty-fifth year.

Dr. WELLINGTON D. PIERSOLL of Philadelphia, Pa., on December 2, 1912. Deceased was a graduate of the Philadelphia Dental College.

Dr. HENRY M. CLIFFORD of Boston, Mass., on November 4, 1912, of heart trouble. Deceased was a graduate of the Harvard University Dental School.

Dr. MORGAN A. YULE of Mendota, Ill., on November 12, 1912, of stomach disease. Deceased was a graduate of the Northwestern University Dental School.

Dr. FRANCIS J. KELLY of Buffalo, N. Y., on October 30, 1912, in his thirty-seventh year. Deceased was a graduate of the Dental Department of the University of Buffalo.

Dr. EDWARD SHACKELFORD of Prattsville, Ala., on October 27, 1912, in his seventy-fifth year of age. Deceased was a graduate of the Dental Department of the Medical College of Virginia.

Dr. HOWARD SPENCER DOYLE of Louisville, Ky., on November 4, 1912, of cerebral hemorrhage. Deceased was a graduate of the Louisville College of Dentistry, and a member of the Jefferson County Dental Club and the Kentucky Dental Association.

Dr. ALBERT H. FULLER of St. Louis, Mo., on October 22, 1912, in his seventy-first year. Deceased was a graduate of the St. Louis Medical College and the Missouri Dental College, emeritus professor of operative dentistry and formerly dean of the faculty of the Washington University Dental School, member and ex-treasurer of the National Dental Association, member and ex-president of the Missouri State Dental Association, ex-president of the St. Louis Dental Society and the Society of Dental Science of St. Louis, and a veteran of the civil war.

SOCIETY NOTES AND ANNOUNCEMENTS.

NOTICE OF CIVIL SERVICE EXAMINATIONS.

City of Philadelphia.

FOR CHIEF OF DENTAL DISPENSARY, ALSO FOR ASSISTANT DENTIST.

February 20, 1913, 9.30 A.M.: Chief of Dental Dispensary, Bureau of Health, Department of Public Health and Charities. Salary $2500 per year. Duties are to take charge of the city's dispensaries. Work supervisory rather than operative. Whole time required.

February 20, 1913, 9.30 A.M.: Assistant Dentist, Bureau of Health, Department of Public Health and Charities. Salary $700 per year. Half-days' service required. Both men and women eligible.

For further information, call on or address the Civil Service Commission, Room 875, City Hall, Philadelphia, Pa.

THE PANAMA PACIFIC DENTAL CONGRESS.

As one of the attractions of the Panama Pacific International Exposition, a dental congress, international in character, to be known as the Panama Pacific Dental Congress, is to be held in San Francisco, California, beginning on the last Monday in August 1915, and continuing for ten days.

A Committee of Organization has been perfected, including representatives from the Pacific Coast states—California, Oregon, Washington, Utah, Idaho, Colorado, and Arizona.

This committee is now actively engaged in perfecting the work of organization, including the establishment of executive committees in every state of the United States and in every foreign country where dental organizations are known to exist, which will be empowered to promote the business of the congress by bringing it to the attention of their national, state, and local societies, and securing memberships and contributions to the program.

The American Society of Orthodontists and the National Dental Association, of the United States of America, have already made arrangements to meet in San Francisco in 1915 as parts of the congress, and invitations will be extended to other dental societies to take similar action.

The Panama Pacific Dental Congress is the first organization to apply to the Exposition management for space for exhibits, and to ask that a definite time be set aside for its meeting.

Manufacturers of dental goods have signified their intention to maintain during the congress the greatest exhibition of dental supplies ever held. Ample space for this purpose has already been promised by the Exposition authorities, and we are assured of their hearty co-operation in all things pertaining to the success of the congress.

The membership fee has been fixed at ten dollars, and the finances of the congress are being cared for by a corporation, formed within the Committee of Organization, and known as the "Pacific Dental Congress Commission of 1915."

Over $8000 has already been subscribed for promotion purposes by the dentists and dental societies of the Pacific Coast states, and this fund will be increased by many thousands of dollars before the congress meets.

Ample funds for promotion of the congress are assured, and in due time Committees on Local Arrangements, Transportation, Exhibits, Clinics, Program, etc., will be appointed, and everything possible will be done to insure the success of the congress and make it in attendance and scientific and professional interest the greatest dental congress ever held.

The whole world is coming to San Francisco in 1915 to participate in and enjoy the Panama Pacific International Exposition, which will commemorate the completion of the world's engineering masterpiece, the Panama Canal.

Never in the history of the profession has there been so auspicious a time for holding a great dental congress, and the Panama Pacific International Exposition Company and the Committee of Organization of the Panama Pacific Dental Congress unite in a cordial invitation to the members of the dental profession to come to San Francisco in 1915 to attend the congress and view the wonders of the Exposition and the Pacific Coast of the United States of America.

Frank L. Platt, *Ch'man,*
Committee of Organization.

AMERICAN DENTAL SOCIETY OF EUROPE.

The fortieth annual meeting of the American Dental Society of Europe will be held at Easter, in Florence, Italy. All members of the profession are cordially invited to be present. Florence is one of the most interesting cities of Europe, and Easter is the most favorable time of the year for seeing Italy.

George H. Watson, *Sec'y,*
Pariser Platz 7, Berlin, Germany.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

The regular meeting of the Academy of Stomatology of Philadelphia will be held on Tuesday, February 25, 1913, at the College of Physicians, Twenty-second st. above Chestnut, Philadelphia, Pa., at 8 P.M. Dr. John Bethune Stein of New York will read a paper on "Hypoplasia of the Teeth, of Syphilitic Origin," illustrated with lantern slides.

All members of the dental profession are invited to be present.

Norman L. Jameson, *Sec'y.*

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

The next annual meeting of the Dental Faculties Association of American Universities will be held at Harvard Dental School, Longwood ave., Boston, Mass., April 22 and 23, 1913. The meeting will be called to order on the morning of April 22d, at 11 o'clock.

Edward C. Kirk, *Sec'y-Treasurer.*

UNIVERSITY OF BUFFALO.

Dental Alumni Association.

The fourteenth annual meeting and clinic of the Alumni Association of the Dental Department of the University of Buffalo will be held in the college building, on February 14 and 15, 1913. An excellent program of essays and clinics has been arranged. Class reunions, fraternity banquets, and a general good time is assured. Ethical practitioners are invited to attend.

M. B. Eschelman, *President*,
D. H. McCoy, *Sec'y*.

CONNECTICUT STATE DENTAL ASSOCIATION.

The next annual meeting of the Connecticut State Dental Association will be held in Waterbury, April 15 and 16, 1913.

A. V. Prentis, *Sec'y*,
New London, Conn.

NEBRASKA STATE DENTAL SOCIETY.

The Nebraska State Dental Society will hold its thirty-seventh annual meeting at Omaha, Nebr., May 12, 13, 14, and 15, 1913. Several special men have been secured from without the state, besides the usual array of home talent.

E. H. Bruening, *President*,
Wm. A. McHenry, *Sec'y*.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

The forty-fifth annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May 8, 9, and 10, 1913. There will be the usual reduced railroad rates on the certificate plan.

The first session will open on Thursday at 10.30 A.M. The literary program of the meeting will be rendered in the auditorium of the Educational Building. Headquarters will be at the Hotel Ten Eyck, where the exhibits and clinics will be held.

A cordial invitation is extended to all ethical dentists in New York and sister states. Exhibitors wishing to engage space please address Dr. O. J. Gross, Schenectady, N. Y.

A. P. Burkhart, *Sec'y*,
52 Genesee st., Auburn, N. Y.

IOWA STATE DENTAL SOCIETY.

The fifty-first annual meeting of the Iowa State Dental Society will convene at Davenport, Iowa, May 6, 7, and 8, 1913, beginning Tuesday, May 6th, at 9 A.M. Elaborate clinics and lectures and a large exhibit will be presented.

Further information will be furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

Exhibitors desiring space should apply to Dr. Wm. Finn, Cedar Rapids, Iowa.

C. M. Kennedy, *Sec'y*,
Des Moines, Iowa.

INDIANA STATE DENTAL ASSOCIATION.

The fifty-fifth annual session of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, May 20, 21, and 22, 1913.

The officers of the association recently met at Indianapolis and perfected plans for a three-day "Postgraduate Course." The very best instructors and specialists are being secured for each day. The course will be as follows: Tuesday—"Humanitarian Dentistry." Wednesday—"Preventive Dentistry." Thursday, A.M.—"Prosthodontia"; P.M., a great table clinic. The clinic will also be held in the hotel.

No tuition fee for the members of the association, or visitors from outside the state who are in good standing in their state associations, but all others desiring to take this course must arrange their tuition fees with the secretary.

Otto U. King, *Sec'y*,
Huntington, Ind.

CHICAGO DENTAL SOCIETY.

Election of Officers.

At the annual meeting of the Chicago Dental Society, held at 31 W. Lake st., Chicago, Ill., the election of officers resulted as follows: Geo. N. West, president; P. G. Puterbaugh, vice-president; T. L. Grisamore, secretary; F. E. Roach, treasurer; E. D. Coolidge, librarian. Board of Directors—Wm. H. G. Logan and F. W. Gethro. Board of Censors—P. B. D. Idler, H. C. Peisch, and A. M. Hewett.

T. L. Grisamore, *Sec'y*.

ARMY DENTAL SURGEONS.

MEMORANDA OF CHANGES.

For the week ending December 14, 1912:

James F. Feely, ACT.D.S., December 3d, reports arrival at Fort Terry, N. Y., for temporary duty.

First Lieut. Frank P. Stone, December 8th, reported for temporary duty at Fort Ontario, N. Y.

Lester C. Ogg, ACT.D.S., December 5th, reported for duty at Letterman General Hospital, San Francisco, Cal.

James F. Feely, ACT.D.S., December 11th, granted twenty-five days' leave of absence.

For the week ending December 28th:

Mortimer Sanderson, ACT.D.S., relieved from duty at Fort Slocum, N. Y., and will proceed to the Philippine Islands for duty on transport sailing from San Francisco, Cal., April 5, 1913.

William A. Squires, ACT.D.S., December 19th, reported for temporary duty at Fort Lincoln, N. D.

Itineraries: Each of the following dental surgeons, with enlisted assistant, will proceed at the proper time to the posts named, and report to the commanding officers for temporary duty for the purpose of rendering dental service during the periods indicated.

First Lieut. Frank P. Stone: Ft. Ethan Allen, Vt., Jan. 2d to 27th. Ft. Williams, Me. [incl. Ft. McKinley, Me.], Jan. 28th to March 10th. Ft. Constitution, N. H., March 11th to 17th. Ft. Banks, Mass. [incl. Fts. Warren, Andrews, and Strong, Mass.], March 18th to April 29th. Ft. Rodman, Mass., April 30th to May 6th. Ft. Adams, R. I. [incl. Ft. Greble, R. I.], May 7th to June 4th. Plattsburg Bks., N. Y., June 5th to 30th.

Upon completion of this duty, Lieut. Stone and his assistant will return to Fort Ethan Allen, Vt.

Benjamin C. Warfield, ACT.D.S.: Ft. H. G. Wright, N. Y., Jan. 2d to 22d. Ft. Terry, N. Y., Jan. 23d to Feb. 12th. Ft. Totten, N. Y., Feb. 13th to Mar. 8th. Ft. Jay, N. Y., Mar. 10th to 19th. Ft. Wood, N. Y., Mar. 20th to 26th. Ft. Hancock, N. J., Mar. 27th to Apr. 17th. Ft. Wadsworth, N. Y., Apr. 18th to 24th. Ft. Hamilton, N. Y., Apr. 25th to May 12th. Ft. Porter, N. Y., May 15th to 23d. Ft. Niagara, N. Y., May 24th to June 3d. Ft. Ontario, N. Y., June 4th to June 12th. Madison Bks., N. Y., June 13th to June 30th.

First Lieut. E. P. Tignor: Ft. Dupont, Del. [incl. Ft. Mott, N. J.], Jan. 2d to 29th. Ft. Howard, Md., Jan. 30th to Feb. 13th. Washington Bks., D. C., Feb. 14th to March 10th. Ft. Myer, Va., March 11th to April 8th. Ft. Washington, Md. [incl. Ft. Hunt, Va.], Apr. 9th to May 1st. Ft. Caswell, N. C., May 3d to 14th. Ft. Monroe, Va., May 16th to June 30th.

Arthur T. Knoderer, ACT.D.S.: Ft. Thomas, Ky., Jan. 2d to 14th. Ft. Crockett, Tex., Jan. 17th to 24th. Jackson Bks., La. [incl. Ft. St. Philip, La.], Jan. 25th to Feb. 1st. Ft. Morgan, Ala., Feb. 3d to 18th. Ft. Barrancas, Fla., Feb. 19th to Mar. 10th. Ft. Dade, Fla., Mar. 12th to 19th. Key West Bks., Fla., Mar. 21st to 27th., Ft. Screven, Ga., Mar. 29th to Apr. 14th. Ft. Moultrie, S. C., Apr. 15th to 30th. Ft. McPherson, Ga., May 1st to 31st. Ft. Oglethorpe, Ga., June 2d to 30th.

For the week ending January 4, 1913:

William A. Squires, ACT.D.S., December 28th, left Fort Lincoln, N. D. on ten days' leave.

John A. Snapp, ACT.D.S., December 30th, ordered to San Juan and Henry Barracks, P. R., for temporary duty.

First. Lieut. J. J. Reddy, December 31st, reported for temporary duty at Fort Hancock, N. J.

A. T. Knoderer, ACT.D.S., January 1st, left Fort Oglethorpe, Ga., *en route* to Fort Thomas, Ky., for temporary duty.

Benjamin C. Warfield, ACT.D.S., January 1st, left Madison Barracks, N. Y., for temporary duty at Fort H. G. Wright, N. Y.

For the week ending January 11th:

First Lieut. Frank P. Stone, January 2d, returned to Fort Ethan Allen, Vt., from temporary duty.

Benjamin C. Warfield, ACT.D.S., January 2d, reported for temporary duty at Fort H. G. Wright, N. Y.

First Lieut. Edwin P. Tignor, January 2d, reported for temporary duty at Fort Du Pont, Delaware.

EXAMINATION OF DENTISTS FOR THE U. S. ARMY.

THE Surgeon-general of the army announces that examinations for the appointment of acting dental surgeons will be held at Fort Slocum, N. Y.; Columbus Barracks, Ohio; Jefferson Barracks, Mo.; Fort Logan, Colo., and Fort McDowell, Cal., on Monday, April 7, 1913.

Application blanks and full information concerning these examinations can be procured by addressing the Surgeon-general, U. S. Army, Washington, D. C.

The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-one and twenty-seven years of age, a graduate of a dental school legally authorized to confer the degree of D.D.S, and shall be of good moral character and habits.

Acting dental surgeons are employed under a three years' contract, at the rate of $150 per month. They are entitled to traveling allowances in obeying their first orders, in changing stations, and in returning to their homes at termination of service. They also have the privilege of purchasing certain supplies at the army commissary. After three years' service, if found qualified, they are promoted to the grade of dental surgeon, with the rank of first lieutenant, and receive thereafter the pay and allowances appertaining to that rank.

In order to perfect all necessary arrangements for examination, applications must be in the possession of the Surgeon-general at least two weeks before the date of examination. Early attention is therefore enjoined upon all intending applicants. There are at present a large number of vacancies to be filled.

UNITED STATES PATENTS

ORIGINAL COMMUNICATIONS.

DEMONSTRATION OF METHODS IN THE TREATMENT OF SIMPLE AND COMPLICATED FRACTURES OF THE JAW.

By H. J. KAUFFER, D.D.S., New York, N. Y.,
CONSULTING DENTIST AT HARLEM HOSPITAL.

(Read before the New York Academy of Medicine, Surgical Section, at its regular meeting, November 1, 1912.)

THERE is probably no branch of the healing art in which the operator is called upon to display more inventive genius, mechanical skill, and manipulative dexterity than in caring for a fracture of the mandible. Here each case presents an individuality, and conditions without precedent are constantly met. The surgical requirements are the same as the cardinal principles in the care of fractures of all long bones, with one exception—extension here is neither wise or necessary. Approximation and fixation, however, must be secured, and sanitation maintained; herein the mechanical and inventive ingenuity of the operator is often taxed to the limit.

No set method of splinting can be adopted. One of the recognized interdental splints with slight modifications to meet the requirements of the case in hand will usually suffice, but occasionally conditions are such that an entirely original device must be constructed, if the comfort and welfare of the patient are to be considered.

As the writer intends this paper to be wholly an original contribution, he will not go into the history of the treatment of fractures of the jaw, nor review other operators' methods, or interdental splints with which you are all familiar, but will proceed to present cases which he has selected from the great number which have come under his observation, with a view to covering entirely this branch of oral surgery.

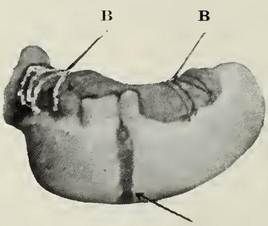
CAST ALUMINUM CAP SPLINT IN MANDIBULAR FRACTURES.

The cast aluminum cap splint adopted by your essayist (Fig. 1) is one which can be used in nearly all fractures of the mandible where the fracture extends anteriorly to the last remaining tooth in the jaw. With this splint, fixation can be maintained without immobilizing the temporo-maxillary articulation.

To make this splint, the operator should obtain a good impression of the teeth of the upper and lower jaw. It is not necessary to attempt to reduce the displacement at this time—or, in fact, until the operator is ready to insert the splint.

Plaster-of-Paris casts are made from the impressions. The cast of the mandible is fractured by sawing through at a point corresponding to the fracture or fractures. The fractured pieces are then trimmed so that they can be waxed together with the teeth in proper occlusal relationship to the teeth on the cast of the upper jaw. (See Fig. 1, A.)

FIG. 1.



When this is done, tin foil is burnished over the cast of the fractured jaw as far as it is desired for the splint to extend. The next step is to pour wax over the tin foil to a thickness determined by the strength required of the splint. Additional strength can be obtained by embedding a platinoid bar in the lingual saddle of the splint. A slight imprint of the occluding teeth is made in the wax, which is then trimmed and cast in the usual manner. Gold or silver may be used; aluminum, however, is preferred by the essayist. This splint can be made if necessary in less than three hours, and has many advantages over vulcanite.

One important feature about the author's splint to which he wishes to draw special attention is that the saddle is discontinued on the labial or buccal surface for a space of several teeth on each side of the fracture. This space enables the operator to see that, when in place, the teeth set well up into the splint as intended, and at no time can the slightest displacement occur without the operator's knowledge.

The splint is made fast by cementing and wiring. The author uses oxyphosphate of copper cement; for wiring, Angle's ligature wire is employed. Two pieces of wire from six to eight inches long are twisted together about three inches from one end; the long ends are then passed on each side of a tooth from the lingual to the buccal side close to the gingival margin, and the wire is twisted until the tooth is held firmly in the wire loop. The ends of the wire are brought from each side up over the top of the splint, twisted together, and cut off just short enough to permit the ends to be turned under the splint and out of the way. In this manner the splint is secured to the teeth in much the same way as one often sees a cork tied into a bottle. Several teeth should be used, and it is well to twist the wire from the lingual side of one tooth to the wire from the buccal side of another. (See Fig. 1, B.)

IMMOBILIZATION BY WIRING.

When the fracture is in the body of the mandible posterior to the last remaining tooth, in the ramus, condyle, or coronoid process, it becomes necessary to immobilize the temporo-maxillary articulation. For such cases the author knows of no better method than interwiring the teeth—that is, binding the upper and lower jaws together by passing the wire around the necks of enough teeth, upper and lower, and interlacing, as seen in the radiograph in Fig. 12. I have employed this method with excellent results for a number of years, and it is gratifying to note that a large number of my colleagues are adopting it. The only advantage the interdental splint has over this method is the small feeding-space left in the splint. However, as the jaws are fixed and the patient is confined to a liquid diet, this counts for very little, whereas, with the interwiring, the operator can see that the teeth occlude, and therefore knows that the fracture is held in apposition. With an interdental splint the jaws are held apart, and notwithstanding that a radiograph taken after the splint is inserted shows the fracture to be in apposition, the body of the bone is held down by the splint, the muscular traction on the ramus and portion of bone distal to the fracture being constantly upward; some time during the period of cicatrization the fractured ends of the bone are apt to ride, and the operator is not apprized of a deformity until union has taken place and the splint has been removed. The parts can be kept just as clean with the one method as with the other; with the wiring, however, the patient can go about without displaying any deformity.

If, for any reason, an interdental splint of this type is preferred, I caution the operator to have a radiograph taken each week, until provisional callus has formed.

TEMPORARY BANDAGE FOR MANDIBULAR FRACTURES.

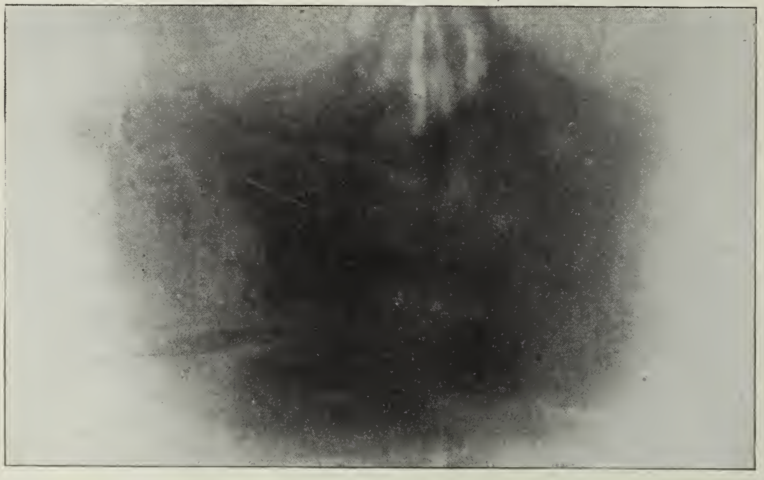
In fractures of the mandible the author employs only a bandage for the first few days after the injury has been received, always removing this bandage the day after the splint has been inserted or the jaws have been interwired, unless there is considerable contusion or deep laceration of the soft tissues. A most secure bandage, which may be classified as a Barton bandage greatly modified, is made by passing a two-inch bandage —linen or gauze—around over the top

FIG. 2.

Radiograph. Taken with right side on the plate.

of the head from under the chin, then from the forehead around the back of the head. Strips of adhesive plaster are placed over the bandage to strengthen it and prevent it from slipping. To complete the hood, a piece of adhesive plaster should be brought from the back of the bandage up over the head, to be attached to the bandage over the forehead. To keep the plaster from sticking to the head, gauze is placed under it except where it passes over the top of the bandage. A four-tail bandage is very effective, and is made by tearing a piece of three-inch bandage—about three feet long—down to within three inches of the middle on each side. The six inches of untorn bandage are placed under the chin, partly extending over the front of the chin. The tails from under the chin are tied up over the top of the head, while the tails from the front of the chin are tied behind the head.

FIG. 3.



Antero-posterior radiograph taken after operation, showing that the lead seen in Fig. 2 has been removed.

A COMPLICATED PRACTICAL CASE OF GUNSHOT FRACTURE.

Case 1. This case was one of a gunshot wound, received by an Italian, age twenty-four years. The bullet entered in the region of the temporo-malar canal on the right side, passed through the head and out through the left cheek, at a place which can be described by a circle, the diameter extending from the distal border of the canine to the maxillary tuberosity. The bullet, being one of large caliber, mushroomed out as it passed, and deposited numerous splinters of lead throughout its entire tract. (See radiograph, Fig. 2, B.)

At the point of entrance (see Fig. 2, A) the bullet destroyed about one-third of the right malar bone, fracturing its orbital and maxillary processes. It then passed through the right superior maxillary bone, removing the first molar and about one-third of the osseous tissue of that bone, including more than half of the palate process. The fracture extended through all the walls of the antrum excepting the orbital. From the socket of the first molar, the fracture extended back through the maxillary tuberosity on a line about parallel with the upper border of the attachment of the buccinator muscle, and forward through the inferior meatus, the anterior point reaching as high as the crest of the inferior turbinate (Fig. 2, C).

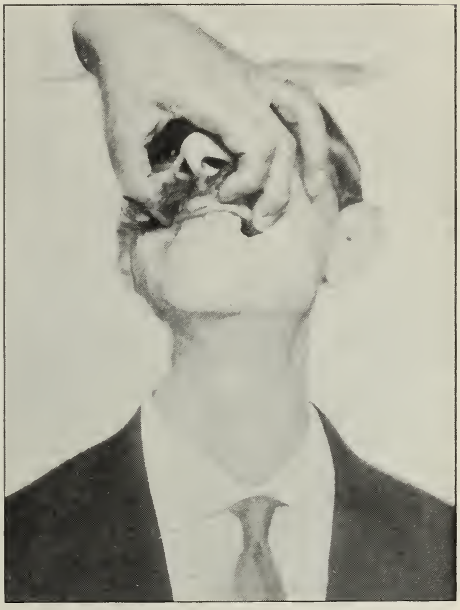
The fracture in the left superior maxillary bone was about the same as in the right, except that considerably more bone was destroyed, including all tissue from the third molar to the canine, and as high as the infraorbital foramen. All the walls excepting the orbital in the antrum of this bone were completely shattered. The patient was brought to the Harlem Hospital, where the author,

Fig. 4.

Roof of mouth. Teeth on the right side and molar on the left shown. The lip hides the left incisors.

as consulting oral surgeon, was called on to operate upon him on November 20, 1910, and successfully removed all fragments of lead (Fig. 3), as well as all segments of bone which were denuded of healthy periosteum, and such soft tissue as showed signs of slough. By plastic surgery at this operation the perforation through the cheek was completely closed. This, however, was not so easy to accomplish on the roof of the mouth, where fully two-thirds of the hard palate had been destroyed by the bullet. A small muco-periosteal flap was

Fig. 5.



Shows articulation.

Fig. 6.

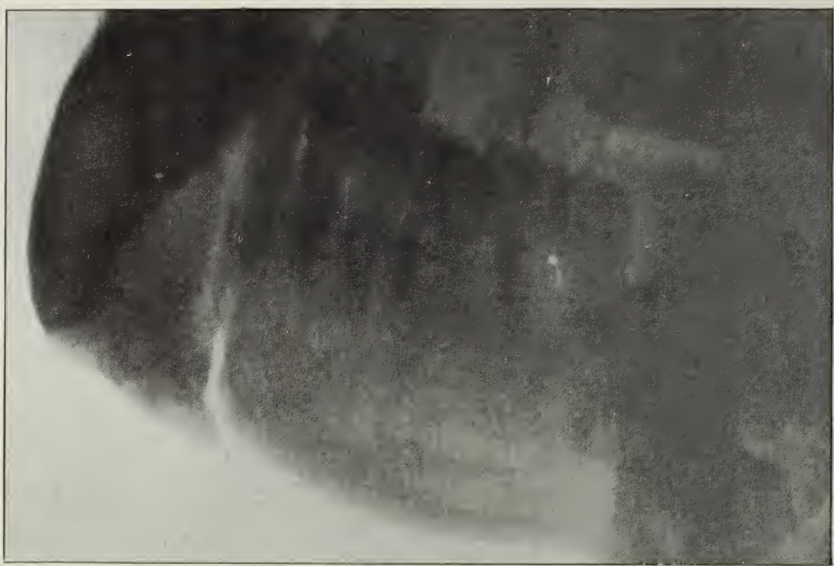
Recent photograph. Scars are hardly perceptible.

obtained from the anterior part of the hard palate, which partly closed the aperture and healed nicely. Other flaps were obtained from the cheek, the result being shown in Fig. 4.

The splinting of the fracture now became a serious consideration. There was no segment of bone with a solid facial attachment in the upper jaw to use as an abutment for the splint, and there was such a considerable loss of osseous tissue that one could not reasonably expect there would be sufficient osteogenesis to establish a good bony union for several months. It was absolutely necessary to devise some method of splinting which would not interfere with the function of the mouth or embarrass the patient from an esthetic standpoint. To accomplish this I employed an Angle's arch, to which were wired all the teeth remaining in the upper jaw, in the proper cusp relation to the teeth of the lower jaw. This made one segment of all the fractures, including the molars, which can be seen, in the radiograph in Fig. 2, D, suspended by soft tissue in the roof of the mouth. These molars, as seen in Fig. 4, are sound and firmly embedded in healthy bony tissue today.

To overcome the displacement, which tended to draw the face inward, I used a modification of the Stanton collar. This collar was made by fitting a silver collar around the lower right first molar and left second bicuspid respectively. From the occlusal edge of these collars was extended upward for about one centimeter a silver shoulder, which intercepted the distal border of the upper left canine and right second bicuspid respectively, when the jaws articulated. In this manner the fracture was held in splint whenever the jaw was at rest. (See final result in Fig. 5.)

Fig. 7.



Mandibular fracture between left canine and lateral incisor.

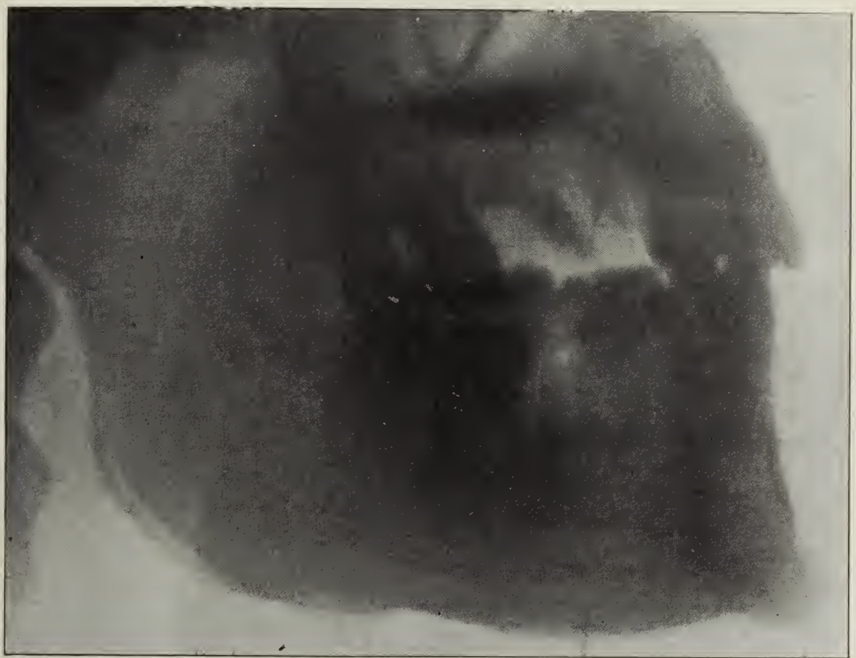
The patient was kept on a semifluid diet during the period of cicatrization, which extended over five months. He was able to attend to his business every day after the second week, and was not at any time embarrassed by having to wear any exterior bandage or anything which would indicate his affliction.

Fig. 6 is reproduced from a recent

photograph of the patient. It shows that, notwithstanding the large amount of tissue destroyed by the bullet, as seen in the radiograph in Fig. 2, the final result displays little sign of the great amount of injury, the scar tissue being hardly perceptible, and the contour of the face well preserved.

cap splint, such as is illustrated in Fig. 1. It should be noticed that the saddle of the splint is discontinued over the labial surface of several teeth on each side of the fracture, also that the left canine approximates the right central incisor in this case. This splint was cemented and wired in place according to the author's method. The temporo-maxillary articulation not being interfered with, the patient was able to enjoy a semisolid diet. Bony union took place in twenty-four days. The radiograph in Fig. 8 shows the union, with the teeth in good occlusion.

Fig. 8.



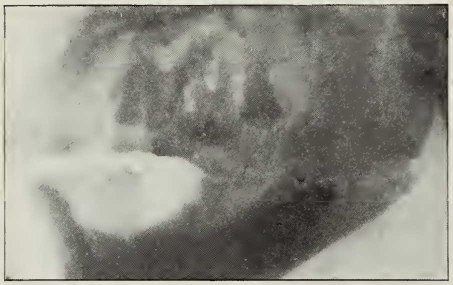
Shows union. ↑

CASES OF MANDIBULAR FRACTURE.

Case 2. The patient, an American, thirty-four years of age, had been thrown from the box of a wagon while driving. He received a fracture of the mandible between the left canine and lateral incisor. A section of bone of the width of and including two incisors was torn away from the body of the mandible. (See Fig. 7.) This sequestrum, being denuded of periosteum, had to be removed in order to prevent sloughing. The fractured ends of the bone were curetted and approximated. They were held in apposition by an aluminum interdental

Case 3. The patient, a girl of American parentage, four years of age, had fallen and fractured the mandible through the mental foramen on the left side. Crepitus was appreciable, but there was no displacement. The periosteum, being only slightly torn, held the fracture in apposition. No splint was necessary. Bony union took place in twenty-one days without any surgical interference. The patient presented later with an induration in the chin, and the X ray disclosed the curious fact that the germ of a permanent incisor, which had become dislodged at the time of fracture, was growing in the soft tissue of the chin.

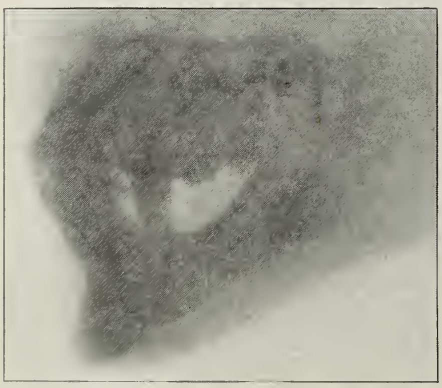
FIG. 9.



Fracture at the angle.

Case 4. The patient, an American, fifty-four years of age, presented a fracture through the angle of the mandible. (See Fig. 9.) In order to secure fixation in this class of fracture, it becomes necessary to immobilize the temporo-maxillary articulation. The author therefore employed interwiring. Several of the upper incisors were wired to the lower ones, thereby overcoming the traction of the hyoid muscles. A good bony union was obtained, with the teeth in normal occlusion. (See Fig. 10.)

FIG. 10.



Shows union.

Case 5. The patient, an Englishman, thirty-one years of age, had received a blow on the jaw. He presented a multiple fracture of the mandible. (See Fig. 11, A, A.) One fracture extended through the angle, the other between the first bicuspid and canine. The radiograph showed perfect occlusion of the teeth, the fractures through the bone being barely appreciable. The method of interwiring was used, and good bony union obtained.

FIG. 11.

A, A, Points of fracture.

Case 6. The patient, an Italian, had received a blow on the jaw, and presented a multiple fracture of the mandible, one fracture extending between the first and second molars and another through the angle of the jaw. The method of interwiring was used. The radiograph (see Fig. 12) shows apposition of the fractures, as well as normal occlusal relationship of the teeth of the upper and lower jaws. Good bony union was obtained.

Case 7. The patient, an American boy of six years of age, while skating, had fallen on a picket of an iron fence and sustained deep laceration under the chin and a fracture of the mandible. (See Fig.

13.) A general surgeon controlled the fracture by intrasuturing, using a kangaroo suture. The entire portion of bone under the suture was necrosed. The author, when called to treat the case, found considerable suppuration, the sinus draining through the wound under the chin. An interdental splint was in-

FIG. 12.

Multiple fracture. Jaw interwired.

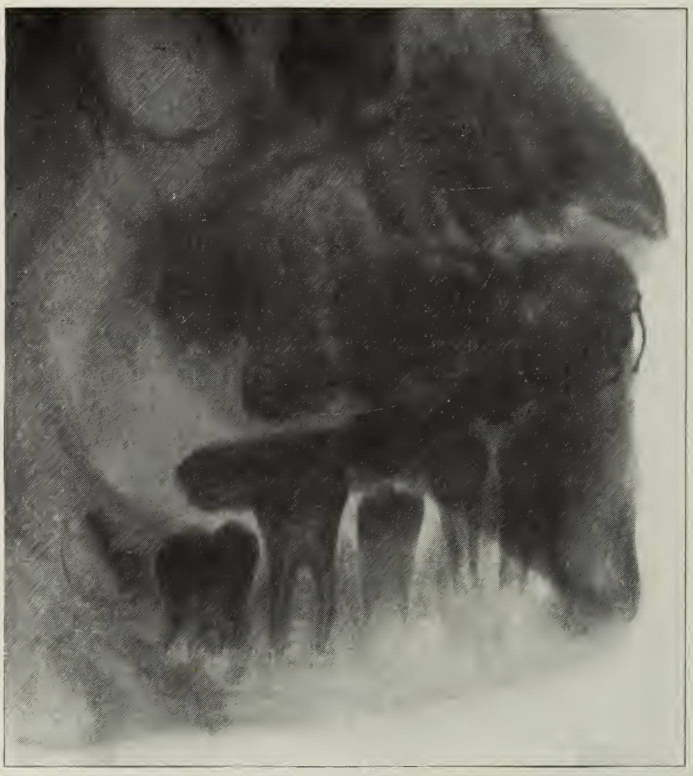
FIG. 13.

Fractured mandible.

serted. The radiograph in Fig. 14 shows that the splint is holding the fractured bone in apposition; it also discloses the large amount of necrosis. This necrosed bone the author removed. Suppuration ceased, and the case progressed to a favorable termination. The interdental splint was worn for six weeks. Considerable provisional callus formed, however, owing to the large amount of periosteum destroyed. It is questionable, in the author's opinion, whether the portion involved will not always constitute a weak spot in the patient's jaw. This case demonstrates the advantages of the interdental splint, and shows the danger of intrasuturing.

Case 8. The patient, an Irishwoman of forty-two years of age, had fallen down stairs, sustaining a multiple fracture of both the upper and the lower jaw. There were seven fractures in the mandible and four in the maxilla. (See Figs. 15 and 16. Fig. 15 was taken with the left side of the face on the plate; Fig. 16 with the right side of the face on the plate.) The lower incisors, with the alveoli, were wrenched entirely away from the body of the bone. A fracture extended through the symphysis; there were two distinct fractures in the region of the lower second molar, and one through the angle on the right side—this is best seen in Fig. 16. On the left side of the mandible there were two fractures, one through the angle, the other extending from the center of the sigmoid notch down obliquely and distally through two-thirds of the ramus. This fracture separated the condyle from the

FIG. 14.



Cap splint. Note loss of bone due to necrosis.

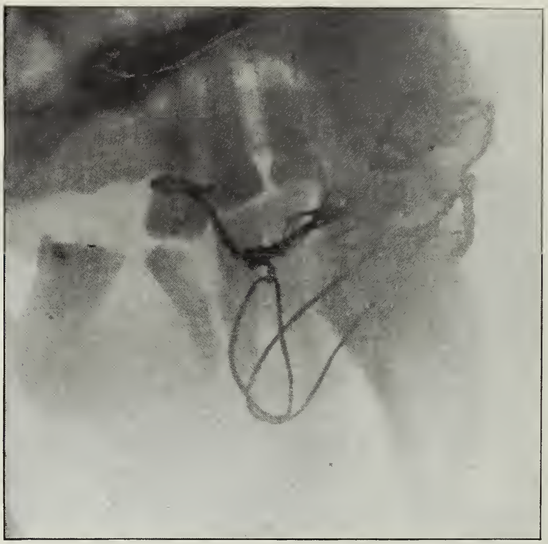
ramus, and permitted of a dislocation of the temporo-maxillary articulation on this, the left side. (See Fig. 15.) In the maxilla, the bones were fractured just distally to the canine eminence through the anterior palatine canal, the displacement being forward and upward. (See Fig. 15.) The essayist was called to care for this case during the second week after the accident. On seeing the radiograph (Fig. 15) I decided that by intra-wiring I could best control the fracture.

Fig. 15.

Taken before operation. Left side on the radiographic plate. Multiple fracture of upper and lower jaws.

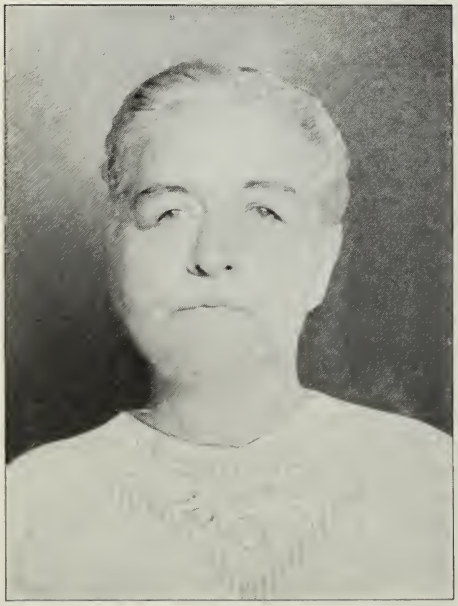
The patient was placed upon the operating table under ether. I dissected the mucosa from the mandible as far down as the attachment of the depressor labii inferioris muscle, just forward of the mental foramen. On the right side I drilled a hole through the bone, and passing two silver wires through, brought them up, passed them between the first bicuspid and canine on each side, and twisted them to the respective wires extending from the drill hole on the labial side, thus making two loops around the segment of bone, including the lower incisors, and so holding this segment in apposition to the body of the bone. One end of the wire on each side, after making the loop, was brought up and laced around an upper bicuspid on its respective sides; the other end was attached to the upper lateral tooth on the opposite side. This simple procedure brought all the numerous fractures into apposition. (See Fig. 16.)

FIG. 16.



Right side on the plate, after operation. Jaw interwired.

FIG. 17.



Recent photograph of patient.

The pterygoid muscles took care of the fractured condyle as soon as the temporo-maxillary articulation was immobilized.

The radiograph Fig. 16, which was taken shortly after the operation, showed a small sequestrum of bone just below the second bicuspid, near the lower edge of the mandible. This, as well as the root of the third molar, was removed.

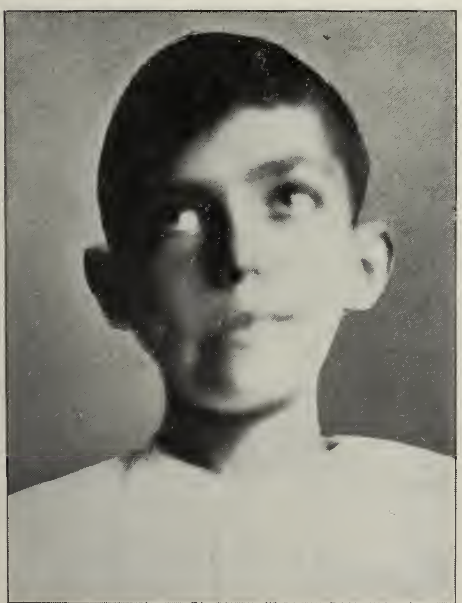
The patient was discharged thirty-two days after the operation with a good bony union of all fractures, and without any deformity. (See Fig. 17, which photograph was taken about two months after the operation.)

Case 9. The patient, an American boy, twelve years of age, had been run over by an ice-wagon, and sustained deep laceration of the right cheek, severing the malar and infraorbital branches of the temporo-facial division of the facial nerve. A fracture of the mandible was present on the right side between the first bicuspid and the canine. An interdental splint was inserted, and the patient was placed on a full diet. The splint was removed in twenty-one days. Union took place with the fracture in apposition. (See Fig. 18, A.) There is a scratch on the radiograph plate just distally to the point of union. This scratch

FIG. 18.

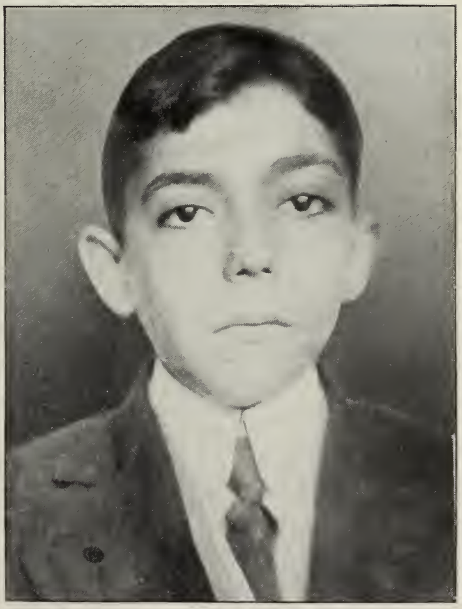
A, Point of union.

FIG. 19.



Shows paralysis.

FIG. 20.



Shows cure.

shows in the picture, and may confuse a casual observer. Note that the teeth are in normal occlusion.

In caring for the lacerated cheek, the author, not wishing to have suture scars, instituted treatment according to his method. Strips of tape were saturated with collodion and placed on each side close up to the lips of the wound. When the collodion had hardened, the sutures were made through the tape, and the lips of the wound drawn together. In order to assist in holding the wound closed, and to relieve the traction of the buccinator muscle, a semicircle of spring wire was placed on the cheek, and held fast by means of tape saturated with collodion. The wound healed with very little appreciable cicatricial tissue. The deep laceration and extensive traumatism, however, caused the loss of all motor-nerve impulse to the muscles supplied by the malar and infraorbital nerves. Consequently, facial paralysis ensued. (See Fig. 19, which photograph was taken eight weeks after the accident.) To overcome this paralysis, the author employed the ultra-violet rays. With occasional omission, the patient was exposed to the rays from five to ten minutes every second day. After continuing this treatment for two months, a second photograph of the patient was taken. (See Fig. 20.) The illustrations speak for themselves; apparently an anastomosis of the nerves has taken place, and the paralysis is fast disappearing.

I wish to express my thanks to Dr. W. H. Stewart, to whom I am indebted for the radiographs, which have been a considerable factor in my work, and have enabled me to depict my methods of treatment.

Discussion.

Dr. Willy Meyer. It has been my pleasure to know Dr. Kauffer for several years. I have watched his work with keen interest. There may be others who are doing good work in this field of surgery, but surely what Dr. Kauffer has shown us tonight—the many difficult cases controlled by such simple methods—is convincing that the care of these patients belongs to a skilled dentist. We as surgeons are often called upon to care for these cases in our hospital work; they are the meanest kind of cases we have to treat. When we wire the jaw it means a scar, and, if the patient is a woman, this is a pity. I am therefore glad to know someone who can take such good care of these unfortunates.

Dr. W. H. Luckett. Since Dr. Kauffer has been connected with the Harlem Hospital, whenever a case of this class presents it has become a habit with the surgeons to instruct the house surgeon to call up Dr. Kauffer, and the reason therefor has been amply illustrated.

Dr. Charles Goodman. I wish to thank Dr. Kauffer for the opportunity of hearing his excellent paper. It has proved to me that the treatment of fractured jaws is work for a dentist.

SUPPURATIVE CONDITIONS OF THE ALVEOLAR PROCESS.

By W. LOUIS CHAPMAN, M.D., Providence, R. I.,
PATHOLOGIST AND ASSISTANT SURGEON, ST. JOSEPH'S HOSPITAL, PROVIDENCE.

IT is the purpose of this paper to urge on physicians and surgeons the great importance of suppurative conditions of the mouth, to show both usual and unique radiographic findings in such cases, to suggest therapeutic measures to practitioners, and to offer suggestions regarding operative procedures.

SERIOUS SEQUELÆ OF NEGLECT OF PATHOLOGICAL CONDITIONS IN THE MOUTH.

In the writer's opinion, it is high time that our knowledge of the microbiology of the mouth were put to some practical use. For many years it has been thought that carious teeth were an important source of auto-infection, and that apical abscesses might contribute infectious particles to the glandular and circulatory systems. But it is not until now that an active propaganda has been instituted, and at the present time the work is being pushed with only a portion of the vigor it deserves.

The writer has for some time urged the need of cleaning up the mouths of children who were in need of tonsil and adenoid operations, and has seen many cases dismissed from the hospitals after such operations with coated tongues, physical signs in the chest, a mouth full of carious teeth, and with suppurative conditions of the alveolar process. The nose-and-throat department had done its work, but no directions were given to the anxious parents regarding hygiene and the need of care of the mouth. Prescriptions for indigestion are of but little value if there are foul cavities in the teeth, and for these reasons such cases should have bad teeth removed at the time of the tonsil and adenoid operation. If it is not convenient to have a dentist in attendance, then the operator should do the extraction. A surgeon who is unable to do the ordinary operation of extracting teeth should take with him an associate who has that talent. In cases where there is doubt whether a tooth should be left, whether it is a deciduous or a permanent tooth —and often a radiograph is necessary to determine this important point—the tooth should be left, and later removed if necessary.

It is impossible to calculate how many persons acquire cardiac, renal, arthritic, digestive, and nerve lesions owing to the distribution to the circulatory and lymphatic systems from chronic suppurative foci in the alveolar process. The mechanical activity of the mouth prevents the surrounding of pus-chambers by an impermeable pyogenic membrane such as may be found in soft and nonmotile parts, and the constant friction of spicula of bone favors extensions of small round-celled and bacterial infiltration.

It must not be supposed, however, that all persons with carious teeth, apical abscesses, interstitial gingivitis, and palatal necrosis suffer from a considerable impairment of the general health. Instances are numerous in which patients suffer from any or all of these and still seem perfectly well. On the other hand, in a case of impaired health there may be other contributing causes—such as a dilated and dependent stomach, chronic catarrhal enteritis, or a cardiac valvulitis with consequent congestion of the abdominal viscera—whereby the digestion, than which there is no more important function in the body, is made imperfect, and all of the other dependent functions suffer also.

The progressive steps toward actual destruction of tissue are gingivitis, focal precipitations, caries of the teeth, alveolitis, alveolar osteomyelitis with sequestra.

CONDITIONS CONCOMITANT WITH GINGIVITIS AND TREATMENT.

Attacks of gingivitis which are accompanied or followed by focal precipitations are frequently a part only of a clinical syndrome with the following features: Malaise, mental depression, rheumatic pains over the sacrum, severe facial neuralgia, anorexia, fugitive pains all over the body, frequent urinations, and occasionally rise of temperature of one or two degrees. The gingivitis usually comes last, and either persists to a stage of suppuration or else subsides in three or more days. The gums are swollen, bleed easily, and are relieved by the bleeding. The treatment is medicinal—generous catharsis and antilithemic preparations; surgical—compound tincture of iodin locally* and later the scaling of the teeth; dietetic elimination of foods rich in the purin bodies.

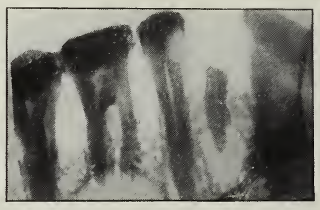
* The writer has found that scarifying the gum prior to the application of the tinctura iodi, Churchill, N. F., will often help where the simple application fails.

FIG. 1.

DIAGNOSTIC IMPORTANCE OF THE RADIOGRAPH.

We have in the X ray a diagnostic means of the greatest significance in the solution of these important problems. Without good radiographs the dentist often works in the dark, inflicts needless suffering on his patient, and frequently attacks his problem from the wrong angle and with the wrong instruments. A good dental radiograph should show the detail of the part, the granular structure of the alveolar process, the peridental membrane, the pulp chamber, and the root-canals. The radiographer should have sufficient knowledge of dental pathology and sufficient experience with dental radiology to be able to interpret the film to the dentist, unless the latter be familiar with radiographs. Some considerable experience in dental work is necessary before a radiographer is able to give opinions of value in obscure cases, and for that reason there should be in every community a surgeon capable of doing oral work, to co-operate with dentists and to share the responsibility in cases of importance.

FIG. 2.



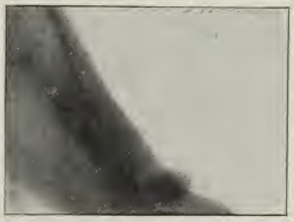
PRACTICAL CASES.

Carious alveolitis. Figs. 1 and 2 illustrate very well the condition of carious alveolitis, with corresponding X-ray film, and teach the great need of thorough operation in such cases, not only for cosmetic results, but as a means of depriving the system of continuous bacterial auto-infection.

Fistula in edentulous mandible. In

the case illustrated in Fig. 3 the problem was to find the cause of a fistulous opening at the site of the lower second molar, all the teeth of the lower jaw having been lost, with complete physiological absorption of the alveolar process. It is often quite difficult to take radiographs of the lower jaw in the

FIG. 3.



region of the first, second, and third molars, on account of reflex gagging and vomiting, and the radiograph was taken in the face of this obstacle.

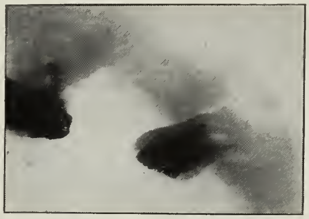
Globular swelling at angle of mandible. The radiograph in Fig. 4 was taken in a woman of sixty, with a globular swelling at the angle of the mandible. All teeth had been extracted many years before. When one recollects that the

FIG. 4.

mandible is the strongest bone of the face, and if one will operate on the mandible of a skeleton and then imagine the presence of the other structures which prevent easy access, the great difficulty of operating on a case like this becomes apparent.

Abscess pointing to the outside. The patient in whom the radiograph in Fig. 5 was taken had consulted numerous dentists and surgeons for a "salivary fistula." The face was enormously swollen and there was obviously a fluctuating sac of pus, ready to rupture ex-

FIG. 5.

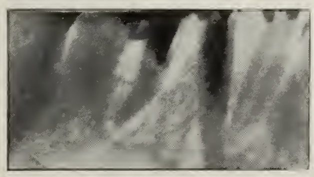


ternally. This was not incised, but punctured by an aspirating needle, and drained away as much as possible. Then, when the swelling was reduced and it

FIG. 6.

became possible to insert a small film, the above condition was found, viz, a much-filled rudimentary third molar with suppuration around and almost complete

FIG. 7.



absorption of the roots. Extraction of this was of course easy. There is left only a tiny dimple on the cheek, the patient's ill health ceased, and the fistula was cured. The writer recommends this procedure in cases where an abscess is ready to rupture, as it is often efficacious, there is no unsightly scar, and no structures of importance are cut.

Neuralgia, pus, and rarefaction of alveolar process due to root-canal perforation. In the case illustrated in Fig. 6 there were obscure neuralgic pains, and pain about and discharge from the roots of the upper left first molar. The film showed rarefaction of the alveolar process at the apex of the second bicuspid and the first molar. It will be readily seen that the cause of the suppurative process is the drilling through the roots outside of the proper root-canals, and the filling of the canals thus made subsequently.

Fistulæ of alveolar process. The interesting case shown in Fig. 7 is illustrative of a number of important features. The patient, a woman of forty-six, has had fistulæ of the alveolar process for ten years. She now has fistulous openings of the anterior palatine fossa, of the upper right lateral incisor, canine, and first bicuspid, and of the upper left second bicuspid. The patient is very nervous, and it was difficult to secure her co-operation in taking radiographs. Her dentist, curiously enough, is interested in but one of the fistulous openings. Note here the difference between the surgeon's and the odontologist's conception of the case! The surgeon, appreciating the importance of focal infections as nidi for the distribution of infectious particles to the system, would doubtless advise the extraction of all doubtful teeth and a surgical clearing up of the alveolar process. The dentist thinks of the cosmetic result, and, if he advised extraction, it is quite probable that the patient would seek other treatment.

Fig. 8.

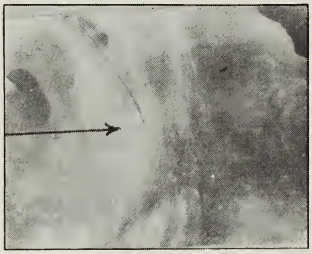


Fig. 9.

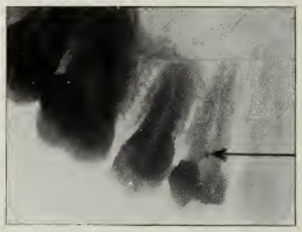

Fig. 10.

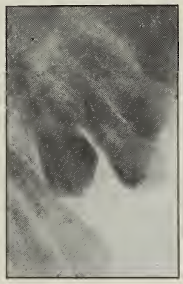
Fig. 11.

The radiograph (Fig. 7) is not a good one; it does not show as it should the finer structure of the alveolar process, but it does show absorption of the pericemental membrane and the cause of the fistulous opening.

FOREIGN BODIES.

The Roentgen ray is the only reliable means of finding foreign bodies in the root-canals, and a few examples are shown in Figs. 8 to 11. The more the body penetrates the alveolar process, the more trouble it causes. By radiographs we find the cause of fistulæ which otherwise would go undiscovered. Any case which does not respond readily to treatment should be radiographed, not only to find out conditions, but also to spare the patient unnecessary suffering and

Fig. 12.



septic infection incident to exploratory procedures.

RETENTION OF DECIDUOUS TEETH A CAUSE OF SUPPURATION.

Retained deciduous teeth are found at almost any age, and can be readily diag-

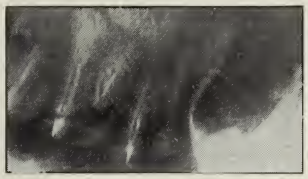
Fig. 14.

nosed as such by the radiograph. The appearance of such radiographs, showing the impacted condition of the permanent tooth below the retained deciduous tooth, is familiar to every dentist. They are frequently the cause of suppuration until removed, and when crowned or made the support of artificial dentures are examples of the well-known adage—"Uneasy lies the tooth that wears the crown."

MALPOSITION OF TEETH A CAUSE OF SUPPURATIVE ALVEOLITIS.

Malposition is a very common cause of suppurative alveolitis, and the follow-

Fig. 13.



ing cases, with illustrations, are offered: One case was referred to me by Dr. Forrest Eddy. The patient, a boy of fourteen, had been treated without success for headaches of the greatest severity. A radiograph of the centrals and laterals showed the condition illustrated in Fig. 12. This did not seem to furnish sufficient grounds for such severe manifestations, and the condition of the third molars was investigated, with the result shown in Fig. 13. The extraction

Fig. 15.

of the second molar, for the purpose of allowing the eruption of the third molar, was followed by the cessation of the headache, but one attack occurring after the extraction.

Another case of particular interest to the writer, because it occurred in his

Fig. 16.

own mouth, is illustrated in Fig. 14. Obscure headaches, neuralgic pains, etc., the well-known symptom complex, were relieved by the extraction of the offend-

Fig. 18.

ing tooth. The tooth was shaped exactly as shown in the illustration.

Fig. 15 shows an interesting combination of a malposed tooth, together with suppurative alveolitis around the second bicuspid. In such a case the radiograph shows clearly the cause of the fistulous opening and suggests the only practical remedy.

Figs. 16 and 17 are instructive specimens of radiographs of a class of cases

Fig. 17.

in which a correct idea of the condition could be obtained only by a radiograph.

ABSORPTION OF ALVEOLAR ARCH.

The radiograph in Fig. 18 is illustrative of absorption of the alveolar arch in the neighborhood of the anterior palatine canal, the foramina of Stenson, and the foramina of Scarpa. In such a

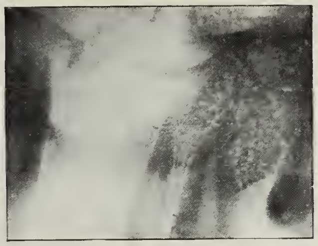
Fig. 19.

case the osseous tissue is of the consistence of paper, the mucous membrane is thickened, and in some cases a pyogenic membrane has formed which contributes pus to the buccal cavity by one or more fistulous openings.

Fig. 19 shows a more advanced condition. There is more complete destruction and absorption of the alveolar process, and two teeth have been deprived of their support.

Fig. 20 shows a similar case which was operated on by the writer. Although considerable tissue was removed by cutting instruments to be described later, the process of repair was so complete that the patient had no difficulty in wearing a plate.

Fig. 20.



TECHNIQUE OF OPERATION IN ABSORPTION OF ALVEOLAR PROCESS.

In cases presenting such a radiographic appearance, the operator should remove all friable tissue. The patient should be etherized; such operations should not be undertaken under local anesthesia. The mouth should be made as aseptic as possible. All sponges and instruments should be sterilized, and the operator should wear rubber gloves. This latter measure is of the greatest importance as a protection to the operator, for such cases are often of syphilitic etiology; furthermore, a very little experience in the use of bone-cutting instruments makes one familiar with the "feel" of sound and diseased process.

The writer has devised a number of bone-cutting instruments which he has found to be of considerable use in operating on the alveolar process, on the palatal arch, between teeth, and behind the first and second molars. Although no great originality can be claimed for them, they are very useful in such operations, and were devised for the purpose after a thorough search of numerous instrument shops and catalogs.

Fig. 21 shows a right-angle bone curet which is useful for both the palatal arch and behind the first, second, or even the third molar. It is almost impossible properly to curet these localities with the usual straight curet without injuring the soft parts. These curets should be made in several sizes for use in narrow spaces, as in the case of the extraction of an incisor or bicuspid.

Fig. 22 shows bone-cutting forceps which are very useful for removing carious portions of the process after extraction. The beaks are thin and strong, and may be readily inserted between the process and the gum, thereby saving considerable time in the granulation process. The more thorough the removal of the fragments of the process, the less annoyance the patient experiences of having small spiny portions come away in the mouth from time to time, and the more remote the possibility of obstinate or permanent fistulæ. This forceps removes as well as cuts off the fragments.

Fig. 21.

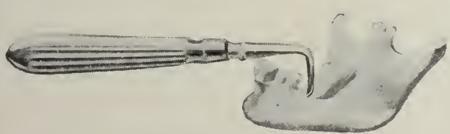


Fig. 22.

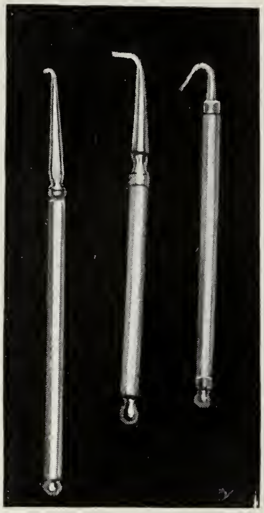
Fig. 23 shows three reversed chisels which supplement the work of the curet and the bone-cutting forceps. They are used with a drawing instead of a pushing motion, and for that reason are much more easily controlled and not likely to slip.

Fig. 23.



The after-care of oral operations is of more than ordinary importance as regards the surgical result, the period of repair, and the comfort of the patient. While it is true that with the removal of diseased tissue, the extraction of suppurating teeth, and the suitable drainage of suppurating foci, regeneration is usually rapid, it is equally true that the process of repair is materially hastened by frequent cleansings of the denuded areas, by forced feeding with liquids, and by the local application of iodin. Mouth-washes act largely by their mechanical cleansing, and mild astringents add to the comfort of the patient. The tincture of iodin applied to the denuded area after careful drying is a positive antiseptic, and although somewhat painful at first, is anodyne in its later action.

For the proper after-care of inflammatory and suppurative states following the extraction of second and third molars it is absolutely necessary to have the denuded areas cleansed with antiseptic medication at frequent intervals. Argyrol 20 per cent. should be used every four hours until the symptoms are improved, and when the patient cannot open the mouth, as is often the case, it is necessary to have suitable dressing forceps with the beaks at right angles, to be used like the author's right-angle curet already described. If the submaxillary and parotid glands are enlarged, ice-caps must be applied over the entire area, and if the infection tends to become general, cultures from the suppurative area and even from the blood must be taken, that autogenous vaccines may be made and the patient given the benefit of this well-proved method of treating septic infections. Without suitable dressing forceps it is absolutely impossible to properly cleanse alveoli. Enlarged glands should be incised only when the operator is absolutely sure they contain pus by exploration with a fine hypodermic needle.

CONCLUSION.

In conclusion, the writer urges the more frequent and careful inspection of the mouth by physicians and surgeons, the application of the principles of asepsis and antisepsis in oral operations by both surgeons and dentists, more thorough and complete operations for the best results in alveolar suppuration, and a better appreciation of the importance of suppurative conditions of the alveolar process as factors in the contribution of septic particles to the system.

SOME PHASES OF PROSTHETIC ESTHETICS.

By GEORGE H. WILSON, D.D.S., Cleveland, Ohio.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, November 26, 1912.)

DENTAL prosthetics is defined as the science, art, and esthetics of restoring a lost dental organ or organs with an artificial substitute. However important the science of the materials used may be deemed, and however essential the method for retention of an artificial denture may be considered, it is equally essential that attention should be given to the esthetics involved. That the esthetics of prosthesis is entirely ignored by a large proportion of the members of our profession is only too apparent, when cognizance is taken of the fact that many dentists are sending their patients, needing prosthetic appliances, to specialists; or that, desiring to retain the patient, they take an impression, a bite, and shade number, and send these to a laboratory and demand a completed denture. To say the least possible of the dentist who thus avoids the responsibility of prosthetic esthetics, it may be said that he is depriving himself of a valuable means of self-cultivation and a pleasant study.

ESTHETIC DENTAL PROSTHESIS.

Esthetics is all that constitutes prosthesis a profession. Prosthesis devoid of esthetics is a trade. Esthetics is ideality —it is a product of mentality, and when made to dominate the mechanical art it lifts the product of mechanics and makes of it a creation, something superior to a manufactured article, therefore a profession. It must be manifest to all that a workman in a laboratory detached from the operating room can use no mentality in the making of the dental appliance sent to him for construction, other than as a mechanic; hence he is a mechanical dentist, and his business is a trade. A truly prosthetic dentist is one who restores the lost anatomical portions of the lower third of the face in an harmonious manner. His business is a profession, because he combines with the science of materials and methods the art of a skilled workman and the esthetics which conceals the artificial.

If we concede the relative importance of esthetics as an essential part of dental prosthetics, then we may well spend this evening in considering that which constitutes its fundamental principles. We may well interrogate the recognized principles as to their truth and value. If these recognized fundamental principles underlying the teaching of dental esthetics are untrue, wholly or in part, we cannot too soon recognize the fact and endeavor to correct the fault. If they are true and adequate to the needs of the profession, their investigation can do no harm, but must tend to establish their truth and importance in the dental curriculum.

It is with considerable trepidation that I come to this city, the cradle of dental education—and, I believe, the birthplace of dental esthetics—to question the efficiency of applied esthetics. Nevertheless, feeling my own deficiency in the practice of the esthetics of prosthesis, and recognizing the ignorance of the subject among the laity or the profession, I appeal to you for more enlightenment; therefore, in presenting the subject as it appears to my conception, it is with a desire for intelligent discussion.

FACIAL HARMONY.

In a word, *What is esthetic dental prosthesis?*

It is the making harmonious, in a greater or lesser degree, the lower third with the upper two-thirds of the face, in comparison with an accepted standard.

What is harmony of the face?

It is a balance of the features and of the expression of any individual face. It is the sum and substance of the factors seen and desired for the best appearance of the patient.

How do we know what constitutes harmony of the features of the face?

By systematic study of faces, which consists of, first, learning what is to be looked for, and second, how to see that which is desired.

What is to be looked for in a face?

Types or classes. As it is a logical procedure in any study to begin with the simple and advance toward the complex, so in the study of the face, the student should first consider the simple generalities and then work toward the complexities of the individual.

RACE AND NATIONALITY.

The first classification to be observed is that of race and nationality. If the person under study is of a pure racial and national type, then all further consideration must be founded upon the recognized basis of the race as modified by the national characteristics of that type. If, however, the subject is a blend, then he must be studied from the dominating, and an estimate be made of the modifying influence. Because of the heterogeneous nature of our population, we dentists in America have perhaps a greater field for the study of faces than any profession in any part of the world. Therefore with our boasted American aggressiveness, we, as a profession, should not shirk the responsibility placed upon us. As time is necessarily limited I shall not further consider this phase of esthetics, but invite only a discussion of the facial characteristics of the Caucasian race.

TONE OF COLOR OF FACE.

The second classification concerns tone of color, whether light or dark, blond or brunette. Either extreme of tone of color is easily recognized, and suggests certain facial characteristics to the least observant mind; but as the person of a perfect blend of the two types of the second classification is approached, a more diversified classification is made necessary.

CONTOUR OF FACE.

The third classification concerns contour. The face should be studied in full-face and profile. The full-face may be subdivided into forms such as square, parallelogram, circle, oval, and triangle. The profile may be divided into straight, convex, and concave. These various contour types will each have a certain characteristic which, if prevailing through the entire anatomy of the face, will convey the sense of harmony. Thus in an edentulous person with a convex profile, the lower third of the face will be concave, and the inharmony of the face will be apparent at a glance. If in another type of face with circular form, teeth of the triangular type (nervous temperament) are inserted, the expression of that face will not only be incongruous, but hideous.

LIPS.

The fourth classification comprises the lips. The preceding classification concerns the face as a whole, but the lips are so important as to require especial consideration, for their contour gives much of the expression and beauty to the face. The lips should first be studied together, the proportion of one to the other, whether they are well proportioned, or whether one is too large or the other too small. Their occlusion may be straight or curved, and the angles elevated or depressed. The red of the lips may be but a line, or it may be excessive; it may be straight, or curved and beautiful. The lips may be refined or coarse, they may be closed firmly or loosely, and may be compressed or relaxed.

The lips should also be studied separately. The median perpendicular line of each lip is first observed, and will be found to vary between long, short, straight, concave, or convex, and between very thick and very thin. The tuberculum and philtrum may be pronounced or absent. The lips at and near the angles of the mouth may be thin or thick even to coarseness. The linea naso-labialis should be carefully considered, because there is no line of the face more expressive than this. The naso-bucco-labial triangle requires especial attention in restoring the features with an artificial denture, as no portion of the face is more indicative of the lost dental organs. The sulcus mento-labialis may be marked, excessive, or almost obliterated.

TEMPERAMENTS, AND THEIR CLASSIFICATIONS.

The fifth and last classification is concerned with temperaments. Tempering means modifying or mixing in due proportion. Hence the term "temperament" has been used since the days of Hippocrates, who observed the differences of bodily organization, functional activity and their accompanying mental peculiarities. The temperaments according to Hippocrates' theory depended upon what were then known as the four primary fluids of the body—the blood, the phlegm, the yellow bile, and the black bile. The temperaments were called the sanguine, phlegmatic, choleric, and melancholic. Dr. Gregory added a fifth, which he called the nervous temperament. Cullen reduced the temperaments to two, and called them the sanguine and melancholic. Dr. Spurzheim, in the early part of the nineteenth century, classified the temperaments as lymphatic, sanguine, bilious, and nervous. Dr. Jacques in his book on "Temperaments" published in 1904, says that—"It remained for the later phrenologists to eliminate from the old systems all of the abnormal conditions and place the doctrine of the temperaments on a strictly anatomical and physiological basis, and to adopt the simple classification which includes them all under the three heads of the motive, vital, and mental temperaments. Each of these temperaments is determined by the preponderance of the class of organs from which it takes its name. The first is marked by a superior development of the osseous and muscular systems, forming the locomotive apparatus; in the second the vital organs, the principal seat of which is in the trunk, give the tone to the organization; while in the third the brain and nervous system exert the controlling power."

Dr. Jacques defines temperament as—"A state of the body depending upon certain combinations of the various systems and organs and certain functional conditions affecting them."

Dr. Jacques further says of the modern normal classification that a balance of the temperaments implies that the three systems of organs or temperaments are so well blended that no one of the three can be said to predominate; that in compounding the names of the temperaments, the predominating one should be named first, and the modifying ones in the order of their influence. Also, that two of the temperaments may be strongly marked, while the third is almost negligible, when they can be compounded, for practical purposes, as—Motive-vital, motive-mental, vital-motive, vital-mental, mental-motive, and mental-vital.

Thus the normal anatomical classification comprises three primary temperaments, a balance of temperaments, and six compound temperaments; while the older pathological anatomical classification consists of four primary temperaments, a *temperamentum temperatum,* and twelve binary temperaments.

It is now a quarter of a century since the Doctors Flagg compiled the dental classification of temperaments, based upon the four primary temperaments as described by Spurzheim. Their work has been of much value to our profession because it has directed attention to some facts and many ideas, presented in a compact and convenient form for study. But are we as practitioners and teachers satisfied to require the rising generation of dental students to accept and to learn by heart this cumbersome classification of a few facts and many ideas; or, shall we not present the few facts and ideas that have stood the test of time in a more concrete form? Has the dental classification of the temperaments proved an infallible guide? Let us investigate.

In the "American System of Dentistry" the binary temperaments are arranged with the modifying temperament used as a prefix to the predominating one, as "nervo-sanguine," meaning that the nervous temperament modifies the strongly marked sanguine temperament. The text-book does not state that this is the method, but your essayist cannot comprehend the classification otherwise. Dr. Gustavus North, who has written quite extensively of the temperaments, explicitly states that this is the method of forming the compound name. In the "American Text-book of Prosthetic Dentistry," Dr. Thompson has rearranged the classification of the Flaggs, and has added a division which he calls "basis." Thus, under the heading Nervo-sanguine and division Basis, he states: "Nervous and sanguine elements, the nervous predominating," and then proceeds to detail the same description of the nervo-sanguine temperament as found in the "American System of Dentistry." This incongruity appears throughout the whole classification.

So it seems that we as a profession tacitly accept the temperamental classification as the only way by which esthetic artificial dentures can be constructed, and are equally successful with whatever classification we follow. Does this not imply that the dental classification of temperaments is too finely spun? Why should we consider temperaments as more than a quasi-science? All writers on temperaments acknowledge that the primary temperaments are ideals, and practically do not exist. Why have an elaborate detailed classification? I believe, however, that the four basal temperaments of the older classification and the three of the modern classification are valuable, and should be taught as ideals with which the patient should be compared, as an aid in arriving at an opinion of that which will produce harmony of the features of the face.

FACTORS IN FACIAL HARMONY TO BE OBSERVED.

In recapitulation: What, then, is to be looked for in a face? We should keep in mind five factors: (1) Race and nationality. (2) Tone of color. (3) Contour. (4) Lips. (5) Temperaments.

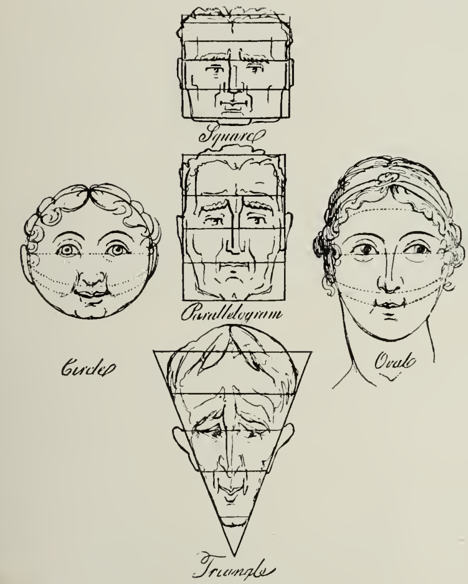
How to see the face? By observation and reflection—both by individual work and the recorded work of others. It would indeed be tedious work to educate oneself in the esthetics of the human face by individual effort; however, the literature upon the subject is quite extensive, so that one may quickly and pleasantly equip oneself with a fair working knowledge. The various text-books upon dental prosthetics and orthodontia contain chapters upon facial art which serve very well as a *résumé,* but a comprehensive study of physiognomy and expression will necessitate the reading of such authors as Lavater, Bell, Darwin, and Mantegazza. Also, much information may be obtained in reading any of the many works on phrenology, as Spurzheim, Jacques, Sizer, Drayton, and Stanton. However, such works should be used for a specific purpose—that is, a comprehensive understanding of the features, for developing harmony in dental restorations; therefore much of the text of such books may with profit be skipped by the dental student.

Illustrations. How to see the face by observation and reflection can best be presented by illustration. The first classification is not illustrated, because we have excluded it from further study in the paper, and the second classification is not an appropriate one for stereopticon demonstration, therefore the illustrations begin with the third classification.

ILLUSTRATION OF FACIAL CONTOUR.

Fig. 1 is taken from an English work on the "Theory of Beauty," by Mme.

Fig. 1.



Schimmelpenninck, published in 1815, and is valuable as an analysis of "contour," which comprises our third classification. It is apparent that the geometrical figures grossly describe all forms of faces and heads, and that harmony in any individual case will require that the component features shall be of the form of its type. Thus a face of the square type would require short, square, angular teeth arranged in a square dental arch; the parallelogram would be of the same angularity with added length; the circular type would be short, flat, and round; the triangular type would require long teeth narrow at the neck, broad at the occlusal edges and surfaces, with well-defined cusps and conformity in arch; and the oval will be marked by easy, graceful curves.

Fig. 2 is taken from Sizer and Drayton, and is a study of contours in profiles. These faces are numbered from 1 to 11 from left to right, with the name of each subject underneath and in order. Numbers 1, 3, 7, and 8 are straight profiles, 2, 5, 6, and 9 are convex profiles, while it is questionable whether 4 and 10 should be classed as straight or concave profiles. No. 11 is of a race not included in this study.

Profile may be described as the relation of five points of the face to a perpendicular line, and its class is determined by the relation of the nose and lips to a straight line drawn between the extreme points, namely, the frontal and mental eminences. The straight profile has the lower lip and middle of the wing of the nose touching the line, while the upper lip slightly protrudes over the line. The three points named being either in protrusion or retrusion determines the convexity or concavity of the face. The straight and convex classes are types, but it is questionable whether the concave class should or should not be ranked as a type, or whether it should

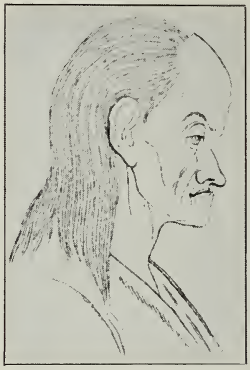
Fig. 2.

be considered only as a perversion of the straight profile.

Fig. 3.

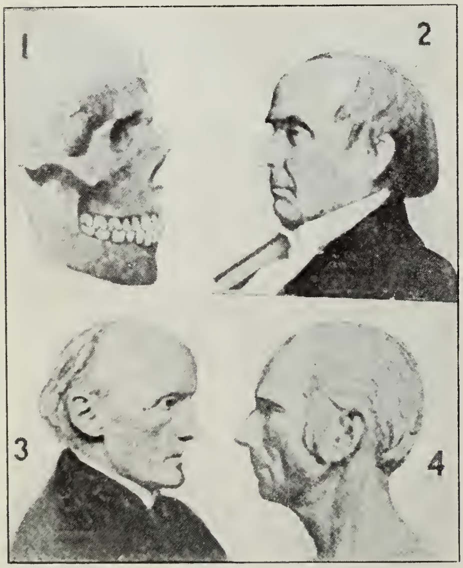
Fig. 4.

Fig. 5.



Figs. 3, 4, and 5 illustrate the three profiles. The intellectual and harmonious straight profile upon the left, Fig. 3,

Fig. 6.



Portraits: 2, Webster. 3, Newman. 4, Clay.

is that of Jane Addams; the convex profile, Fig. 4, that of a capable attorney of New York City; and the concave profile, Fig. 5, is a drawing by Lavater representing melancholia.

Fig. 6 represents Dr. Cigrand's illustrations of the three profiles. Webster and Clay represent the types, but it is questionable if Cardinal Newman should not be classed with the straight profile

Fig. 7.

Fig. 8.

type with a slight enlargement of the mental eminence.

Figs. 7 and 8 are a pronounced concave

profile, but cannot be classed as a type, because the concavity is mostly owing to an abnormally developed mandible. However, it is possible that the middle third of the face is slightly undeveloped.

ILLUSTRATIONS OF LIPS.

The fourth classification—viz, the lips—should be carefully studied, for their conformation very largely determines the contour of the dental arches and gum restoration, especially of the anterior teeth.

Fig. 2 presents an excellent opportunity for study and comparison of the lips. No. 2 presents a well-proportioned and balanced convex profile. Were this an edentulous patient under our professional care, it would be necessary, in restoring the contour of the lips, to take into account the balance of the two lips; the amount of red showing and thickness would indicate fulness, convexity. No. 3 is an harmonious straight profile, has medium thin lips, with only a moderate amount of red showing. They show that they are well supported by dentures, and in harmony with the rest of the face. No. 4 has short lips, which are medium thick and probably quite pliable. The picture gives an impression that there is deficient dental support; to determine this factor, however, it would be necessary to study the face in action. No. 5 has a straight immobile upper lip, probably thick, although the red is narrow, indicating that the teeth cannot be prominent. No. 6 shows George Eliot, who certainly did not have a beautiful mouth, if she looked like the picture. The lower lip is very thick and overlarge for the upper one. Either the lower lip is deformed, or there is an extrusion and protrusion of the lower incisors. No. 7 has a stiff, longitudinally convex, thick upper lip, which would require an artificial denture to be nicely contoured in the vicinity of the incisive fossæ; otherwise this feature would be exaggerated. No. 8 shows a thin, short, and depressed upper lip. Apparently Professor Bush needed a new artificial upper denture, or the maxillæ were underdeveloped as a result of early extractions. No. 9 shows a straight, firm, immobile upper lip, and a pliable

CLASSIFICATION OF TEMPERAMENTS.

(*Dr. Prothero.*)

Basal Temperaments.	Eyes.	Hair.	Teeth.	
			Color.	Shape.
Lymphatic	Pale blue or gray.	Fine and silky, but without luster.	Pallid, opaque, or muddy yellow.	Poorly shaped, broad and flat.
Sanguine	Blue, brilliant, and expressive.	Blond-red or chestnut, seldom dark or black.	Cream-yellow, darker at neck.	Well proportioned, curved and rounded.
Nervous	Light gray or blue, restless, often morbidly brilliant.	Fine, light, and soft.	Pearl-gray, or blue tinge.	Long, conical, and rounded.
Bilious	Black or brown, small and piercing.	Coarse, dark, often black, and abundant.	Strong, bronze yellow.	Conical, long, and angular.

lower lip supported by an underdeveloped mandible, which probably would give very poor support to an artificial denture. The mouth of No. 10 stands in almost direct contrast to No. 9.

ILLUSTRATIONS OF TEMPERAMENTS.

The fifth classification is well represented in the tabulation by Dr. Prothero, and it seems to your essayist that it comprises the essentials in a terse, concise, and easily learned form [preceding page].

The student should, however, be thoroughly impressed with the fact that the so-called temperaments are ideals—simply a representation of ideas valuable in the study of the physiognomy of men. Is it reasonable to assert that the millions of people belonging to the Caucasian race, having no two individuals alike, can be placed into sixteen groups, and made to answer to as many set descriptions? If this is logical, it is still more logical to place them in a much smaller number of groups, because their description is that much more generalized and farther away from an attempt at a predetermined individual description.

Figs. 9 and 10 show two types of the lymphatic temperament. The one can as well be taken to typify the ideal lymphatic temperament as the other, yet one is parallelogram in form, while the other is circular-oval. In youth the one was of strongly bilious, the other of strongly sanguine temperament, and probably the lymphatic temperament was not apparent in either. If artificial teeth were to be selected for each of the subjects, what should the form of teeth be? Should they have the temperamental form of youth or that of old age? The

FIG. 9.

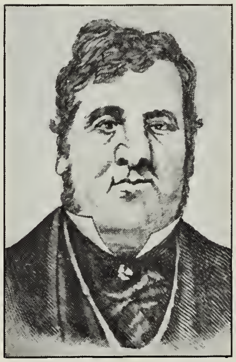


FIG. 10.

FIG. 11.

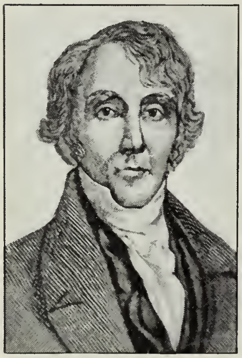

FIG. 12.

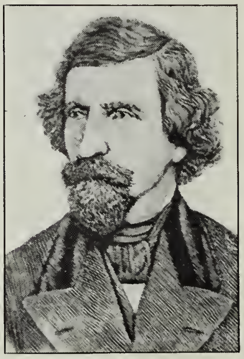

FIG. 13.

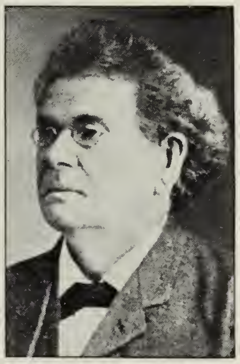
author's desire is to impress the fact that the form of teeth is to be selected by the typal form of the individual rather than by the form associated with the temperament. Harmony will be produced by selecting the form of the teeth by the typal form of the individual, which does not change, rather than by the temperament, which may change with age and environment.

Figs. 11, 12, and 13 show the sanguine, bilious, and nervous temperaments respectively, representing the oval, square, and triangular forms.

Fig. 14.

Fig. 14 shows the Apollo Belvedere, representing the Greek ideal, considered by artists as perfect in contour, proportion, and harmony. Notice should be taken of the thirds of the face, the relation of the chin, lips, nose, and forehead to the perpendicular line. Lavater, in 1775, wrote: "However famous and extolled the forehead of the Vatican Apollo may be, and however it may deserve its fame, I cannot discover its greatness and perfection. It may be answered, 'It is the head of a god'—and so be it; but nothing is, in my opinion, divine which has no similitude to the human. We cannot here discover whether it is the forehead of man, woman, or deity; or, rather, we know it is neither, nor can be either." In another place he says: "I maintain that nothing resembling it can be found in nature. We know no forehead, no nose, much less can we imagine such, in ideal patterns of perfection, in which the outline is, for the thousandth part of an inch, rectilinear. Such a forehead may domineer, pursue goddesses, persecute enemies—may, in comparison with a thousand feeble ones, be called royal; yet it is not true, cannot think—and the forehead which does not think, can as

Fig. 15.



little be called true or beautiful as an eye which does not, cannot see."

This quotation has been given to show that one of the best of observers and students of the human face accepted the Apollo only as an ideal, and that we should use it only as an ideal, with which to compare faces of the straight profile class; but in no case should we attempt to force the features of the patient to the contour of the ideal, as exemplified in the Apollo, further than to produce ease and grace of poise.

The well-known face seen in Fig. 15 is a fine example of that which is found in practice—that is, contour and proportions that are anything but ideal. The lower third of the face is much longer than the middle third. By the rules of art, the ear should be the length of the nose, but in this instance it is the length of the lower third. Here we see a portion of the face, the upper two-thirds, to be of the square type, while the lower third is of the parallelogram type. What, then, should be the form of the teeth suitable for this complex physiognomy? The square type of tooth would produce a more harmonious face than the longer tooth suitable for the parellelogram type, because it would reduce to a limited extent the exaggerated length of the lower third of the face.

SELECTION OF ARTIFICIAL TEETH.

Form and color in teeth for artificial dentures are two of the most troublesome factors for the dental prosthetist, and it is for the determination of these two factors that the dental temperamental classification was designed. I submit to you the proposition that the typal form and the tone of color of the individual better meet the requirement.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE TREATMENT AND FILLING OF ROOT-CANALS.

By J. J. MOFFITT, D.D.S., Harrisburg, Pa.

(Read before Section II of the National Dental Association, at its sixteenth annual meeting, Washington, D. C., September 11, 1912.)

THE subject of root-canal treatment and filling seems to be as important as any within the field of dentistry, because the stability and continued usefulness of the teeth depend on the condition of their supporting roots.

A tooth with a vital pulp is more stable and durable than one in which the functions of the pulp have ceased, and therefore it is our stringent duty to see to it that it never, through negligence on the part of either the patient or the dentist, becomes so afflicted;—but this does not come within the scope of the subject we are considering. Neither can we, in this limited time, take up a history of the treatment and filling of roots and the evolution that has brought us to our present knowledge of this branch of our profession, interesting though it be.

VALUE OF NATURAL TEETH IN THE PRESERVATION OF HEALTH.

We all know the ancient stories of worms in the teeth, and of incantations for odontalgia, with other evidences of ignorance concerning the dental structures that do not antedate us by so many years. We know also that the turnkey and the forceps were invented and employed long before excavators and broaches, from which we may conclude that the world's best thought has been given to other sciences—such as law, art, music, philosophy, etc., for a thousand years, and the men of learning engaged in these sciences have been dying, prematurely spent, because none of them gave attention to the science of supplying their bodies with nourishment. The mass of the people today, and the majority of physicians and dentists, do not appreciate the incalculable value of the natural teeth as factors in the nourishment and preservation of the individual. When a permanent tooth is gone, it is gone for good;—so much surface for grinding is lost every time the jaw is closed in mastication; so much area for pushing saliva through the food is lost every time the teeth are brought together; so much more unconverted starch and imperfectly masticated food is conveyed to the stomach to be disposed of; so much earlier the perfectly adjusted mechanism of the economy is broken up. Who can determine the value of a tooth, when upon it depend not only personal appearance, facility of expression, and healthfulness, but length of life itself?

ENCAPSULATION OF ROOT-APEX THE OBJECT OF ROOT-CANAL FILLING.

When we undertake the filling of a root we must have in mind, first, a certain object to be attained; and second, a definite course of procedure to be employed during the operation. The first of these, the object to be attained, is the *encapsulation of the apex of the root** under consideration, so that any portion of it that is not in vital relation with the surrounding tissue may be separated from and rendered unirritating to the surrounding parts. Then the repair process will go on uninterruptedly, and the stability of the root be assured.

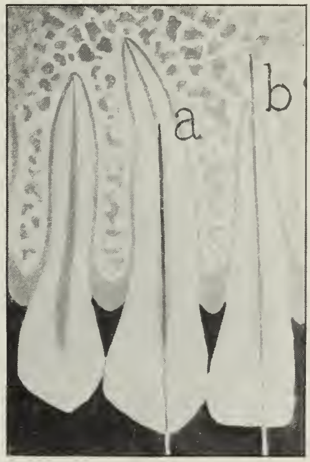
Encapsulation of the apex explains the durability of certain cotton root-fillings, long after the virtue of their medication had departed; of suppurated roots that give no trouble as long as gases find other exit and do not force the capsule; of teeth devitalized by concussion that cause no discomfort, and of the permanent success of surgically correct treatment and filling of root-canals.

Radiographs are indispensable in expert root-canal treatment and filling. They can be completed in less than ten minutes (see DENTAL COSMOS, August 1912, p. 868), and save many hours. The operator should not attempt to discover the length of the root by prodding the apical tissue with a broach to see if he can feel the end of the root or produce sensation outside the foramen.

Sometimes a little pulp tissue left in a long root (see Fig. 1, a) reacts like the tissue outside an apex; sometimes in a short root (see Fig. 1, b) with a large foramen the tissue outside reacts like remaining pulp.

No instrument should ever be used for work about the apex of a root of which the operator could not be certain that it would give a negative result in a control culture.

FIG. 1.



CONDITIONS INTERFERING WITH THE ENCAPSULATION OF A ROOT.

There are five conditions that may interfere with the encapsulation of a root, which for the convenience of consideration in this paper have been divided as follows:

(A) Infections from unsterilized instruments, or from instruments that have been sterilized but have touched the bracket, the lips, or adjacent teeth before being inserted into the root-canal, or that have passed through the septic matter remaining in the root-canal or from proliferation, and growth through the apex, of germs remaining in the root-canal.

(B) Pressure necrosis from gases forming in the pulp chamber that have not sufficient external exit.

(C) Eschars from too strong drugs having been forced through the apical foramen by too tight dressing or by compressed air under the temporary filling.

(D) Too short a root-filling, permit-

* See DENTAL COSMOS, December 1911, vol. liii, p. 1418.

ting serum to enter the apex and decompose within the root-canal.

(E) Too long a root-filling, a broken-off instrument point, or other projection, causing irritation of the parts outside the apical foramen and permanent interference with the formation of the capsule.

CONDITIONS DETERMINING METHODS OF TREATMENT.

Having in mind the object to be attained and these five conditions that may interfere with it, we will next determine the course of procedure to be employed during the operation. There are five conditions here also that determine the differences that should be made in the methods of treatment. This is not a complete classification, and like the former simply serves for the present consideration:

Class I. Exposed pulp with no infection.

Class II. Exposed pulp with infection not reaching the apex.

Class III. Root infection extending beyond the apex, with the pericementum not involved. This class has three subdivisions to be mentioned later.

Class IV. Root infection with destruction of the pericementum about the apex.

Class V. Puncture of the pulp chamber or root.

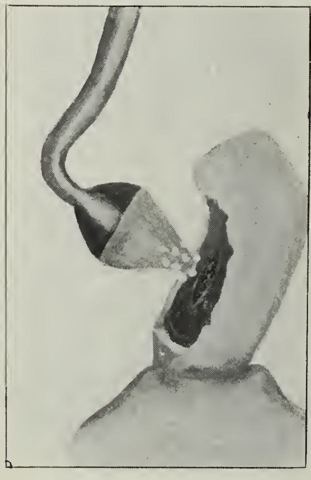
When a tooth is presented to us for treatment, we may determine, first, which of these classes (as denoted by numbers) it comes under; then we follow the course of procedure indicated in this class for inducing the formation of the retention capsule, bearing in mind and avoiding the five conditions (as denoted by letters) that interfere with this process.

We will now consider in turn the variations in treatment determined by these different conditions, our purpose being to induce encapsulation of the apex, and our technique being devised to guard against the five errors that would defeat this object.

I. EXPOSED PULP WITH NO INFECTION.

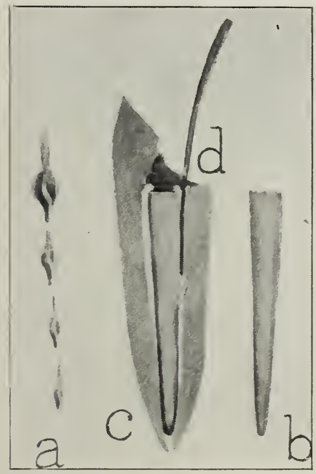
Since the addition to our resources of the hollow inlays, pulp capping has been more successful than previously. It belongs logically to this first class, but will not be discussed in this paper. Assuming from the patient's history, or because we need anchorage for a bridge, or for some other reason, that the pulp under consideration must be removed: First, a radiograph of the case is made in order

Fig. 2.



that full knowledge of the shape and number and length of the roots, or of any other condition bearing upon the operation which the radiograph may disclose, may be obtained by the operator. All necessary instruments are in readiness. An assistant or attendant marks all bristles and broaches with the length of the root. Nitrous oxid and oxygen are administered nasally by an assistant. In order to avoid dropping the cocain or loss of time in placing it, a cone-shaped piece of gutta-percha previously fitted to an instrument and shaped so as conveniently to reach the exposure is warmed in such a manner that the point alone is softened. With this some cocain crystals are picked up (see Fig. 2) and pressed quickly against the exposed pulp, the bulk of gutta-percha of the cone preventing leakage and insuring pressure. This is done just as the analgesia stage is reached, twenty to forty seconds after beginning the administration; the nitrous oxid is shut off, and a few inhalations of oxygen are allowed, during which the broach is inserted and the pulp removed. It is best to drill the root-canal to the size desired for a filling at once, using the largest drill first so that

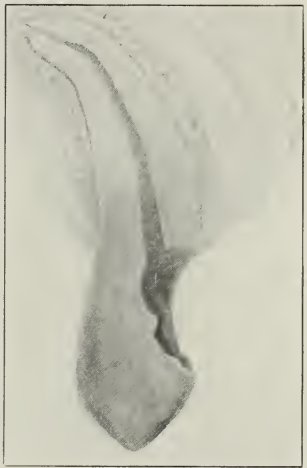
Fig. 3.



The space between root-filling and apex is exaggerated to show how the cold end of the gutta-percha prevents pressure on the zinc oxid paste with which the space is filled. Encapsulation then seals the apical end of the root, the other end being sealed by the process described.

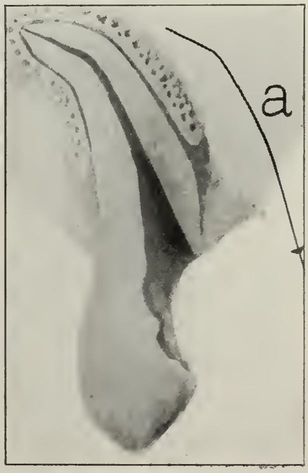
more room is available for the work, then the drill next in size, then the third largest, and finally the fourth (see Fig. 3, a). The drills used should be round-pointed, so that the walls of the canal may not be cut into (for absolute smoothness is necessary), and flexible for following the curves, and the operator's touch must be light and skilful, for the technique of successful root-canal treatment and filling is as exacting and should be as expertly performed as a similar proceeding in any science where a moment of indifference may cause failure in result. Any portion of the root that cannot be safely reached with a drill is cleansed with a broach.

Fig. 4.



By using each one of the four drills in the order mentioned for about one-fourth the length of the root, a uniform

Fig. 5.

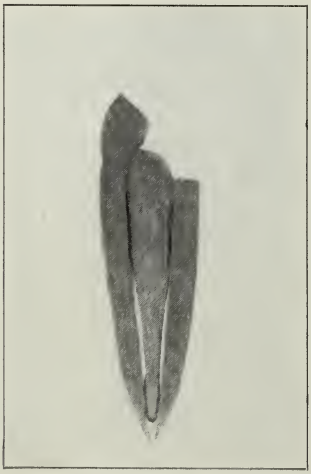


taper is given to the canal, and furthermore the membranes and loose tissues that impede the progress of drugs toward the apex, and which also lessen their efficiency, are thus early removed. When the curve in a root as disclosed by the radiograph (see Fig. 4) makes access

FIG. 6.

to the apex impossible through the ordinary opening, the tooth should be cut in such a direction that access may be

FIG. 7.



gained (see Fig. 5). If the curve in the root is so great that the apex cannot be reached when the opening has been brought to the gingival line, the remaining portion of the root beyond the curve must be treated by means of a steel bristle bent by aid of the radiograph (see Fig. 5, a) or a fine silver probe, together with the adhesive property of certain medicaments. The root-canal is next treated with an oxidizing or bleaching agent until all organic matter is removed. It is then washed out and dried. A gutta-percha root-canal filling (see Fig. 3, b) has meantime been prepared by the assistant, the length of which is

FIG. 8.

In this case restoration is completed by baking a reinforced occlusal edge to a facing, fitting it to the broken tooth with wax, and casting the wax support in gold. The facing had an imitation porcelain inlay on its mesial surface, and the appearance of a gold filling distally, done with china paints.

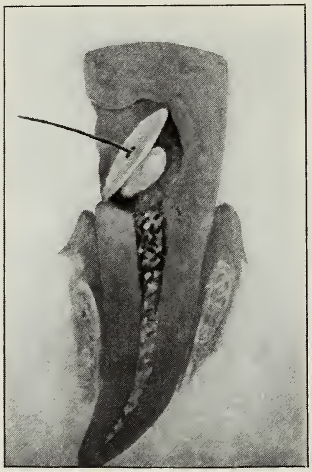
determined by the radiograph, and the diameter by the drills that have been used. This gutta-percha point, after having been fitted fairly accurately to the root-canal, is immersed in 70 per cent. alcohol and dried. A paste is then made of medicated zinc oxid (or a commercial preparation called "pustolene"), which, having been brought to the proper consistence, is pumped into the tooth to the apex by means of a *measured* and *marked* broach. An assistant having coated the gutta-percha point with the same paste, the root-filling is pushed into place cold (see Fig. 3, c) in such a manner that the excess of paste comes out around it. A fine silver root-canal drier is placed in the root and pushed up between the gutta-percha and the side of the root-canal about half the length of the root, and the current is turned into it until the outer half of the gutta-percha point is softened (see Fig. 3, d). The outer part of the gutta-percha point being thus softened is pressed tightly into place and the root is sealed. Warm air from the syringe is also frequently employed, care being taken not to soften the entire point, as the cold end at the apex serves as a stopper to prevent pressure through the foramen. The excess of zinc oxid (see Fig. 6) is wiped out, and all traces of it within the pulp chamber are removed with alcohol. An additional piece of gutta-percha may then be added to the root-canal filling if desired (see Fig. 7). Restoration of the remainder of the tooth is completed according to the requirements of the case (see Fig. 8).

Applying to this procedure the five conditions that may prevent encapsulation of the apex, we have avoided the infections that may occur under A. Division B is not applicable to this class, there having been no gas formation in the pulp. Regarding division C, we have, by noting measurements of the root as shown by the radiograph, carried no drugs beyond the apex, and have avoided such pressure as would force them through the foramen, thus avoid- an eschar outside the root. Regarding divisions D and E: By placing the cold gutta-percha point in the root with an exact knowledge of the length of the root and the point, we know that there has neither been a discrepancy in the length of the filling nor a projection of the filling outside the root. Having thus systematically and scientifically completed our operation, we have the satisfaction of knowing that we have not relied upon chance or experiment or the healthy organic nature of the patient, but have accomplished a scientific operation of assured success even in patients of low vitality.

II. EXPOSED PULP WITH INFECTION NOT REACHING THE APEX.

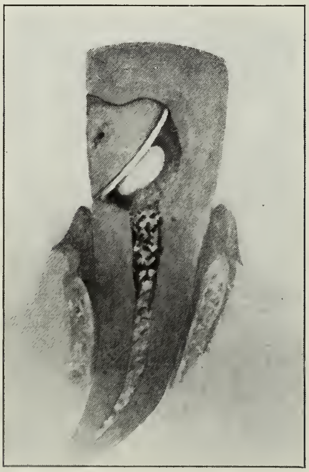
The second condition determining the method of procedure in the treatment and filling of root-canals involves cases where the pulp is exposed and infected, the infection having not reached the apex (see Fig. 9). A growth of micro-organisms, the presence of their products, the disintegration of the pulp tissues, and the attendant congestion of the bloodvessels, all unite to prevent the absorption of cocain, so that an attempt at pressure anesthesia may be extremely painful. A radiograph is first made of the case to disclose the necessary conditions and measurements, as mentioned in class I. In this class anesthesia with nitrous oxid and oxygen is carried just to the point of unconsciousness. The five conditions (represented by the lettered divisions) unfavorable to encapsulation being carefully observed by the operator throughout the operation, the pulp is removed just as complete anesthesia is reached; the attendant at the same time turns on the oxygen. The removal of the pulp is in this manner accomplished with no pain or inconvenience to the patient, and with no danger of forcing the infection to the apical area—which is sometimes the case when pressure anesthesia is used. The most important of the five conditions to be guarded against in this class is found in the first, or division A, viz, the danger of carrying the infection in the pulp to the apex by means of the instruments used in removing the pulp and in subsequently preparing the root-canal. This is guarded against by having the assistant make limit marks on all the broaches and bristles with the aid of the radiograph before the patient is anesthetized, thus enabling the operator to so control them that they will always fall short of the apex. As soon as the pulp is removed, the root-canal is sterilized to the apex so that any remaining infection is destroyed. It is even better in this class, when the condition permits delay, to prepare the tooth the day before the operation is made, by placing a cotton pellet containing a penetrating germicide—that is, one that will not cause coagulation of the tissue—loosely against

FIG. 9.



the exposure. This cotton pellet containing the antiseptic should be protected from pressure with a piece of thin

FIG. 10.



metal plate sealed in with gutta-percha. A hole is punched in the plate and a bristle inserted touching the cotton pellet (see Fig. 9), around which the gutta-percha is packed, so that, when the bristle is withdrawn (see Fig. 10), an escape for any gases from the pulp is afforded, while any infection entering from the mouth is rendered harmless by the sterilizing agent on the cotton pellet. Thus the conditions listed under B and C are avoided. In the few cases of this class not taking kindly to nasal inhalation, either owing to chronic mouth breathing or nervousness, the pulps may be devitalized with one of the preparations of arsenic, always under protection of a metal plate to prevent pressure. When the pulp is removed and the canal sterilized, the operation of root-filling is completed as described in class I.

III. ROOT INFECTIONS EXTENDING BEYOND THE APEX WITH THE PERICEMENTUM NOT INVOLVED.

This class is divided into three subdivisions: The first, with no pus present; the second, with the formation of pus begun; the third, with the presence of pus with fistulous opening.

Subdivision 1: *No pus present.* The pulp being destroyed by bacterial action, there is no need of an anesthetic in any subdivision of this class. A radiograph is first made. The canal is cleansed with no attempt to pass beyond the apex, and every precaution is taken to avoid carrying any of the matter within the tooth through the apical foramen. When the root is thoroughly cleansed, a cotton dressing twisted on a bristle is made, and, being saturated with a non-coagulating and sufficiently permanent antiseptic, is inserted so that it will reach as close to the apex as possible. This dressing must not be packed in, but lie loosely along the root-canal, thus avoiding the danger listed in division C, of eschars from too strong drugs being forced through the apex. A pellet of loose cotton is next placed in the pulp chamber, touching the end of the root-canal dressing and taking up any of the excess antiseptic that may have flowed down from it. The cotton is then touched with a little more of the antiseptic, until it is just moistened, leaving no excess. A valve is then made with thin metal plate as described in class II (similar to the valve in Fig. 10), permitting any pressure from within to escape, but no infection from the mouth to enter. This dressing is allowed to remain for a week or more, when it is removed and the root is washed with alcohol. The root may then be enlarged and prepared for filling, with no danger of adding to the infection beyond the apex—which will usually have been removed by the blood, since the source of its activity is gone—and the filling is inserted as before described.

Subdivision 2: *Pus present.* When pus is present the root is sterilized and an opening made at once through the apex. Sterilizing agents or strong antiseptics are contra-indicated in the cancellated structure outside the apex. The pus tract, after having been evacuated, is washed with an antiseptic just strong enough to temporarily inhibit bacterial proliferation. A root-dressing is then made, similar to the one described in subdivision 1, but containing the mild antiseptic just mentioned for washing out the pus tract. The pellet of cotton in the pulp chamber beneath the valve may be saturated with a stronger antiseptic to destroy any infection entering from the mouth. This dressing must be changed every day for the first week, and for the remaining two weeks should be changed according to the indications given by the drainage on the cotton dressing. It takes about three weeks for the destroyed area outside the apex to be filled up with fibrous tissue, in which ossification afterward may or may not occur. If the root is hermetically sealed, the drainage from the process of repair will back up and prevent its progress. When there is no further need of drainage, the root-filling is inserted as described before.

Subdivision 3: *Involvement of the tissue beyond the apex with fistulous opening.* All traces of septic matter must first be removed from the root-canal, and the canal thoroughly sterilized: the apex is then opened, and the tract well flushed with a mild antiseptic. This is best accomplished by drying the tooth and packing the metallic point of an abscess syringe into it with gutta-percha, the point having been bent in such a manner that the syringe may be refilled with a medicine dropper. Sometimes the syringe may be refilled, and pressure supplied with the compressed-air spray. The tract should be washed out twice a day, and in the meantime a cotton dressing containing the mild antiseptic solution should be inserted, with a provision for drainage as before described. This antiseptic solution should be no stronger than 70 per cent. alcohol, as that is the greatest strength of the ordinary antiseptic solutions that will not interfere with penetration by causing coagulation. The dressing inserted in the root permits drainage of the abscess tract so that the fistula and the abscess tract both heal up at nearly the same time, and when the fistula has entirely disappeared, and the dressings within the root indicate no further need for drainage, the root-canal is filled, particular care being taken (with the aid of the radiograph measurements) to have the end of the gutta-percha root-canal filling fill the enlarged foramen completely and without protruding.

IV. ROOT INFECTION WITH DESTRUCTION OF THE PERICEMENTUM ABOUT THE APEX.

This condition is disclosed by the radiograph (see Fig. 11). No matter whether there is a fistulous opening or not, in nearly all cases amputation of the apex must be resorted to before the abscess can be healed, except perhaps that autogenous vaccine treatment may be resorted to—which, however, is as yet too little known. In amputation of the apex, the root-canal filling is always inserted prior to the operation (see Fig. 11). The root, having been first thoroughly sterilized, is treated as in other classes. The opening for the amputation and the amount of apex to be amputated are determined with the object of establishing unobstructed drainage (see Fig. 12), the measurements for which are made with the radiograph. Any necessary curetting

Fig. 11.

of the bone is done with a large round bur that is properly sterilized. The tract is then washed out with a mild anti-

Fig. 12.

Incision so sloped that serum will not stagnate about apex.

septic solution, and drainage is maintained by cotton or gauze containing the same solution, which will not prevent the formation of reconstruction tissues, but is inhibitory to bacterial action. This dressing should for several days be changed twice a day and the patient be instructed to sleep so that drainage will be facilitated.

V. PUNCTURE OF THE WALL OF THE ROOT-CANAL.

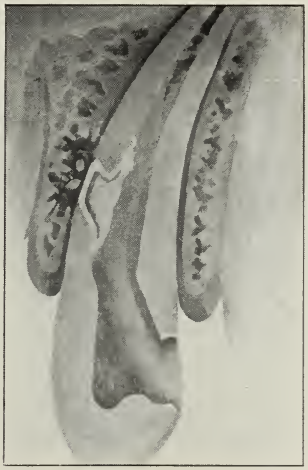
This condition may have two subdivisions—the first (see Fig. 13, a) being abscesses caused by a puncture or by drugs or instruments passing through

Fig. 13.

the puncture; the second subdivision (see Fig. 13, b) being abscesses at the apex of the punctured root due to putrescent matter that was not removed from the part beyond the puncture. In subdivision 1 the apex of the root has already been encapsulated, and no trouble can occur from it. The fistula is usually present in each of these subdivisions. In subdivision 1 the fistulous tract is washed out and the puncture closed, either by making a wax impression of the interior of the root, which is then cast in gold and is inserted with chloro-percha, or by placing a little cement at the side of the puncture (see Fig. 14), after having dried the root thoroughly, and inserting in this the edge of a piece of platinum foil cut sufficiently larger than the puncture. When the cement is set, the platinum and the adjoining root-canal are thoroughly sterilized with 70 per cent. alcohol and then dried with warm air; then the platinum is burnished down over the opening and sealed in with a layer of cement (see Fig. 15). When the cement has hardened, access to the apical portion must be obtained with the aid of the radiograph, and the treatment carried on as in class II, care being taken not to puncture the encapsulation which was permitted to form, because there was always drainage through the puncture. When this is accomplished, the root-canal filling may be inserted, and the condition will soon heal up and the fistula will disappear.

FIG. 14.

FIG. 15.



In subdivision 2, where the abscess is due to putrescent matter remaining in the part beyond the puncture (see Fig. 13, b), access must be obtained to this apical portion with the aid of the radiograph, and the treatment carried on as in class III. Entrance to this apical portion of the root is more or less difficult, because instruments have been passing through the puncture and will have a tendency to continue doing so. The old root-canal filling will sometimes be found outside of the puncture, having been placed there with the supposition that it was in the root. This mistake is made by using too strong drugs in the root-canal, the puncture having been accidentally caused at the portion where the root has a sudden curve, and too strong medicaments used in the root-canal and passed out through the puncture. By their escharotic action these drugs have destroyed the sensitivity of the tissue outside, and have led the operator to believe that he was working inside the root-canal (see August 1912 DENTAL COSMOS, p. 873, Fig. 15). Inserting a filling in this tract outside the root-canal caused inflammation, and the need of drainage established a fistulous opening, so that, in treating these cases, the remaining pieces of the misplaced filling must be sought for by the aid of the radiograph and removed.

When the upper end of the root is finished, the apical portion is filled. The puncture is closed afterward as before described, for the presence of the cement, if platinum is used, or of the gold casting, if this method of closure be employed, will prevent ease of access for the treatments sometimes necessary in class III. After the apical portion is filled and the puncture closed, the remainder of the root is filled. Fistulous openings caused by either of these subdivisions will close up at once when the condition is corrected. A very large puncture in the pulp chamber should be covered for several weeks with platinum foil held in place with gutta-percha, until the tissue has grown firmly against the platinum and established a membranous layer that will not bleed. This must be done with all antiseptic precautions. After about three weeks the gutta-percha and platinum foil may be carefully removed and a soft wax impression made of the punctured

FIG. 16.

portion, which when cast with pure gold makes an efficient covering. The root-canal openings must, of course, be preserved in the gold. Great care must be taken not to push cement or chloro-percha into the membranous covering of the tissues outside of the root, or an irritation will be set up which will defeat the operation.

When a puncture in a root is inaccessible for closing, and the remaining portion of the root is too difficult of entrance for treatment, the root is filled to the puncture with the root-canal filling previously described in cases for amputation. and is amputated at the puncture.

COMPLICATED CASES AND TREATMENT.

There is an additional condition that may be encountered in any class when a badly broken down tooth is involved with suppuration of long standing in the canals, with a bad history, or in certain other difficulties (see Fig. 16). A radiograph may not be available, or an infection beyond the apex may not have progressed sufficiently to be discernible, or there may be so tortuous a root that a satisfactory root-filling is impossible with every aid. We cannot be sure that our treatment is successful, and we hesitate to fill such a tooth at once for fear of future trouble. Temporary fillings with so large a masticating surface pack down, and sometimes exert force through the apex, causing pressure necrosis, or eschars from drugs, and they sometimes fracture the tooth or destroy the attachment of the gingival tissues, and add to the liability of inflammation or food impaction. All this may be avoided, and all hesitation about filling such a tooth may be ended by the following method:

Preparation for a gold casting restoring the original contour of the tooth is made. When the wax form for this is hollowed out with the suction carver and in readiness for investing, a hole is made in its occlusal surface, through which the roots can readily be treated. After casting, an impression of this hole is obtained and a casting made to fit it. This plug is put in place in the filling, and the combination articulated and polished, after which the plug is fastened into the filling with base-plate gutta-percha. The root is then filled as before described, the zinc oxid being inserted as near the apex as possible with a fine silver probe. The contoured gold filling is completed and set with cement (see Fig. 17). If trouble occurs, a little heat will remove the core (see Fig. 18), and access to the root-filling may be had without destroying the contour of the tooth. This form of root-filling, too, is readily removable, is the best kind of dressing that can be put into a root, and becomes a permanent root-filling whenever the apex is encapsulated.

In my opinion root-canal fillings made in the manner described in this paper are preferable to any other form, although success is just as certain with other methods in the hands of careful and skilful practitioners.

ADVANTAGES OF GUTTA-PERCHA.

Gutta-percha treated with solvents loses considerable of its toughness, and when dried is somewhat weakened in structural quality; and, though strength is not needed in a root-canal filling, to my mind gutta-percha softened by heat in the manner described and then pushed into place and carefully sealed is impervious to any deleterious conditions that may arise. Furthermore there is no danger of pushing any of the root-canal filling through the apical foramen if the gutta-percha be inserted cold, having the apical end solid and of known length, so that when it stops at the apex we know it has gone no farther than was intended. There can be no danger of the filling either falling short of the apex or protruding beyond it. Root-canal fillings that cannot be removed at will should never be inserted in roots, as there are times when it is necessary to remove them, and it not only is less difficult and less painful, but also it cannot endanger the future of the tooth, if the fillings are constructed in the beginning with the provision that such a necessity may arise.

VACCINE TREATMENT.

It is well known to bacteriologists that in the kind of infections with which we have to deal, to insure complete success autogenous vaccines should be used—for vaccines made from germs obtained from other sources will not give as successful results as those made from the germs taken from the individual case to be treated, even though the variety of germs in each case be the same. Some germs found in the teeth cannot be grown as yet in artificial media. Conditions occurring from them can have no autogenous treatment; nevertheless, since I have seen stubborn and obstinate cases of abscess in the antrum that were originally caused by diseased teeth, cured by the autogenous method after twelve years' resistance to all other methods of treatment, it is probable that this treatment will be of great service to us in the near future.

Fig. 17.

Fig. 18.

CONCLUSION.

The theory on which this method is based is that we must restore artificially only the parts that cannot be restored by nature (dentin and pulp), and cause no impediment to the natural processes nature is equipped to employ in the restoration of the surrounding tissues.

The illustrations are made from colored charts and are not so descriptive in black-and-white. They are designed to show the conditions described, and are not supposed to be anatomically correct.

No drugs or medicaments are mentioned, but each operator, judging by the conditions and requirements presented, may choose them from his own knowledge of materia medica and therapeutics, which is the only way in which medicaments should be employed.

Painstaking care is of the utmost importance in the treatment and filling of the root-canals of teeth. When a tooth has arrived at the stage where it needs such treatment, it is in danger of being lost. Its crown, in which its actual usefulness is located, is more or less damaged and in need of careful restoration by large fillings or an artificial crown, or must be preserved in order to serve as an abutment supporting a bridge. These restorations are of the utmost importance for the patient in retaining the efficiency of his masticatory surfaces, and they can be made only with untiring and skilful labor on the part of the operator. Therefore the supports to which they are attached, the foundations of their usefulness, must be of certain and lasting durability in order that our painstaking labor may not be in vain, and in order that our patients may be served to our utmost capabilities in the preserving of their appearance, facility of expression, comfort, healthfulness, and even length of life.

IS OPERATIVE DENTISTRY DEGENERATING?—EXTENSION FOR PREVENTION *VS.* PINHEAD METHODS.

By Dr. W. R. CLACK, Mason City, Iowa.

(Read before Section II of the National Dental Association, at its annual meeting, Washington, D. C., September 10, 1912.)

IN 1891 Dr. Black first gave to the public the result of his researches concerning recurrence of dental caries at enamel margins, and the tendency to be dislodged by the stress of occlusion of fillings made in the proximal surfaces of molars and bicuspids and retained only by pits or parallel grooves. At the same time he indicated a method whereby these difficulties might be overcome. Since that time there have been many differences of opinion as to what those methods were, and as to what he really did or did not say concerning those principles.

THE ATTITUDE OF THE DENTAL PROFESSION TOWARD DR. BLACK'S PRINCIPLE OF EXTENSION FOR PREVENTION.

Many men who had access to Dr. Black's operating room at Jacksonville, Ill., and who were granted the benefit of his personal instructions, were able to grasp his ideas at once and apply them in practice, with benefit to themselves and their patients. But the larger number tried to learn from articles in the dental journals, with the result that comes to the majority who try to learn operative dentistry from print. Some of these operations were "fearfully and wonderfully made," and nearly as many teeth were ruined by the misapplication of the Black principles as were lost under the old pinhead methods; but these men profited by their mistakes and sought by every means in their power to obtain a better understanding of what Dr. Black intended to teach under the head of extension for prevention, and eventually won out.

Others never took the trouble to investigate the principles taught by Dr. Black, but opposed them for various reasons. First of all was the objection that these "revolutionary methods" were propounded by a man living west of the Alleghanies, and as all dental knowledge —as knowledge—was known to exist only on the eastern slopes of these mountains, and as the expounder was not a shining light in the dental atmosphere of the "older sections," but had actually sprung from the common people of the West, it was thought best to ignore this fanatic and his teachings.

Secondly, to admit the truth of his contention would necessitate a change in the methods that had been taught since "Washington crossed the Delaware," and that was not to be thought of, so the word went out to ignore as far as possible and to treat with silent contempt these methods that were incorrect simply because they were opposed to the teachings of the "fathers."

But study clubs were formed all over the central West, and either Dr. Black or some of the men who had studied with him would act as censors, correct the errors, and teach in their stead the true gospel of saving the teeth.

The club which is perhaps best known to the dental world is the G. V. Black Club of St. Paul, Minn., organized on May 20, 1898, and incorporated on December 10, 1902. Dr. E. K. Wedelstaedt of St. Paul has been the censor of operative dentistry since the organization of this club. Monthly meetings were held, and as soon as a sufficient number of operators were able to demonstrate these methods, annual midwinter clinics were given, at which Dr. G. V. Black always appeared in person, and all questions of operative procedure were referred to him, and his opinion was final as far as the teachings of that club were concerned. From this club and others in Iowa, Illinois, and Missouri, went out the men who were mainly responsible for the spread of the doctrine of extension for prevention.

I have explained at length the origin and spread of extension for prevention, and the make-up of its sponsors, because the class of detractors spoken of have seen fit to convey the idea that extension for prevention is a sort of "catch-colt" indigenous to that region which a century ago was the home of the buffalo and wild horse, and without either legitimate parentage or godfathers.

It is a source of great sorrow to the dwellers of the western prairies to learn that "their originality has been a shock to the old civilization" east of the Alleghanies. But the truth was this: These unfilial children had tired of waiting for the fathers to evolve a method which would do away with the necessity of remaking every two or three years the pinhead fillings that had failed owing to recurrent caries.

They wanted a method by which they could make a filling in a cavity of the first or second class that would be permanent. Twenty-one years ago Dr. Black began his teachings of extension for prevention. The suggestions he made have been thoroughly tried out; in some cases they have been modified, and in some intensified, but the original principles still stand as they were given out. A very large percentage of the dentists of the middle West have proved to themselves and to those who have given the matter careful attention that those methods when intelligently carried out will save the human teeth.

It makes no difference, as a matter of fact, if the opponents of extension for prevention yell themselves black in the face crying—"In the end it is a failure." Too many thousands of dentists have tried its merits, and know for themselves.

Extension for prevention prevails today in the central West. It has strong advocates in every state west of the Mississippi, and is being taught in greater or lesser degree in nearly all the dental colleges from Pittsburgh and Buffalo to San Francisco.

It is being taught in Tufts Dental School and in Harvard—the "Athens of America"; New York City has its Conzett Club; Wedelstaedt and Searl clubs abound in the western states, and there is even one in far-away New Zealand.

The latter club has at different times sent delegates to spend from three to six months at a time with the different members of the Black Club, learning their methods and carrying them back to the islands of the South Pacific.

If the principles of extension for prevention are wrong, and its advocates, as has been asserted, have written little upon this subject, why is it that it has obtained such a hold upon the dental world? Is it not a calamity that the select coterie of standpatters sat so snugly in their mandarin coats of conservatism and let this evil spread over the country? Why did they not arise in their might, and, like Mrs. Partington, attempt to sweep back the tide, before it overwhelmed the world?

RULES FOR CAVITY PREPARATION BY THE BLACK METHODS.

In the preparation of cavities in the human teeth according to the Black methods, certain rules are laid down, some of them relating to extension for prevention, some to retention, and some to interior preparation.

RULE 1. Extend the cavity margins in all directions until sound enamel is reached.

RULE 2—Seat. The seat must be flat or in steps (which is equivalent), and at right angles to the long axis of the tooth or the direction of the stress.

RULE 3—Preparation of the margins. Cut the enamel to such a point that the surface of the filling may be so formed that the enamel margin will be self-cleansing, or be protected by the gum margin.

RULE 4. Do not leave an enamel margin in such a position as to leave a small portion between it and one of the developmental grooves.

RULE 5. The lingual, buccal, and axial walls of all cavities exposed to stress should be parallel to each other and to the line of stress.

RULE 6. Leave no enamel unsupported by dentin, except on the labial surfaces of the upper anterior teeth.

RULE 7. A fissured, sulcate, or angular developmental groove should be cut out in its entire length.

PROXIMAL CAVITIES AND FILLINGS.

Cavities of decay in proximal surfaces of teeth—and this is where extension for prevention applies chiefly—are seldom presented to the dentist until a smaller or larger quantity of the enamel rods have fallen out. When this is the case it would be poor practice to fill only a pinhead-size cavity, because there would be recurrence of decay if the patient lives. The gingival margin of the cavity should be carried beneath the free margin of the gum. This free margin is not so far rootward as the men who have opposed this method without knowing the details of the work would have us believe.

Though it is not a part of extension for prevention, all students of Black are taught to restore the normal interproximal space, and to preserve it by tight contact points in all fillings made in the proximal surfaces of the human teeth. When this is done, the gum will return to its normal position and securely cover and protect the gingival margin of the filling without this filling being carried "to the dentin of the root, cutting away the cementum and pericementum and dangerously encroaching on the pulp—and, in any event, subjecting that organ to thermal shock that in due course of time will arouse an inflammation there and ultimate devitalization, with pathological sequelæ not pleasant to contemplate."

What a vivid imagination! If all this terrible trouble arises from polishing a filling just under the free margin of the gum, what unheard-of horrors will follow a pyorrhea treatment where the root is "scraped clean" to the very apex!

We are taught that every particle of deposit on the cementum of the root must be removed. In that case, what becomes of the pericementum that originally covered the root? I am not advocating the needless destruction of a particle of the tissues in the interproximal space, but am at a loss to know why, if we can trust nature to repair the damage caused by the deposit thought to be responsible for pyorrhea, and by the removal of this deposit, it is necessary to go into hysteria because someone makes the gum bleed a little in finishing a filling. Not that such a result is any more necessary where extension for prevention is practiced than where it is ignored.

If the standpatters could spend a few golden hours at the chairs of some of the progressives of the land of the buffalo and wild horse, and see how quickly the gum will cuddle down behind one of those contact points, and fill the whole interproximal space with healthy gum tissue beneath which bacterial plaques do not form, they would see that the slight irritation caused by the finishing of the filling at the gingival margin does not bring about all the disastrous consequences so pathetically painted by those word-artists of a past age.

If we may not place and finish the margin of a filling under the free margin of the gum without subsequent loss of the tooth, what, may I ask, do these ultra-conservatives do when a patient presents himself with a cavity of decay in the proximal surface of a tooth in which, from backward decay, the cavity extends under the gum and often into the concavity of the tooth?

This is one of the teeth that "need saving." The advocate of extension for prevention saves these teeth, because he makes a filling there, and finishes it smoothly so that it will have no overhang and irritate the gum; then he makes a contact point to protect it, and trusts to the same power that made the tissues in the interproximal space in the first place to restore it to normal condition.

I had the honor of showing to this association at Buffalo, seven years ago, casts of cases in which such restoration of the gingival tissue had taken place. Some of the men who saw them acknowledged that the restoration had taken place, but asserted that it would not be permanent. I have here today some of the identical casts which I showed at Buffalo—they will no doubt be recognized by many who saw them there—and I have casts made from impressions taken from the same cases within the last two weeks, which show that the gum septa are as perfect today as they were seven years ago. The teeth show a slight shortening from seven years' wear, but the fillings, contact points, and gums remain the same. In one case a third molar has been erupted.

In each of these cases, the first molar had been lost several years, the teeth had drifted apart, and food pockets had formed so that caries had affected the concavity of some of them. I was obliged to remove some of the alveolar process in order to make my restorations. The casts will prove more eloquently than words how perfectly nature restored the lost tissue after I had made it possible for her to do so.

PREPARATION OF CAVITIES IN OCCLUSAL SURFACES OF MOLARS.

The simplest form of cavity is one in the occlusal surface of a molar. As this surface is usually self-cleansing, little extension is required when gold is used. All margins must be carried to smooth surfaces in order that they may be properly finished, and all imperfect developmental grooves must be included in the preparation. No enamel should be left unsupported by dentin.

The walls are made parallel to each other and at right angles to the pulpal wall or seat of the cavity. This seat should be flat. All enamel margins are beveled when gold is to be used; about fifteen degrees is a safe rule. To these rules, however, I make two exceptions. The first one comes under the head of extension for convenience. When operating on lower second and third molars, and sometimes upper third molars, the mesial wall of the cavity must be beveled at an angle of forty-five degrees to nearly one-third of its depth, else the gold will not be condensed against that wall, as the line of force of the plugger will be faulty, and the gold will be driven away from that wall; but with a heavily beveled margin, the difficulty will be overcome.

This rule does not apply to cavity preparation for an amalgam filling. For amalgam, the margins are not beveled, but planed smoothly so that there are no overhanging margins or short enamel rods. *Care must be taken, however, in placing the margins.*

The mesio-lingual cusp of many upper first and second molars is often of such a shape that, if it occludes on the margin of an amalgam filling in the central pit of a lower molar, that margin is in great danger of fracture. If that margin is extended so that the point of the cusp does not strike it, the life of that filling is greatly lengthened. This is precautionary extension.

PREPARATION OF CAVITIES IN PROXIMAL SURFACES OF ANTERIOR TEETH.

We will next take up cavities in the proximal surfaces of the anterior teeth, using the mesial surface of an upper central incisor for an example. These cavities almost invariably start just gingivally of the contact point, owing to the inability or neglect of the patient to keep that surface properly cleaned.

First, all overhanging enamel is cut away, then the cavity margins are extended under the free margin of the gum gingivally and labially until the margin of gold will reflect the light. This procedure will put the margin where it will be constantly cleansed.

The lingual margin should be extended to the crest of the mesio-lingual line angle or mesial margin ridge. If there is lack of sound dentin to support the enamel, cutting must be continued until the enamel is so supported. The margin is extended incisally just past the contact point.

No half-moon should be cut in the labial surface. If the dentin in the linguo-axio-gingival and labio-axio-gingival angles and in the incisal angle is squared out, ample retention will be afforded.

If an angle in an anterior tooth has been lost, the cavity is prepared in practically the same way gingivally as the one last described, but the preparation of the incisal third differs very radically. Take for illustration an upper central incisor with a cavity in the distal surface involving the incisal angle. For retention and protection from occlusion we resort to a step, cut in the incisal portion, but mostly at the expense of the lingual surface.

A step is ground in the labio-incisal angle deep enough to permit of sufficient gold being packed there to protect the labial plate of enamel from the stress of occlusion. This step is deepened on the lingual surface sufficiently to permit of cutting a groove in the dentin between the lingual and labial walls. This groove should end in a small pit just before or just beyond the opposite developmental groove. If there is sufficient dentin, the groove may be slightly widened near the end, and the small pit dispensed with. The angle formed by the union of the step with the axial wall is slightly rounded.

PREPARATION OF CAVITIES IN THE PROXIMAL SURFACES OF BICUSPIDS AND MOLARS.

All cavities in the proximal surfaces of bicuspids and molars are prepared on the same general plan, varying slightly as the positions of these teeth in the dental arch may vary, the principles applied being the same.

Caries in these surfaces is the result of habitual uncleanliness, and it is essential that the buccal, lingual, and gingival margins be extended to self-cleansing areas, if we wish to avoid recurrence. The lingual, buccal, and axial walls must be made parallel to each other and at right angles to the gingival wall. Where this is done, the lateral walls are too weak to permit of grooves for retention, so that we are compelled to resort to a step in the occlusal surface. This step should be cut just through the enamel, and should include all the imperfections to be found in that surface.

The pulpal wall—or floor—of this step must be flat, and the surrounding walls at right angles to it. The angle formed by its junction with the axial wall should be slightly rounded.

Formerly, the lingual and buccal walls were cut to diverge as they approached the gingival border, with a view to better retention, but now many operators cut these walls parallel so that the same cavity may be used without change either for a gold filling or an inlay.

Dr. Conzett and I have given many clinics on this subject.

DEPTH OF CUTTING.

But this is merely an interior detail and does not necessarily come under the head of extension for prevention, but I have spoken of it to show that the very deep cutting with which the pinhead cavity conservatives charge the advocates of extension for prevention exists only in the imagination of the former. Unless caries has already penetrated more deeply pulpward, we seldom cut as deeply as the retaining pits made by the pinhead cavity men. On hearing some of them talk, one would think that they anchored their fillings in the enamel, but such is not always the case.

I will pass around for inspection a tooth extracted by the patient's physician because of incessant pain. In this tooth the pulp-chamber was penetrated by one of these retaining pits. I prepared a cavity in the same surface of the tooth, going a trifle deeper than would have been necessary in the first place, in order to square out the axial wall to the depth already cut, and, as will be seen, there are two of these retaining pits remaining, much deeper than the so-called "ruthless sacrificer of human teeth" ever thinks of going.

STEP AND DOVETAIL ANCHORAGES.

The one great argument in favor of the step anchorage—both occlusal and incisal—is that it places the resistance at the point at which the dislodging force or stress is applied.

There is another form of anchorage which is sometimes used for fillings in the anterior teeth, where the angle is involved, and which is more esthetic than that described, and successful if no stress is brought to bear on the filling.

This method consists in cutting a dovetailed slot in the lingual surface of the incisor or cuspid, and anchoring the filling in that. Stress, however, is a factor that must always be reckoned with. Stress is difficult enough to overcome when we are opposing it on even terms, but in this case we are giving it the long end of the lever.

In many cases the curvature of the gingival line is so great that by cutting squarely across the tooth for the gingival seat either that margin would be left exposed at the linguo-gingival and labio-gingival angles, or we would cut too deeply toward the gingival line at the middle third. To obviate this, the seat may be cut on a curve from labial to lingual, which will afford the same stability of the seat and avoid cutting into the gingival line. But the seat must be flat from the axial wall to the beginning of the cavo-surface angle.

TERMINOLOGY.

In this connection I would digress a moment in an effort to make clear the difference between the gingival *line* and the gingival *margin*.

Gingival line. The line around the neck of the teeth at which the gingiva is attached, the line of junction of enamel and cementum.

Gingival margin. The portion of the tooth next to the gingival line.

Gingiva. That portion of the gum tissue enveloping the necks of the teeth crownwise from the attachment at the gingival line. The free margin of the gum.

Gingival curvature. The deviation of the gingival line from the horizontal in its course around the neck of the tooth.

EXTENSION OF CAVITY MARGIN UNDER THE GUM MARGIN.

Carrying the seat or wall under the gum margin is good practice, and insures freedom from recurrence of caries. This is taught and practiced by the followers of Black.

Carrying the gingival wall or seat

under the gingival line is malpractice, and is not now, and never has been, taught by the followers of Black. But it has been persistently taught by the opponents of extension for prevention, as witness the following quotation from an article on page 414, of the DENTAL COSMOS for April 1912. The author of this article states that—"It is not the writer's purpose to answer Dr. Clack or to defend Dr. McCullough's paper. His aim principally is to *give his own views* on this much neglected subject."

He then proceeds to tell us how a cavity is prepared under extension for prevention rules, and, when he has arrived at the making of the gingival wall or seat, he says: "To proceed with the illustration, the pinhead cavity is then carried down below the gingival border. To accomplish this the said cavity must be extended to the dentin of the root, cutting away the cementum and pericementum, and dangerously encroaching on the pulp."

The making of such an extension is not now taught by Black's followers and never has been taught by them. Those who have never investigated extension for prevention fail to differentiate between placing the gingival margin of the filling under the gingival margin of the gum, and placing it under the gingival line, and I challenge any man to show me a word written by a man acknowledged to be a Black disciple advocating the cutting below the gingival line, and into the dentin of the root. "This is all an hallucination of the man who is opposed to extension for prevention."

EXPERIENCES WITH PINHEAD CAVITY METHODS.

No doubt many of you will be disappointed because I do not deliver myself of a tirade against the pinhead cavity and its followers, but I have it not in my heart to do so. Why should I? Was I not one of them myself for fifteen years? My old preceptor from Rome, N. Y., taught me to make those pinhead fillings in the proximal surfaces of the teeth. Not only did he teach me to make them that way, but he taught me to make all cavity preparations with hand instruments. He never used a dental engine, and I practiced a year without one myself. I have gone through all these "throw-away-your-pluggers" sieges, and still have all my pluggers. I have the old ivory-handled hand drill and pluggers with which I prepared cavities and filled them thirty-nine years ago, and it would be a mistake to think that I cannot use them today.

The ability to manipulate gold is like the ability to swim; the man who once masters the art, never forgets it. I am not ashamed that I was once a pinhead operator. I was one because I was taught so, and knew no other method. I was honest in my efforts to save teeth, and was probably no better and no worse than the men who practice that way today. But during those years I had so many patients who had "soft teeth." It was remarkable how the enamel margins melted away around those "concealed" fillings in two or three years. Then I had to fill those cavities again, telling the victim—"If I can only keep your teeth until you become immune, you will be all right yet," and it was a remarkable coincidence that by the time recurrence of caries had extended the margins of the cavities to self-cleansing areas, the "period of immunity" came for these teeth, and there was no recurrence of caries. I was a wonderful operator! I had saved those "soft teeth," and I could save the rest of the patient's teeth just as soon as the margins had extended to lines of immunity.

A CONVERSION TO EXTENSION FOR PREVENTION METHODS.

I was particularly impressed with these observations in the late eighties, when I had been in practice at Clear Lake for ten years, and I remember telling other dentists that my large fillings lasted the best, but I could not see why, after the patient had reached the age of immunity, the pinhead fillings in his teeth should continue to fail in the same manner. In this way I stumbled along in the dark until, in 1891, I read Dr. Black's articles on "The Management of Enamel Margins" published in the DENTAL COSMOS. Then I knew why the margins I have spoken of were immune. I read more of his writings and thought him an extremist, but I followed him—a long way off—and tried to make a compromise between the method I had been taught and the method I imagined him to be teaching. But soon it was my good fortune to meet Dr. Black, and hear from his lips the principles of extension for prevention. Then began ten years of monthly trips to the G. V. Black Club of St. Paul, where, under the teachings of Dr. E. K. Wedelstaedt and Dr. A. C. Searl, I became soundly converted to extension for prevention. I believe in it, I practice it, I preach it, I teach it, I dream it, and, if occasion requires, I fight for it. And my own experience has been the experience of hundreds of other dentists who are now unqualified advocates of extension for prevention.

This fact, of course I realize, does not necessarily make our claims true, but just as we may judge a tree by its fruit, so extension for prevention has certainly borne fruit that a Burbank might well be proud of.

A trial of twenty-one years has demonstrated that the principles of extension for prevention, if intelligently carried out, will prevent recurrence of caries for ten, fifteen, and twenty years. What more can we ask, and what other method can show like results? I am aware that there are men who, by misstating methods of procedure and attempting to ridicule the West because it is not the East, can convince themselves that extension for prevention is a failure, just as conclusively as the medieval Italian philosophers proved (?) that the theory held by Galileo that the earth revolves on its axis was incorrect. Think of it! Only a few hundred years ago a man was imprisoned, was tortured and excommunicated for believing that the earth revolved. To save his life a man of seventy was obliged to kneel once a week for three years and recant his belief. But it is reported that old Galileo, on arising from his knees, would stamp on the ground and exclaim, "E pur si muove!" (It still moves!) So methinks it has often been with "Galileo" Black. When treated with silent contempt, hissed, ridiculed, misrepresented, and maligned, he has smiled his quiet smile and affirmed—"Extension for prevention still prevents."

INLAYS.

By H. H. JOHNSON, D.D.S., Macon, Ga.

(Read before Section II of the National Dental Association, at its annual meeting, Washington, D. C., September 10, 1912.)

SINCE the days of pioneer dentistry, with its crude equipment and forceful methods, an ever-increasing demand has been made by reluctant victims for more humane time-saving processes.

NECESSITY FOR TIME AND NERVE-SAVING DEVICES IN MODERN DENTISTRY.

In compliance with this demand we have, step by step, made repeated advances. But as we have progressed toward more humane methods, the advance of civilization, with its rapid pace and ever-increasing grind, has continued to raise the nerve tension of mankind to a point where men are less able to stand punishment and have less endurance. Thus each improvement has been felt as a necessity to meet ever-growing conditions, and each has been hailed with delight by both operator and patient.

But even with all these modern helps and conveniences, most of us have found it necessary at times to test the endurance of patients to the limit with rubber dam and long-continued malleting, to insert, piece by piece, a large cohesive gold filling.

Many of our expert gold-builders have had their vital force weakened or destroyed in the very prime of life—for example, the late lamented Marshall H. Webb and others. We therefore owe a debt of gratitude to our gifted collaborators who, conscious of this necessity and their own overtaxed strength, have applied their minds at various periods to devise ways and means of shortening these taxing operations by accomplishing like results with less expenditure of nerve and vital power.

THE EVOLUTION OF THE GOLD INLAY METHOD.

Thus, by a kind of evolution, the inlay has been brought up to such a degree of perfection that it can successfully take the place of large-contour, cohesive gold fillings. As is the case with many other improvements, no one person may take full credit for these valuable ideas, for many, even more than can be mentioned, have had a hand in its development.

Dr. G. V. I. Brown reported methods of gold work of this nature in the *Dental Review* of June 15, 1891. More strictly speaking, these were "outlay" fillings, made after the burnishing method, and consisting in an outer plate only, cemented with gutta-percha. Dr. Brown at this time reported that he had successful pieces of this work under observation which had been made eight years previously.

In 1894, at Old Point Comfort, Dr. S. W. Foster of Georgia read a short paper describing a successful method of making what he termed "laboratory fillings." These were gold inlays made by flowing solder on a burnished platinum matrix. He reported that he had cases two years old which were still doing good service. (See DENTAL COSMOS for September 1894, page 720.)

Dr. C. L. Alexander also—"the wizard of North Carolina"—endeavored for a long time to perfect his method of gold inlay and hood work so that he might present it to the profession in a high state of development. At Asheville, N. C., before the Southern Dental Association, on July 28, 1896, he presented a paper, elaborately illustrated (see DEN-

TAL COSMOS, October 1896, p. 850), describing the most valuable and perfect system of gold inlay and hood work that had ever been read before a society up to that date, and probably up to the present time.

Many of us in the South took private instruction of Dr. Alexander in his burnishing methods of hood and cast work, and have been wonderfully rewarded by the durability of the fillings and the strength and esthetic effect of the hoods in supporting anterior ends of bridges. Others have developed methods of burnished work supported, as his was, by staples or pins, but the records give Dr. Alexander priority for his original and perfect system, and the members of the dental profession owe him a debt of gratitude.

About 1896 the late Dr. W. G. Browne of Georgia demonstrated before some of the southern state societies what might be termed "hollow gold inlays," but which he named "outlay gold fillings," as they consisted in a shell of gold covering a filling of cement. The system had advantages and did its part in developing the inlay system.

A joke is told of the only original R. C. Young of Alabama that he accidentally discovered an inlay system. While giving a clinic before a class of students in contour cohesive gold work, just as he was hammering home the last few pieces to complete the filling the instrument slipped, and he accidentallly displaced the filling. Quickly turning to his audience, he said, "Now I have come to the idea in this work which I wished to show you." Removing the filling intact, he quickly mixed some cement, filled the cavity with it, and forced the inlay back into place. Finding this idea good, he has since made many inlays in this way.

While these methods of inlay work are good and practical, its development did not stop here. Before the Odontological Society of New York, January 1907, Dr. W. H. Taggart of Illinois read a paper, published in the DENTAL COSMOS for November 1907, p. 1117, describing the wax molding method of casting gold inlays. No method that had previously been suggested was so quickly and universally adopted; that it was a valuable and practical idea was apparent from the very beginning, and Dr. Taggart certainly deserves the thanks of the profession for his method of applying this idea to inlay work.

It was quickly adopted because of the seeming simplicity and novelty of the process, and because the practicability of inlay work in saving teeth had been previously fully established, first by the porcelain inlay, and later by the Alexander methods.

LIMITATIONS OF THE WAX MOLDING METHOD OF CASTING GOLD INLAYS.

Time, experience, and scientific investigation are beginning to show that the simplicity of the Taggart system is somewhat of a delusion. It has been shown by various scientists that the working qualities of the materials involved render it difficult to obtain perfect results. No one can deny, however, that by this wax molding method inlays can be made which either fit well enough for practical purposes or can be trimmed to such a fit by using burs and wheels for a sufficient time. It will be a difficult problem to perfect the method beyond its present state of development, because the shrinkage and expansion of the bolus of metal, as well as the waxes and investments, can hardly ever be entirely overcome. The larger the cavity the more necessary and desirable it is to make a cast filling, and the larger the bulk of metal the more shrinkage and expansion take place.

Dr. W. A. Price, in a very scientific article, published in the DENTAL COSMOS for March 1911, p. 265, covering the shrinkage and expansion of waxes, investments, and golds, as affecting the perfect casting of inlays, gives the following factors of error: (1) Decreased size of the gold reproduction due to its own contraction; (2) change in the dimensions of the wax pattern by the cooling when removing; (3) change in the dimensions of the wax pattern by changes in temperature while investing; (4) changes in dimensions of the investing medium in the process of heating and cooling; (5) in casting over right-angle corners, the passing of the fluid gold over the sharp corners has the effect of brushing some of the investment away; (6) air-bubbles at the marginal groove through error in investing.

Other writers, as Lane and Van Horn (see DENTAL COSMOS, May 1909, p. 546; August 1910, p. 873; June 1911, p. 664; October 1911, p. 1109; August 1912, p. 890; September 1912, p. 973), have elaborated on methods of overcoming shrinkage and expansion, thus admitting the imperfections of the system. Indeed, one has but to make a few castings of saddle fillings in bicuspids and molars to note that this shrinkage is a factor to be reckoned with from a practical standpoint. Such fillings may be made to approximate a fit by careful grinding and burring, but they can seldom be made to seat without these changes.

THE ALEXANDER PLASTIC INLAY GOLD METHOD.

The more recent experiments of Dr. Alexander have effectually overcome all of these objections, and given us a method that is absolutely freed from shrinkage, expansion, or warpage. The Alexander plastic inlay gold can be molded directly into the cavity and invested in a small bolus of investing material, the shrinkage and expansion of which has no appreciable effect on the filling. The porous mass of gold is then solidified by flowing 22-karat solder into it. The result is a perfectly fitting inlay that has sufficient hardness to withstand mastication thoroughly.

If a higher karat is desired than would be obtained with plastic gold, moss fibre or Corona gold may be used. By using cotton rolls to protect the parts from moisture, the mold of the cavity may be made with these golds unannealed, building in and condensing large pieces until the desired fulness and contour have been obtained. The gold mold may be removed by inserting an exploring point into its surface at a point away from the margins, and lifting it out. The mold is invested in a bolus of investing material leaving some portion of the occluding surface exposed. The mass is then completely solidified by melting 22-karat solder into its surface. The solidity of the condensed mold will prevent its taking up very much solder, and will therefore represent a high karat as well as a hardened mass.

In many, not to say the majority of cases, it has been found that a matrix of thin gold greatly facilitates the process of molding the gold directly into the cavity. The matrices are best made of either No. 30 rolled gold, No. 60 gold foil, or Tatham mesh gold. A piece considerably larger than the cavity is cut out, annealed, and placed over the opening. It is so soft and pliable that it may be partially swaged to an approximation with a pledget of cotton in the foil pliers. After this either the Alexander plastic inlay gold, moss fibre, or Corona may be packed into the matrix with sufficient force to adapt its surface to the walls of the cavity. When the cavity has been filled with the gold, the matrix containing the gold mold may be carefully removed from the cavity and the surplus overlapping parts of the matrix cut away with a pair of embroidery scissors, when the filling may be returned to the cavity for a final burnishing and adaptation of occlusion. The matrix and gold mold or unsolidified filling may then be removed for investment. The investment is preferably made with S. S. White investment compound No. 4. This material has a coarse-grained consistence, so that it may be dried rapidly without cracking, and its composition eliminates contraction and expansion. The investment is made by mixing a small quantity of the material with water to the consistence of model plaster. A quantity of the size of a small marble is placed on a piece of paper, and the gold mold is dropped into it with the cavity side down. The mold is tamped down into the investment, and the material worked up over the margins until all is covered except a small opening in the center of the occlusal surface.

The investment may be placed at once upon a wire frame over a Bunsen flame for heating up. The necessary quantity of 22-karat solder, well boraxed, is laid over the opening leading into the filling, the blowpipe is applied from beneath, and heating is continued until the solder melts, when it will literally drop into the porous mass of gold beneath, filling in the interstices and solidifying it. The operation is so simple that little time need be consumed in the process. The thin gold matrix does not affect the fit, as it can readily and perfectly be adapted to every cavity surface, and is a decided advantage in many cases, as it assists in removing the mold of gold from the cavity without distortion, attracts the solder, and tends to pull it down through the mass of gold above. Emphasis is placed upon the impracticability of using thin platinum as a matrix instead of thin 24-karat gold. Platinum is too harsh and unyielding, and should never be used.

Fillings made after this method need no cutting or grinding to adapt them to the cavity, as there is no shrinkage or warpage from expansion or contraction of metals or investment. Every step is direct, there is no transferring from an impression to a mold, and no wax to shrink or expand.

I would emphasize the fact that it is easier to make a perfect mold of the cavity with plastic inlay gold than with wax, and the adaptation is much more certain. It is also easier to make a mold with plastic gold than with moss fibre or any of the fiber golds.

Plastic gold is applicable for occlusal surfaces of crowns, backings of porcelain facings, the mounting of Logan crowns, etc. The certainty of a fit, the time saved in adjusting, to say nothing of the time lost in burning out wax molds, as required in the Taggart process, is well worthy of consideration.

SUGGESTIONS FOR MAKING ALEXANDER GOLD HOODS.

Before closing, it might be of interest to call attention to Price's artificial stone as a help in making the Alexander hoods. After the tooth is prepared and the staple or the pins used are in place, an impression of the tooth is taken with Dr. Price's special wax. The pins or staple will come away in the impression. A model of the tooth is made in "artificial stone." The thin 40-gage, 24-karat gold may now be burnished over the stone model, and, to facilitate burnishing the gold may be soldered to the pins or staple with a tiny piece of 22-karat solder to form an attachment to hold the unfinished hood in place. All annealing and soldering can be done on the stone model, as it stands the heat perfectly. When the adaptation is complete, solder may be flowed over the surface of the gold to the thickness desired, thus completing the hood.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

WHAT IS MEANT BY DRUG STANDARDIZATION?

By F. E. STEWART, Ph.G., M.D., Philadelphia, Pa.

(Read before Section II of the National Dental Association, at its annual meeting, Washington, D. C., September 10, 1912.)

A VISITING physician of one of the large Philadelphia hospitals called me up by telephone for information regarding the failure of fluid extract of apocynum to relieve dropsy in three patients under his care. Finding that he did not know whether or not the fluid extract had been standardized, I suggested the use of a standard preparation. Three or four days afterward my medical friend again called me up to report that the standardized fluid extract procured at my suggestion was promptly effectual, and said: "If standardization means so much for other drugs, it is about time for the medical profession to awaken to its importance."

IMPORTANCE OF DRUG STANDARDIZATION.

A prominent Canadian physician, to whom I was demonstrating the modern methods for drug standardization in the laboratory, said: "The medical profession knows in a general way that drugs vary in strength, but only few physicians are aware of the wide variations in such important drugs as digitalis, strophanthus, and apocynum demonstrated here today. We know that some bicarbonate of sodium is pure, and other lots are purer. This is about my limit of knowledge, but that digitalis fluid extracts on the market may vary 300 per cent. in active constituents, and strophanthus fluid extracts show a variation of 6000 per cent., is an eye-opener to me."

The importance of drug standardization is so great that all intelligent persons, laymen as well as members of the medical and pharmaceutical professions, should be informed of its value. For without this knowledge physicians do not realize the necessity of discriminating in favor of standardized products when prescribing, pharmacists do not appreciate the necessity of standardizing their products, or purchasing their supplies from manufacturing houses engaged in standardization work; and people ignorant of the fact that preparations of the same name may differ so widely as to be dangerous to life, take prescriptions to drug stores where they can get them compounded at the cheapest price, without regard to the character, quality, and strength of the ingredients that enter into them.

NOMENCLATURE.

One of the first factors of importance in the consideration of drug standardization is nomenclature. To every drug a name must be given by which it may be invariably known and dealt in. The Latin language is generally employed, because it is a dead language and is not liable to change, as is the case with a living language.

The name adopted must belong to the common language of science, and not be commercially controlled. So-called trade-mark names or trade names do not meet the requirements of science. If the product is not provided with a scientific proper name, standardization demands that the scientific societies should name it, or the government might well do so in connection with the enforcement of the pure food and drug law. As for the trade names, text-books are adopting them as generic appellations or synonyms without protest from the manufacturers, who therefore cannot justly complain if competitors adopt them for describing identical products.

METHODS OF STANDARDIZATION.

Botanical standardization is absolutely necessary in establishing the identity of vegetable drugs. *Capsicum fastigiatum* is the botanical name for the variety of capsicum designated by the U. S. Pharmacopeia. *Capsicum* indicates the genus, *fastigiatum* the species, to which the plant belongs. In relation to medicinal chemicals the U. S. P. gives in the "purity rubric" the amount of permissible innocuous impurities in each case. More than this amount the substance must not contain to comply with the U. S. P. standard.

Preparations of chemical drugs are standardized by chemical assay. The same applies to preparations of vegetable drugs containing active principles susceptible to assay chemically. But there are a number of important preparations of drugs which cannot be satisfactorily standardized in this manner. I refer to the preparations of digitalis, aconite, cannabis indica, convallaria, ergot, gelsemium, lobelia, squill, strophanthus, and veratrum. These preparations are standardized physiologically by tests on animals.

Physiological or pharmacodynamic standardization is likewise employed for standardization of adrenal glands, thyroid glands, etc.

Antitoxin and curative sera are also standardized physiologically; bacterins (bacterial vaccines) are standardized by bacterial count. The strength of old tuberculin is approximately determined by clinical tests, and the same applies to smallpox vaccine, while the newer tuberculins, "T. R." and "B. E.," are standardized by determining the content in solid substance.

LEGISLATIVE REGULATIONS.

The Food and Drug Act of June 30, 1905, made the United States Pharmacopeia and the National Formulary official standards for interstate commerce in drugs and medicines. Most of the states have enacted similar legislation. Consequently drugs and preparations sold under the U. S. P. and N. F. names, must be made in accordance with the standards laid down by these authorities, or they are misbranded and are liable to seizure by the government. Manufacturers and dealers who do not follow these standards are amendable to the law. The national law and the laws of most of the states permit the sale of products differing from these standards, if the differences are plainly stated on the labels. Some of the state laws are more strict and permit no deviation.

EXAMPLE SHOWING THE ABSOLUTE NECESSITY OF STANDARDIZATION: APOCYNUM.

By way of illustration let us consider the method of physiologically standardizing fluid extract of apocynum. Apocynum belongs to the group of so-called heart tonics, of which digitalis is the chief exponent. I have two reasons for considering apocynum first. One is that it permits a continuance of my story relating to the use of this drug in the treatment of dropsy in the clinical service of my medical friend; and the other is the opportunity of pointing out the advantage of physiologic tests for a drug not properly standardized botanically.

"Fluid extract of apocynum" is the U. S. P. name for a preparation of the "dried rhizome and roots of *Apocynum cannabinum,* or of closely allied species of apocynum," and is made by percolating the dried and powdered drug with a mixture of alcohol, water, and glycerin. The Pharmacopeia directs that each cubic centimeter of a fluid extract shall contain the active constituents of one gram of the drug from which it is prepared. Fluid extract of apocynum should therefore represent the drug volume by weight. In other words, one minim (drop) should approximately represent in activity one grain of the dried and powdered drug.

Apocynum is commonly known as Canadian hemp, or black Indian hemp, and is also called incorrectly "Indian hemp." It belongs to the *Apocynaceæ,* or dogbane family. This remarkable family of plants consists of about 130 genera, including more than a thousand species, growing abundantly in most tropical countries, thence decreasing to rarity in temperate regions. The plants are trees or erect climbing shrubs, rarely perennial herbs, and are among the handsomest and many of them among the most fragrant in the vegetable kingdom, and are largely used for decoration. Otherwise, except for a few edible fruits, and the rubber-yielding species (African rubber is chiefly the product of this family), this species is interesting chiefly from its medicinal and poisonous properties. So numerous and abundant are these plants, and so generally and intensely poisonous are they, that their appearance should be noted by everyone, to be avoided. A botanical description would exceed our space limit.

The active constituents of the plants are alkaloids and glucosids, which may be encountered in any of the plant parts, but are especially common and abundant in the bark and seeds. Among savages these are very common agents of criminal, military ordeal, and legal poisoning, and accidental poisoning by them is not infrequent. Some of the most powerful arrow poisons are derived from this family.

We are in complete ignorance as to the species of apocynum which should yield this drug. Up to a very recent period, five or more distinct species were included under the name *Apocynum cannabinum,* even in our standard botanical works, and the plants themselves are not distinguished. It is therefore impossible to ascertain which species should yield the drugs whose actions have been reported under that name. This fact doubtless explains, in great part, the conflicting testimony regarding the medicinal activity of the drug.

The drug as it appears on the market is of indefinite length, one-eighth to one-third of an inch thick, cylindrical, wrinkled, fissured, orange brown, becoming gray brown on keeping, almost inodorous, and in taste starchy, afterward becoming bitter and somewhat acrid. The active constituents are the bitter glucosids, apocynin and apocynein. Its effects are similar to digitalis (common name "foxglove"). Apocynum is usually given in the form of fluid extract, the average dose of which is 5 minims.

From the foregoing it must be very apparent to any thinking person that fluid extract of apocynum, when prepared from a drug not properly standardized botanically, is a very uncertain preparation. As already stated, we are in complete ignorance as to the species of apocynum which should yield this drug; so we are not sure when purchasing it that we have the species containing the glucosids to which its medicinal value is due. No way is provided by the Pharmacopeia for determining whether and in what quantity these constituents are present. Even though an assayed drug should be employed, no directions are given to ascertain whether the finished preparation contains them in proper amount. Unless the finished fluid extract is subjected to standardization, the dose of five minims may be too large, or, on the other hand, the preparation may be inert.

Is it any wonder under such circumstances that the hospital physician who called me up did not obtain satisfactory results from fluid extract of apocynum in the treatment of dropsy? But a very different report followed the substitution of a standardized fluid extract. The dropsy which threatened the patient's life commenced at once to yield, and the heart and kidneys to resume their functions. Let us therefore consider how fluid extract of apocynum is standardized.

Apocynum belongs to the so-called "digitalis series," which includes digitalis, or "foxglove," apocynum, convallaria (commonly known as "lily of the valley"), squill, and strophanthus. The drugs of this group have the peculiar power of stimulating the heart, and are of enormous value in the treatment of certain diseases of the heart and kidneys. When given in medicinal doses, they cause the heart to contract and empty itself with greater force, thus restoring the circulation of the blood to the kidneys and other organs in case of heart weakness.

This property of strengthening the heart's action is invaluable in dropsy, in which impaired circulation is a prominent factor. By their action on the heart and arterial system—which is, in fact, a continuation of the heart, by reason of its muscular walls with their contractile power aiding the circulation—such drugs as apocynum, digitalis, and strophanthus also act as diuretics. Forcing more blood through the kidneys, they aid in purifying the blood of urea—the ash of tissue waste—and so preventing death from uremic poisoning. By their use the most severe forms of dropsy may often be quickly relieved, the weak and dilated heart restored to normal action, and the patient at death's door returned to fairly good health and continued many years in a life of usefulness.

STEPS IN STANDARDIZING.

The first step in standardizing preparations of drugs is to assay the crude drugs before purchasing. The manufacturer of standardized drug preparations would soon find himself out of pocket if he neglected this precaution. Drugs are of value in direct proportion to the active principles they contain, and these constituents vary in different lots.

The next step consists in assaying finished products and adjusting the amount of active principles present to fixed standards. This is accomplished either by chemical assay, or by physiological tests on animals, or by both methods, one being used as a control for checking results obtained by the other.

STANDARDIZING BY THE "LETHAL DOSE" METHOD.

A number of physiological methods for standardizing the digitalis series of drugs are in use, among which is the so-called "lethal dose" method of Reed and Vanderkleed. The first step in this method consists in determining the lethal dose; this is accomplished in the following manner: A series of guinea-pigs is selected, each weighing approximately 250 grams. The preparation to be tested, if a tincture or fluid extract, is then freed from the greater part of alcohol by evaporation, and diluted with water to the desired quantity. Into a series of four of the guinea-pigs this dilution is now injected in amounts equal to 9/10, 10/10, 11/10, and 12/10 of the standard lethal dose. The animals are then placed in cages and allowed to remain for twenty-four hours, when they are examined, and a note is made of those which are living and those which are dead.

The result of this preliminary test, in which the range of dosage is quite wide, enables the investigator to form some idea as to the strength of the preparation. Basing the dosage upon these results, other series of guinea-pigs are injected with progressively increasing or decreasing doses, as the case may be, still further diminishing the variations between doses, until the smallest amount is found which will prove fatal within twenty-four hours. The probable minimum lethal (toxic) dose of the preparation, unless it deviates considerably from that of the standard, is generally obtained by one or two series of injections.

In order to express the percentage results, it is necessary to adopt for each drug or preparation assayed a standard minimum lethal dose (m. l. d.) with which the preparation being tested may be compared. For example, the m. l. d. of fluid extract of digitalis is 0.1 cc.; that of fluid extract of strophanthus, 0.0025 cc.; that of tincture of strophanthus, 0.025 cc.; that of fluid extract of apocynum, 0.075 cc. After comparing the preparation to be standardized with the standard m. l. d., it is diluted or concentrated, if necessary, to bring it down or up, as the case may be.

As already stated, digitalis fluid extract on the market may vary 300 per cent. in strength. This fact was stated in Bulletin No. 48, issued by the U. S. Bureau of Hygiene, Washington, D. C. Later researches show the variation to be from 30 per cent. to 400 per cent.

FATAL RESULTS OF SLIPSHOD METHODS.

Now, as digitalis is one of the most important drugs in the treatment of diseases of the heart and kidneys, and conditions often arise in practice when the patient's life is entirely dependent upon its prompt and decided action, accuracy in dosage is essential. Unless the dose is large enough to produce the required effect upon the heart and circulation, failure results. If the dose is too large, the patient dies of digitalis poisoning. Imagine the danger resulting from neglect to use standardized digitalis preparations: The patient takes the prescription to the druggist, who secured his pharmaceutical education before the advent of the modern drug standardization, and obtains a fluid extract or tincture below standard. The dose prescribed fails to relieve the patient, and is therefore increased. We will assume that the tincture is prescribed in 15-drop doses. This dose failing to relieve, 20-drop doses are given, to be rapidly and progressively increased for effect until 60 drops are used per dose, and the same administered three times a day. After a week or more the phial is emptied, and the patient sends to the drug store for renewal of the prescription. In the meantime the druggist has purchased a fresh supply of tincture of digitalis which happens to be three times as strong as the weak preparation first used. The patient goes on with the 60-drop dose as before. But now he is taking three times as much drug at a dose, or an amount equal to 180 drops. The toxic action of the drug soon manifests itself, the patient grows worse and worse, and finally dies in convulsions which are ascribed to uremia—when they were, in fact, due to digitalis poisoning.

"How careless the doctor!—how careless the druggist!" say you. Nay; rather say, "How ignorant and negligent are both of the importance of drug standardization!"

Or, the physician, fearing to give larger doses of digitalis than that laid down in the text-books as a maximum, goes on with his ineffectual dosing, and the patient finally dies in uremic convulsions. In either case death is the result, and the cause is the same—namely, want of standardization of the digitalis preparation employed.

CENTRAL BOARD OF CONTROL ADVOCATED.

It may be asked why not separate the active constituents and use them for medication instead of trusting to the uncertain fluid preparations of the drug? There are insurmountable difficulties in this matter; in the first place, the active principles of digitalis are only partially known, and the isolation of those with which we are acquainted is attended with considerable difficulty. There appear to be at least four glucosids in digitalis which possess the characteristic action on the heart and circulation, and these are accompanied by one or more glucosids decidedly different in their effect. The therapeutic action is composite and is due to the combination of a number of principles which act and react on one another to produce the characteristic effects of digitalis as a therapeutic agent; therefore, the only way to be sure of obtaining the desired effect is to use a physiologically standardized preparation of digitalis itself.

Therapeutic standardization by the coöperative investigations and impartial discussions of competent observers are necessary. Progress in scientific materia medica is dependent upon it, and public welfare demands it. How can we as physicians meet our obligations in this regard when new products are controlled commercially and introduced by advertising? Until some plan is adopted for the protection of professional interests, impartial discussion is impracticable. If reports concerning advertised products are adverse, there is a danger of lawsuits;

if they are favorable, there are suspicions of purchase. A strong central board of control representing commercial as well as professional interests is urgently needed, to prevent dishonest exploitation of common interests by selfishness.

DETERIORATION OF DRUGS BY THE ACTION OF THE AIR.

One of the problems of standardization is to prevent the finished product from deterioration on account of the action of the air. Preparations of ergot, digitalis, strophanthus, aconite, and several other important drugs soon lose their strength on this account. It has never been realized until lately that most of the deterioration going on in fluids owing to the action of the air, is due to the air held in the fluid rather than to the air in contact with the fluid in the container. For example, a container may be completely filled with a fluid and then hermetically sealed, yet the oxygen of the air in the fluid will continue to act and cause its deterioration.

Researches were made in the Mulford laboratories by Pittinger and Vanderkleed to determine the influence on deterioration of exhausting the air from fluids, and then sealing them hermetically under vacuum. Fluid extract of ergot was chosen for the experiment. First of all, the fluid extract was tested by injection into dogs, and gave an immediate rise of blood-pressure represented by 44.8 mm. of mercury. The total assay for alkaloids by the process of Meller gave a percentage of 0.163. This fluid extract of ergot was then divided into four portions, as follows:

A: The first portion was put up in vacuum in tubes specially designed and made for this purpose.

B: The second portion was filled into bottles which were tightly corked, and allowed to remain for one year unopened.

C: The third portion was filled into bottles which were kept loosely corked for one year, this being obtained by boring a small hole in the cork.

D: The fourth portion was tightly corked, but opened occasionally throughout the year.

These four samples were tested upon dogs at the end of twelve months, with the result that, with A, no loss of blood-pressure-raising power was sustained; this was also true of the percentage of total alkaloids. Of the other samples, the tightly corked sample, B, deteriorated the least (about 35 per cent.). A greater deterioration was noted in C, while D (bottles tightly corked, but opened occasionally, under which conditions the preparation is commonly kept) showed the most marked deterioration (67 per cent.).

These investigations would indicate that, with complete exhaustion and exclusion of the air from the container and its contents, practical permanence may be secured.

CONCLUSION.

I hope my paper has proved of sufficient interest to excite your desire to investigate the subject of standardization more deeply, and I am sure, if you do so, that many astonishing revelations await you. Among other things you will discover one of the causes of therapeutic nihilism, and you may find out that drugs possess powers undreamed-of, that can only be revealed by drug standardization.

ARISTOCRACY IN DENTAL EDUCATION.

By B. HOLLY SMITH, M.D., D.D.S., Baltimore, Md.

(Read before Section II of the National Dental Association, at its annual meeting, Washington, D. C., September 10, 1912.)

CARLYLE says in his "French Revolution"—"Aristocratism rolls in its carriage, while patriotism cannot trail its cannon."

Those who are disposed to reflect upon the growth and progress of dentistry, to recognize its vast scope of usefulness to the human race, are bound to con over in their minds the causes of that growth, and to estimate whether the forces which have influenced it have been as effective as they should. As a prominent factor in that development, the dental college has, from time to time, come in for a great deal of criticism, much of which was just and helpful, but some of which, your essayist thinks, was neither fair nor well intended.

EDUCATIONAL PRINCIPLES OF EARLY DENTAL COLLEGES.

The beginning of the dental college was, fortunately, in the hands of men who held in high esteem, and promulgated, a system of ethics which at once became the foundation of the new profession. From that time to the present there has been a gradual growth in appreciation of our services on the part of the people, and a corresponding development, on our part, of a keen sense of our responsibility to them. Associate and affiliate as much as we will with men of other professions or specialties, we are unwilling to have that growth of appreciation abridged or that responsibility divided.

In the organization of the dental college, the founders recognized the importance of having the strictly medical branches of the dental curriculum taught by medical men, so that physiology, anatomy, chemistry, and allied branches were always so taught; but these courses were always supplemented by dental instruction of a special character. For instance, to the course of chemistry was added metallurgy; to anatomy and surgery, special or oral surgery, to materia medica dental materia medica and therapeutics. In other words, the instruction was so shaped as to create a broad-minded specialist, equipped by training that could not be gotten in mere medical courses.

While in the early days of dental education the names of Baxley and Bond were associated in high esteem with those of Harris and Hayden, all the Bonds and Baxleys from that day to this have not and could not have made a dentist. This unique product is the result of the special training which alone could produce it.

MODERN TENDENCIES IN DENTAL EDUCATION.

It was the work done by these specialists, graduates of dental colleges, which caused medical schools and universities to consider it of sufficient importance to establish departments of dentistry in their institutions. These departments have done good educational work in a field where such work was needed, and where, but for them, it could not otherwise have been accomplished, and it is not the purpose of your essayist to criticize the results of that work. He does, however, deprecate a "holier than thou" attitude of mind which has recently grown up among them toward that class of education which existed before they entered the field.

Some of these special pleaders, without establishing their claim to authority and with no proof of superiority, have advocated the abolition of all dental colleges—strictly speaking—have charged against these institutions abuses and deficiencies which do not exist, and have fomented opposition and antagonism until some of their boldest followers are advocating doing away altogether with the degree of Doctor of Dental Surgery. They are barnstorming about at dental meetings crying—"Down with the D. D. S.!" "Come and take a ride in the university aeroplane!"

Not only have such advocates no respect for precedent, no veneration for the heroic deeds of their forebears, but they entertain a very mistaken notion of the needs of the hour. They exhibit a boastfulness and vanity never an accompaniment of the truly great. They would besmirch a title which great men have been proud to honor; they insult the flag under which the pioneers and leaders of our calling have so ably and successfully fought.

I never hear these theorists—and who attends meetings of our specialty that does not hear them?—without being reminded of words of wisdom (?) which emanated from a dear departed old bachelor friend on the subject of the proper bringing up of children. He denounced mothers in general as imbeciles or idiots, because they did not compel their children to wear tight-fitting caps which came well down over their ears, so that those appendages might be trained to sit flat against the side of the head and not stick obnoxiously out at an angle. The quotation "Little pitchers have big ears" aroused my bachelor friend to scorn, and the youthful chap who could hear from the distant meadow the cry of the plover, or from the deep tanglewood the sharp sweet song of the cardinal, possessed no advantage in his eyes.

THE LARGE UNIVERSITY DENTAL DEPARTMENT VS. THE SMALL DENTAL COLLEGE.

Dental education in the United States has made very satisfactory progress in the past seventy years. Since the organization of the Baltimore College of Dental Surgery in 1839, there has been a general and steady improvement in the methods of training, the preliminary requirements exacted, and the time occupied; until today the dental student must present for admission a diploma from a recognized high school or its equivalent; must spend three years of seven months each in attending upon lectures and demonstrations, and has the opportunity to spend the intervening time between sessions in the infirmary in the actual practice of dentistry. The equipment of the average dental college is ample; besides this, the institution becomes in any community a center of training, not only by the regularly authorized teachers, but by clinicians who are not connected with the school, but who by inventions or demonstrations of skill become prominent.

The almost inevitable output of these institutions should be prepared to meet the requirements of the most exacting; and yet we know that they do not invariably exhibit satisfactory evidence of proficiency. Much of the delinquency is due to personal characteristics or habits, and perhaps could not be weeded out by any system, but unquestionably much can and should be done to prevent the advancement to graduation of an inattentive or delinquent pupil. This, in the judgment of your essayist, can be done only by establishing a closer personal contact between pupil and teacher. In many of our professional schools the student is a free lance; if he makes good with the attendance officer and passes his examinations, nothing more is required of him. There is little effort made to discover and direct unusual outcroppings of genius or skill, or to better by advice or encouragement lapses of discipline or breaches of good habits. The pupil is left too much to his own resources, and many of his efforts are not well directed. He is more like a careless gleaner than one of a well-organized company of reapers. In the Baltimore College of Dental Surgery the students are divided into sections of eight, with a section captain and a section quiz. The section captain keeps in touch with his eight men, and reports to the teachers as to their progress and behavior. In this way, when a man is found to be falling behind, he is sought out, and an effort is made to start him over or help him up. Many times these men are simply involved in unfortunate companionship or are discouraged or homesick. In professional schools where the classes run into hundreds, individual neglect is almost unavoidable. Frequent examinations, it is true, help to keep the whole class in line and at work, but many students need and should have the constant supervision and friendly advice of the teacher. During the seven years that I acted in the capacity of demonstrator, I can recall with great pleasure the wonderful unfolding of cleverness in the young dental operator, after a little straightening out by friendly advice and demonstration, whereas with pain I recall the blunderings of my own student days, when, for lack of these helps I often arrived by some circuitous and difficult route.

The problems of dental education, in the judgment of your essayist, will not be solved by any syndicate of universities with enormous classes a considerable proportion of which speak and can understand only a foreign tongue, but who, by the use of their quiz compends and other helps, move on with the army of students from promotion to promotion, and emerge finally by graduation without having a sufficient knowledge of the language to enable them to comprehend intelligently the lectures which they attended. No one would be so stupid as to deny that equipment is essential both to the individual and the institution, but no amount of equipment can take the place of the personal skill and ability of the operator or teacher. The latter must not only be well-informed in his subject and its corollaries, but he must be able to impart a knowledge of these to the student, and this he cannot do so successfully at a distance as he can when he is in close contact with that student. In the schools where the classes are smaller, the opportunities for this close personal supervision are greater, and the student is more than compensated for lack of volume in the "rah-rahs" of his class yell by the inspiration he gets from his close association with his experienced teacher.

NECESSITY OF POSTGRADUATE COURSES IN UNIVERSITY DENTAL SCHOOLS.

The value of this intimate relation is fully appreciated by everyone of experience. Who but can recall the wonderful influence upon operative procedure of such men as Robert Arthur, Varney, Webb, Bonwill, Palmer, Brown, and others? These men taught as clinicians, and their demonstrations were followed at the chair by as many as could see—those in the outer circle reaped practically no benefit. Postgraduate courses are today almost necessary to the students, because special training in small sections has not been carried out in the regular course. It certainly does not seem fair that, for this postgraduate instruction, the student is expected to pay a special fee to the very man whom the college circular advertises as its specialist upon that branch. If the student can be made more proficient by this method of teaching in small classes, then the method should prevail invariably, and not be a matter of selection by the student who can pay the price. If the advertised fee of the institution is not sufficient properly to compensate the teacher for teaching the whole class in the most effective way, then the fee should be raised, and so advertised. No one who is employed as a teacher in an institution should be allowed to accept a special fee from a student of that institution, and his services should be as free to one as the other. His ambition should be to send out only prepared men, and to this end he should be willing to spend his time and effort freely with those who need it. If there is a place in the world for altruism, it is in the heart of the teacher. Everywhere we find him overworked and underpaid, and so, perhaps, it will always be, but the teacher has other compensations which count for more than money. No man who has really taught can cast a scornful glance at his past effort. He knows he must live on and on, in the execution by his pupil of the principles which he imparted.

DRAWBACKS IN THE DENTAL STUDENT'S ATTENDANCE ON MEDICAL COURSES.

In line with the argument for a closer contact between the teacher and pupil, I cannot avoid what I think is a just comment on medical schools and universities having dental departments, which, for economical reasons, compel their dental students to take many of their branches of study with the students of medicine. In many cases they form but a small minority of a very large class, but are compelled to spend their time in attendance upon lectures where the professors too often are poorly informed as to the principles in the science and art of dentistry. They are either ignored as to any special training in the subject or are treated as an ever-present source of pleasantry and amusement, both by the professor and their associates of the medical classes, not only in the lectures but also in the examinations. "Oh, you are only a dental student," not infrequently follows identification. Can anyone tell me that this is a wholesome atmosphere in which to build respect and love for one's calling? Does the makeshift hold his head higher under such identification? Is the time of the dental student most advantageously spent in picking up crumbs that fall from the medico's table, following, often at great distance, in the labyrinthine excursions through the domain of therapeutics and materia medica? If that medical professor were informed as to the necessities of the dental practitioner and condescended to lead him by the hand, well and good; but to make him a rank outsider, as is too often the case, involves both the institution and the student in a fraudulent transaction.

DURATION OF COURSE OF INSTRUCTION.

A knowledge of medicine is of unquestioned advantage to the dental practitioner, but any greater knowledge than is gained in the regular course of dental instruction should be acquired in other time than that which is allotted to obtaining a dental degree. In some of our universities, the D.D.S. and the M.D. degree have both been awarded after four years, the same time which is demanded for the acquirement of the M.D. degree alone. Certainly, an injustice on one of these degrees must have been perpetrated. Three years is short enough time to prepare the most earnest student for the practice of dentistry, and the Association of Medical Colleges has declared that four years is not too long to prepare the medical student to become a practitioner of medicine. Railroading students into both of these degrees in four years cannot be looked upon with favor.

THE TEACHER AS THE MOST IMPORTANT FACTOR IN DENTAL EDUCATION.

The most important factor in dental education is the teacher. Our schools must involve in their work the co-operation of men of broad minds—men who are students, and who possess the rare quality of being able to impart information; men who can inspire the pupil with a desire to be a credit to his calling, who can persuade him to make the sacrifices required, and impress upon him the fact that college work is only the beginning, a training that will fit him for study which will yield greater results when experience is added to correct effort.

The Institute of Technology, which holds a yearly meeting of a few days, might readily hold a sort of summer chautauqua, where as many weeks could be profitably spent in demonstrating methods of teaching. It is safe to say that enthusiasm might be engendered and technique improved if, at some cool mountain resort, several of these meetings could be held in different sections of the country. The writer knows scores of men whom he would go a great way to sit under and hear explain the details of their work in the classroom—not all old men, either.

After all, the question is one of idealism, of unselfishness, of personal service; personality that will inspire, accompanied by the requisite knowledge and ability.

THE NECESSITY OF GREATER NUMBERS OF PRACTICING DENTISTS.

Statistics show that only ten per cent. of the people have any dental attention at all, that much over ninety per cent. are sorely in need of such attention. In almost every township and city in this country these facts are being impressed upon the authorities and people in general. A few municipalities are employing dentists to correct this evil, but the universal employment of such dentists seems to me the only solution of the effort to reclaim the teeth of the nation and restore their owners to health.

In the examination of the teeth of about a thousand children in the public schools of Baltimore, ninety-seven per cent. were found defective, and in many cases we were confronted with the statement that it was absolutely impossible for the parent to pay for dental attention. What are we going to do about these conditions, which probably prevail in most communities? If a laboring man, a father of five children, gets \$1.50 per day, how many amalgam fillings at \$2.00 per filling can he afford to pay for?

I do not want to cheapen dentistry, but I do wish to place needed dental attention within the reach of every man, woman, and child in this country. They need it for the protection of their lives, for the increase of their comfort and happiness, to augment their efficiency. It is our place to see that they get it. There should be thousands of young men and women working in municipal dental infirmaries for \$25 a week, and there will be. The time is not far distant when any community which has proper regard for the health and comfort of its citizens will make some such provision.

If I am right in this prophecy, what five universities can train the army who will be needed for this service? A few of them, I expect, will have to be trained at the dental colleges.

Proceedings of Societies.

NATIONAL DENTAL ASSOCIATION.

Sixteenth Annual Meeting, held at Washington, D. C., September 10 to 13, 1912.

SECTION II: Operative Dentistry, Nomenclature, Literature, Dental Education, and Allied Subjects.

Chairman—F. O. Hetrick, Ottawa, Kans.
Vice-chairman—Joseph Head, Philadelphia, Pa.
Secretary—E. P. Dameron, St. Louis, Mo.

(Continued from page 192.)

Tuesday—*Evening Session.*

The first session of Section II was called to order on Tuesday evening, September 10, 1912, at 8 o'clock, by the chairman of the section, Dr. Hetrick.

The Chairman announced as the first order of business for Section II the reading of a paper by Dr. B. Holly Smith, Baltimore, Md., entitled "Aristocracy in Dental Education."

[This paper is printed in full at page 310 of the present issue of the Cosmos.]

Discussion.

Dr. H. L. Banzhaf, Milwaukee, Wis. The essayist has prepared a thoughtful paper—I may go farther than that, and say that I consider it a beautiful paper. His diction and the flow of his words, the arrangement and expression of his thoughts, elicits my admiration, and it occurred to me while listening to Dr. Smith that it is pleasant to know that we have men in the dental profession who can lead us into the green fields and by the side of running waters in literature.

I have no intention, in fact it is contrary to my policy, ever to affront any audience by offering an apology, but I am sorry, nevertheless, that time did not permit the preparation of an analysis of Dr. Smith's paper. I read the paper over, but did not have the time to prepare an analysis, and I fear, therefore, that I might not do justice to the subject. It seems to me that the crux of the proposition is whether the attitude of the so-called dental departments of the universities toward dental education and toward the so-called private dental colleges is an equitable one; whether there is the proper co-ordination, or whether there is the proper sympathy for dental education and for the purpose for which dental colleges were organized.

I do not know whether there is a holier-than-thou attitude in dental education; possibly such an occasional expression may have been misinterpreted as being the thought of one man. Possibly he is the executive head of a university dental school, but I am inclined to think that he does not represent the thought, conviction, and belief of the teaching force of that school. I believe the teachers in a dental school, if they have any justification for being teachers, do more to make for thoroughness than a dozen executive heads of schools put together.

I am inclined to believe that there is room for all dental schools that so wish to conduct themselves honestly. There never was any criticism of dental colleges to amount to anything until some years ago, when so many dental colleges sprang into existence. Then, by and by, the supply became too large, as it were, and it was discovered that some schools had no endowment, which is an important factor, and their income was so small that they could not be properly managed. I believe, however, that time is curing these conditions, and there is a place for the majority of schools at least, so that we need not quarrel about this particular.

The essayist has spoken of the personal contact between teachers and students that exists in schools that have small classes. It does not necessarily follow, however, that small schools and small classes make for the greatest efficiency. Endowed schools, provided they have the necessary number and the right kind of teachers, can do quite as well as the smaller schools, however much I appreciate the element of personal contact.

The essayist has touched upon the social side of dental service in a very sympathetic and beautiful manner. The National Dental Association started some years ago a great health movement, and I can well understand why it is vitally interested in the kind of men who are entering the dental ranks.

Despite the essayist's criticisms, I think it is still possible for dental education to make progress and be of service to humanity. To use Browning's words, which you probably remember—

Then welcome each rebuff that turns earth's smoothness rough,
Each sting that bids nor sit nor stand, but go!

Dr. H. E. Friesell, Pittsburgh, Pa. I am somewhat astonished to see two papers on dental education on the program of the National Dental Association for this meeting. It seems to me that there are subjects of enough importance that belong particularly to the National Dental Association's province to eliminate for the time being the problems of dental education. In the past it has been said by overworked executive committees in state and national societies that a hit at the dental colleges would always start up an interesting discussion, but I do not believe in hitting anybody, unless there is a principle involved and unless it is intended to carry the issue to a proper solution.

As to this particular paper, I personally do not comprehend its aims, therefore my ability to discuss it is particularly limited. We have among the dental associations three that exist principally to cover these questions of dental education, and I think these bodies are able to take care of this question. The national and state societies should therefore be left to look after subjects that pertain more particularly to the work of the profession itself. The bodies mentioned are the National Association of Dental Faculties, the Institute of Dental Pedagogics, and the Educational Council of America. The National Association of Dental Examiners and the National Dental Association are represented on the Educational Council, and it seems to me that subjects pertaining to dental education should in the future be very properly referred to the Dental Educational Council as a section of this body to consider educational methods.

One item in the paper appeals to me strongly, *i.e.* that in the dental departments of medical schools and in many university dental schools various subjects in the curriculum are being taught by teachers who are not dentists, and the dental students are mixed with the medical students—as a necessary but relatively unimportant portion of the class. Personally, as a dental school teacher, I do not believe in these methods. I believe that every subject in the dental curriculum should be taught by dentists. Unfortunately, however, up to this time very few of our dentists seem interested in such subjects as anatomy, pathology, materia medica, bacteriology, etc., but this is the fault of the members of our dental profession. If you will give the schools teachers who are dentists, we can have the medical subjects that belong to the dental curriculum taught better by dental teachers than can be done by medical teachers. The combining of medical and dental students in studying a given subject is pedagogically and professionally wrong.

Dr. R. L. Simpson, Richmond, Va. If you had been in Baltimore during the democratic convention and had seen and heard Dr. Smith singing that Wilson song, you would have known that he was a genuine progressive, but from his paper tonight you would surely think he was a standpatter, going to vote for Taft.

Dr. Smith has attained much of his reputation because of his progressive ideas in dentistry, and it is with a great deal of sorrow that I have heard this paper. We have no imaginary thing confronting us; we have a condition to meet, and we must meet it squarely and without fear and trembling on our part. We must consider only the usefulness of dentistry.

Drs. Hayden and Harris never originally intended that there should be a separate degree. They tried to get dental instruction incorporated in the medical course like other subjects, such as surgery and diseases of the eye, ear, nose, and throat. In taking the M.D. degree the student does not take simply the specialty he intends to practice, but he has a broad knowledge of all branches, so that he will know how far each branch extends into his work, and how intelligently to send patients to men who specialize in other lines. We need broader knowledge in dentistry, and when the essayist mentioned the names of Varney, Webb, and others, I could not help thinking how much more useful these men would have been if they had been more broadly educated. Dental education has been so narrow that we have hardly any D.D.S. who is capable of scientific research—we can point with almost unanimity to Dr. G. V. Black. The reason for this lamentable condition is that the D.D.S. degree has been given without a proper knowledge of the medical branches. It is a notorious fact that we dentists have been trying to deceive ourselves; we assure our patients that we receive an education in the fundamental medical branches, when we know that those fundamentals are largely abbreviated for the dental student. I cannot blame the medical men for saying, "Oh, you are just a dental student!"

WHAT IS OUR SALVATION?

In Virginia we have given an answer by passing a law, to go into effect January 1, 1914, requiring everyone who desires to practice dentistry to first secure the M.D. degree, and pass the Virginia medical board, and also pass two dental men attached to that board. We also have provided a way to prepare medical men to pass these dental examiners This law is not such a hardship; let me remind you that all colleges are increasing their entrance requirements, and we are getting into dentistry men who have better literary educations. Such men are demanding the right to transfer from one department to another —from dental to medical, or conversely. It is most embarrassing to dentistry when these men find they can transfer from medicine to dentistry with full credits, but not the other way, because their medical branches are abbreviated if taken in the dental course. This drives our best-prepared applicants into medicine, when they really would prefer dentistry. We find that more and more are state universities inclined to include in their B.S. degree some of the medical branches, such as bacteriology, chemistry, physiology, and others. Some of these days some state university will transfer such B.S. men to the medical or dental departments and graduate them in *two* additional years with the M.D. degree—*and they are not going to ask your permission either,* for the reason that these men enter the proper classes better prepared than you were when you entered them.*

Please excuse this rather lengthy explanation, but it is necessary.

Let me repeat my question, and answer it in a purely personal way. What is our salvation? The salvation of dentistry is the topheaviness of the medical degree. The colleges are not going to give a course longer than four years for this, but they are adding to this course until it is almost impossible to take it in four years. Medicine has already developed into specialties—surgery, general medicine, eye, ear, nose, and throat diseases, diagnosis, venereal diseases, orthopedic surgery, etc. They all receive the M.D. degree. To our shame, dentistry is the only branch of medicine with an abbreviated course and a separate degree. Medical education has always taken longer and cost more than dental. At the same time there has never been a lack of medical men to fill places in charity hospitals. The trouble at present is to keep men out of medicine.

In view of these facts, I believe the time is coming when something like the following plan must be adopted:

Let every student who desires to study any branch of medicine, including dentistry, study the fundamentals for two years. For these two years of work, let him receive the B.M., or Bachelor of Medicine degree. If he does not know what branch he would like best, these two years will enable him intelligently to decide. For two years more he studies his specialty and so much of the other courses as will best fit him for his lifework. On the completion of these four years, let him receive the M.D. degree. In order that the specialties may be of equal value, the Carnegie system of units can be used to balance them.

By means of this plan dentistry receives trained students, with fundamental education the same as the others, and when the dentist receives his M.D. degree he knows, and the other specialists and the public know, that his course is the equal of any. Thus will the stigma be removed from us.

There is a demand, and a growing demand, for better trained dentists. The public is demanding better dental service; state boards are demanding that colleges give more thorough courses. The statement that a school is the oldest or largest means less and less each year. The demand now is, Tell us how your students stand before the state examining boards! Some here are not connected with the Faculties Association or Examiners Association, and it is only necessary to tell you that the reports of the joint Tabulation Committee from these organizations in reference to state board examinations are most interesting reading. Many of us find figures there that make us ashamed of our schools; figures that are eloquent reasons why university schools should exist—I mean genuine state universities. Thank God, we now have a Wiley in dental college affairs!

In the days gone by, the dental and medical schools were conducted at a profit, and they need not be ashamed of it. The men who *lectured* in those schools received a most satisfactory compensation, but the men who *demonstrated* received very little. Medical education has already changed, and any medical school which desires to stand in class A must have at least six full-time demonstrators, and their pay must be satisfactory. Dental schools have just begun to wake up to this fact. It does no good for a lecturer to talk and draw on the blackboard unless he has an equally competent demonstrator in the laboratories to drill the facts into the students. Dental colleges are no longer going to tolerate conditions that have existed in the past. In other words, the didactic teacher, no matter how celebrated he may be, is of no greater importance than the demonstrator. These poorly paid demonstrators are going to demand as good salaries as they deserve. Dem

* [Since this statement was made, the University of Virginia has made its B.S. course so elective that a student for the B.S. degree may select the first two years of medicine as his last two years for his B.S. degree. This will enable him to secure both degrees in six years.—R. L. S.]

onstrators in pathology, in bacteriology, histology, chemistry, and physiological chemistry are also necessary; then the independent dental school will cease to be profitable to a few of the professors who own it. Thorough medical education costs more than the income from students, and this fact renders state aid and endowments absolutely necessary. In view of these facts, ladies and gentlemen, I believe the independent medical and dental school is doomed, and we may as well realize it now as later.

For fear you may think that I am ashamed of my D.D.S. degree, I wish to assure you that there is nothing I more esteem. God bless those men who have done what they could! I honor and revere them; they set the standards of the times, and they did splendid work, but they and their methods are no longer needed. The world progresses.

No, gentlemen, we do not need an aristocracy in dentistry; we need broader education, better education, and men in the profession who are willing to serve and sacrifice themselves as medical men have done, for the good of the public, and not for self alone.

Dr. George E. Hunt, Indianapolis, Ind. The paper seems to be a protest against some university schools' attitude toward some of those schools which are not parts of universities, and I cannot help but have a bit of sympathy, naturally, with the essayist's attitude. I believe all who are interested in the education of the incoming members of the profession are honest in their interest. We who are educating the youth of the land in dentistry all desire to do our best, and I believe there ought to be an aristocracy in dental education—but a real aristocracy, and not a pseudo-aristocracy or a mushroom aristocracy. I mean that there should be better teaching forces in the development of the education of the young men who are coming into our profession. All who are interested in the education of our young men are of the same belief, and since we are all working toward the same end, it is to be deprecated and deplored that there should be any dissension in the ranks of the educators. I trust that will be eradicated in the course of time, as other dissensions have been.

Dr. Smith (closing the discussion). Dr. Simpson said he was very sorry. I think the audience should agree with him. I, too, think he is very sorry.

The next order of business was the reading of a paper by F. E. Stewart, M.D., Philadelphia, Pa., and entitled "What is Meant by Drug Standardization?"

[This paper is printed in full at page 304 of the present issue of the Cosmos.]

Section II then adjourned until a later session.

Thursday—*Morning Session.*

Section II was then called to order on Thursday morning, September 12th, at 10 o'clock, by the chairman, Dr. F. O. Hetrick.

The first order of business for the morning session was the reading of a paper by Dr. H. H. Johnson, Macon, Ga., entitled "Inlays."

[This paper is printed in full at page 300 of the present issue of the Cosmos.]

Discussion.

Dr. D. J. McMillen, Kansas City, Mo. Although I have not had time to read the paper beforehand and digest it, there are a few points that I should like to touch upon.

First, in regard to the inlay as a time-saver, I am not prepared to say that it is the best possible means of restoration in every mouth and every tooth. The essayist does not maintain that, but there are many operators who believe that an inlay must be put in every tooth and in every cavity, and they have almost discarded their operative instruments and are making more inlays all the time. This, in my opinion, is a mistake. The inlay is a time- and a nerve-saver, and in its proper place is unexcelled.

The essayist tells us that in 1890 a dentist was doing this kind of work. In

1891 or '92 I went to the Texas state meeting in Waco, and at that time saw an inlay which was called a box filling. It was made by burnishing a layer of gold into the cavity and fitting it to the pulpal wall; over that matrix another piece of gold was fitted to approximate the tooth form, and the occlusion was obtained by the patient biting into the outside layer of gold. These two pieces of gold were soldered together, and fitted into the cavity. The whole was then removed, a hole bored through the outer layer, and the inside filled with solder. The inlay was then cemented into position and seemed to be a nice piece of work. This kind of work has been done for the past eighteen or twenty years. For many years I have, in a few instances, made inlays. My first one was made in a crude way. I burnished a piece of gold around on the outside of the cavity, soldered a loop on the under side, and thickened the metal on the outside. This was cemented back into the tooth, and the inlay burnished around the margins. Many ways have been suggested of doing this work. Dr. Simpson of Kansas has for many years employed various methods, such as burnishing gold into the cavity, sweating solder into the matrix and building the filling up, but after all is said and done, we might as well acknowledge the fact that the Taggart system is the first expedient system for doing this work.

Dr. F. W. STIFF, Richmond, Va. I am very much in the position of Dr. McMillen, in that I did not have the privilege of seeing this paper before it was presented. I have done considerable inlay work since Dr. Taggart perfected it, but I have found the same difficulties in my work that Dr. Johnson has so well explained, viz, shrinkage in large fillings, particularly saddle fillings in molars and bicuspids. I hail it as a boon to dentistry, notwithstanding what Dr. McMillen has said of the Taggart method, that Dr. Alexander has discovered a method which to my mind is better.

I helped Dr. Alexander in Birmingham to demonstrate his method, and I was convinced that it was superior for making large fillings. The trouble that I had in my work, however, was that I could not obtain the same accuracy of fit as Dr. Alexander. He has, however, improved his method since; he did not at that time use plastic gold.

I have no criticism to make of the paper. It covered the ground and was particularly beneficial to me in that the minutiæ of Dr. Alexander's method were explained.

Dr. L. L. BARBER, Toledo, Ohio. By way of explanation, I will say, as all other speakers have done, that I did not know that I would be called upon to discuss this paper until three or four minutes before Dr. Johnson read it. I have used Alexander's plastic gold for some years; before that I used to take ordinary plastic gold and put small bits of wax on the top of it, heat the wax with a burnisher, and allow it to flow into the gold. With this material I made fillings, compressing it to produce contour, allowing the patient to bite to ascertain the occlusion, investing it, and flowing solder into it to make a solid filling.

Dr. Johnson started to tell us how simple the Alexander method is, but I noticed that he used Price's artificial stone.

Dr. JOHNSON. Not in making inlays, but for hoods.

Dr. BARBER. At any rate he uses Price's artificial stone, making a matrix from that and packing the gold into that. To certain people almost any method is simple and easy, but after all, it is a matter of absolute technique. The essayist said that, in making a wax model and a casting from it, the sharp edges were likely to be destroyed by the molten gold wearing off the investment, which might hold air-bubbles. He might well have said that the cervical margin of the filling would quite likely not be a good fit, among other things. I believe that most of these failures are due to carelessness of the operator. It is wrong for an operator to think that he can take a piece of wax at any temperature, warm it a little, put it into a cavity, simply jam it down, make the patient bite on it, take it out of the mouth, carve it a little, invest, and then obtain a casting that will fit. I have made good inlays, and I have made my share of poor ones. I suppose I made one or two hundred inlays in my laboratory, before I attempted to make one in a tooth in the mouth, and even so I have made my share of poor ones. I can, however, almost invariably trace my failure to careless technique. It is not an easy matter to take a piece of inlay wax, no matter by whom it is manufactured, heat it to the proper temperature, and obtain a good accurate impression of an approximal cavity. I have seen operators prize or pull the wax from the cervical part of the cavity, and the defects in their wax patterns were hardly noticeable, and yet the cast inlay made from such a pattern was very defective. Air-bubbles, as you know, will make little globules of gold on the cavity side of the inlay, but such imperfections can be very largely overcome. I have made many cast fillings and have inserted them into the cavity without having to retouch them—but I have also made many others. I have used Dr. Alexander's gold, and I think it is admirable.

Dr. Barnes of Cleveland, with whom I have worked for many years, has a method quite as simple, which in his hands is the best universal method that I have seen demonstrated anywhere. He simply takes No. 4 soft foil, presses it into the cavity with orange-wood sticks, obtains the occlusion, takes the gold matrix out and lays it on a charcoal block, and instead of flowing, just sweats small pieces of 22-karat gold into it with the aid of a blowpipe, thereby obtaining the most beautiful fillings I have ever seen. After all, it is a matter of each operator getting down to a method and studying it until he knows it from A to Z.

Dr. Spalding of Detroit also has a splendid method, involving the use of Detroit modeling compound, which is obtainable in sticks of about the size of a finger. He prepares the cavity, takes an impression with this modeling compound, makes a model of the cavity with alloy mixed quite thinly, allows this to stand over night, and then makes his filling in that model. After this he takes the bite in wax, and can then finish the filling on the amalgam model, so that it is ready to be placed in the tooth when the patient returns. In this way, the making of a compound filling for a molar is considerably simplified. If the cast filling draws a little, it is put back on the model and pinched together with a pair of pincers. Dr. Spalding does this work so well that his inlays cannot be distinguished from malleted fillings. After all, no matter what method is used, it depends upon the dexterity and the care with which the technique is carried out.

Dr. Johnson has covered the ground very well in his paper, and I have no criticism to make, except that I wanted to emphasize that no method has been discovered so far that anyone can say is easy. That is what we are all looking for, of course, but with all the easy methods in dental work that we have heard of, the fact remains that if we would do our work well, we must follow every step with care, and in this way we will succeed, or at least come a good deal nearer perfection.

Dr. Johnson (closing the discussion). I have very little to say in closing the discussion. I wish, however, to refer to the amalgam method which Dr. Barber has mentioned. It seems to me that this method, consisting in taking an impression of a cavity, making a model from that, and then the wax mold, involves so many factors of error that we would simply get a rough casting of gold. One might in that way become an expert carver in fitting the cavity of the amalgam model; still, an imperfect impression of the cavity to start with remains as the source of probable error, and we have to fit the inlay, after all, to the cavity in the tooth. It seems to me that this method is a roundabout way. By the Alexander method the filling is done directly in the cavity with the gold itself. There is no transferring at all, no shrinkage or expansion, therefore the inlay must fit better. The making of the model requires no more time than that of a wax mold, and all the investing and drying out is saved, hence economy in time. Saving of time does not mean slighting the work. This method is simply a shorter one, and, if time can be saved by shortening an operation, at the same time doing the work perfectly, it is worth while to save this time, because for many busy operators time means money.

The next order of business as announced by the chairman was the reading of a paper by Dr. W. R. CLACK, Mason City, Iowa, entitled "Is Operative Dentistry Degenerating?—Extension for Prevention *vs.* Pinhead Methods."

[This paper is printed in full at page 292 of this issue of the COSMOS.]

Discussion.

Dr. C. V. VIGNES, New Orleans, La. Dentists seem to be divided into two classes, those who are in favor of extension for prevention, and those who are in favor of prevention by extension. I do not know to which class I belong; whether I am one of the extension kind or merely a little pinhead one. The extremist who practices extension for prevention is so decidedly "sot" in his ideas that he condemns anyone who should want to practice conservatism; while, on the other hand, the ultra-conservative dentist sees nothing in extension for prevention but a wanton destruction of tooth structure. The great trouble has been, is, and probably will be for a long while to come, that we are not willing to give our fellow man credit for being able to do that which we cannot do. Until all teeth are alike, and the conditions surrounding them are identical, no set rule can or should be adopted. We will have to continue, as I understand it, to prepare cavities with a little judgment, meeting the conditions as we find them.

Dr. E. T. DARBY, Philadelphia, Pa. I do not know why I have been called upon to discuss this paper, unless it be that I am an eastern man. I regret that Dr. Clack thinks there is antagonism between the East and the West in the matter of so-called extension for prevention. As far as I am aware, there are no eastern men who oppose it because the term "extension for prevention" came from the West, nor are they opposed to the principle. Dr. Black has a great many admirers in the East, and they are quite ready to express their admiration. I have long been familiar with the enthusiastic work done by Drs. Wedelstaedt, Searl, Clack, and other members of the G. V. Black Club, and I am confident that they have done great good by the thoroughgoing principles which they have taught.

I would not wish to detract in the least from the credit which Dr. Clack has given in his paper to Dr. Black and others, but I regret that he failed to mention Varney and Webb and Perry, who taught and practiced the same principles which he set forth in his paper. Dr. Varney was among the first to promulgate the belief that all approximal surfaces should be contoured to their original fulness, and that all cavity margins should be left in such position that they could be made self-cleansing. Dr. Webb advocated and practiced the same, and more than thirty years ago Dr. Perry read a paper upon the subject of the treatment of approximal surfaces in the bicuspids and molars, in which he advocated the same principles as laid down in Dr. Clack's paper.

If you ask me whether I indorse all that Dr. Clack has said in his paper, I would reply "Yes, I indorse all that he has said about the bicuspids and molars." It is what I teach and what I try to practice, perhaps with a little less perfection than the men of the Black Club. I teach it because I think it is correct treatment for those surfaces, but when it comes to the incisors, I fear I am not orthodox, if that means sacrificing the whole or nearly the whole of the approximal surface in order to fill a cavity of the size of a pinhead. But pinheads are of various sizes, and some would represent a large cavity. It seems to me that here is a good place to exercise judgment as to which teeth should be cut as extensively as indicated by Dr. Clack, and which shall be cut less. Those of us who have been in practice for forty-five years —and I see classmates of mine in this audience—know that many incisors with small cavities, which we filled forty or more years ago, are still being saved by those fillings. Of course, many such fillings have failed, but there are good and bad fillings, as there are good and bad teeth.

The chief objection to such general cutting is the display of so much gold, but since porcelain and silicate cements are promising so much, it is to be hoped that the anterior teeth can be saved without the necessity of displaying the filling, which under the most favorable conditions is objectionable.

Dr. Clack (closing the discussion). I am very much disappointed. I had thoroughly believed in the honesty and integrity of the men who have opposed extension for prevention, but when the gauntlet is thrown down, and these men are notified months in advance that this matter is to be discussed, and that it is to be discussed partially from statements that they have made, it seems to show a lack of courage on their part when they fail to stand up for their own convictions and fight for what they believe to be right. These men who will refuse and neglect to reply openly to criticisms of their methods, so that their arguments may be answered, and then take advantage of the pages of a dental journal and make their statements in such a way that they cannot be successfully controverted without a great deal of trouble—these men, I believe, from now on, are unworthy of notice. Many points in my paper were brought out because of the criticism that has been made in one of these articles. I have no animosity in my heart toward eastern men as such, as might appear at first sight from my remarks, which were so worded because of the article published in one of the journals by a man whom I respect very much, and who is one of the recognized leaders of the opponents of extension for prevention. It was the slighting manner in which he spoke of the West, and the youthfulness of the men in the West, and the ideas advocated by them, that led to my remarks.

I am very much gratified indeed by Dr. Darby's remarks, and I wish to explain shortly our position. No one for a moment attempts to claim that Dr. Black originated all there is in extension for prevention. The truths embodied in extension for prevention have always existed, and there have been many men who have taught these truths, but very few of these men have taught these truths in such a manner that they could be thoroughly understood. Dr. Darby has referred to the excellent operations made by these old masters, but these men did not arrive at a clear and concise method that governed all their operation. I have not the slightest doubt that the lamented Dr. Webb would in time have evolved a system; after him, Dr Black took up the work, and I believe you will bear me out in saying that he was the man who absolutely systematized that method. His investigations of thousands of teeth containing fillings made after the manner of Dr. Webb and his *confrères* proved that these teeth had resisted the ravages of caries for many years, while fillings made in the other way did not. He then began a systematic investigation of these conditions, and a surprisingly large percentage was found in favor of these restorations. It was through work of that kind that Dr. Black gained his ground. It was not given him to originate all these ideas or to originate the truth. As I said before, the truth concerning this has always existed, but it was revealed to him as a result of his years and days and nights of patient, painstaking investigation, and he noted the conditions found and condensed them to a system that he could teach us.

Nobody reveres the memory of the men we have spoken of more than I do, but we must give somebody the credit, and that is why we speak of the "Black method," because he advanced this system. That is all we contend for, and I have heard Dr. Black express himself to that effect many times; we do not wish to detract in the slightest degree from the honor due to these great men.

A great deal has been said about the terrible irritation of the gingival margin, but if the restorations are finished correctly, so as to prevent further irritation, pleasing results may be expected; while if ragged, overhanging edges are left, no such results can be expected. I have seen cases in which there was more filling material in the interproximal space and under the margin of the gum and pressed up into the concavity of the tooth than was used in the making of the filling. What can be expected from such conditions as that?

I would also emphasize that we do not make such extensive extensions as we are charged with. In an article published in the April COSMOS, it was stated that the advocates of Black's method cut away one-third of the tooth. No one who understands Dr. Black ever cut away in wholesale manner one-third of the tooth. Therefore that statement, I trust, was due to ignorance of the conditions, and was not a wilful misrepresentation.

There is little else to say in closing the discussion, except that I am sorry that I could not show the slides that I brought with me to illustrate the paper.

The next order of business was the reading of a paper by Dr. J. J. MOFFITT, Harrisburg, Pa., entitled "The Treatment and Filling of Root-canals."

[This paper is printed in full at page 280 of the present issue of the COSMOS.]

There being no further business before Section II, the chairman, Dr. Hetrick, declared the section adjourned *sine die*.

(To be continued.)

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held November 26, 1912.

THE regular monthly meeting of the Academy of Stomatology of Philadelphia was called to order by the president, Dr. Otto E. Inglis, in the lecture hall of the College of Physicians and Surgeons, Tuesday evening, November 26th, at 8.30 o'clock.

The President introduced Dr. GEORGE H. WILSON, Cleveland, Ohio, who read the paper of the evening, entitled "Some Phases of Prosthetic Esthetics."

[This paper is printed in full at page 271 of the present issue of the COSMOS.]

Discussion.

Dr. CHARLES R. TURNER. I think that I have succeeded in imbibing the spirit of Dr. Wilson's paper, to which we have just listened with a great deal of interest, and I interpret it as a protest against the inadequacy of our more or less accepted temperamental classification of humanity. In that particular I am indeed most heartily in sympathy with his ideas, agreeing fully with his estimate of the inadequacy of that classification. Having been founded in mysticism, and, as he says, in quasi-science, it has persisted until now, and is utilized at this time in an entirely different sense from its original one. However, if we simply accept it as a classification of mankind according to groups of associated physical characters rather than as collections of the effects of the preponderance of certain bodily humors, I think that it still has some value. It is undoubtedly true, as Dr. Wilson says, that the so-called basal types are almost entirely ideal, and that the combined types are extremely difficult to diagnose. He has very properly called our attention to the fact that in this country, in which so many races have contributed to the population, it is perfectly surprising to see how many people seem to have a combination of the characteristics of all four temperaments, so that as an exact scientific basis of classification the temperamental method is not at all reliable. But I think I accord it a more useful place than he does, as giving us a certain kind of classification of man's physical characters, and I do so largely because we have thus far had nothing proposed which will satisfactorily take its place; and inadequate as it is, it seems to me that it is still useful, since it is the only comprehensive classification we have.

The problem that the prosthetist has to settle may be viewed from two standpoints: One in which the given patient has to have a part replaced by a certain rule—one only a little more elaborate than a rule of thumb—according to which, knowing the patient's type, we know at once the type of the missing part and are able to supply it. Dr. Wilson has, I think, emphatically and most properly come out against the use of this plan alone, as being too mechanical. The plan which he proposes, and which is according to the second viewpoint, is that each prosthetist shall cultivate that sense of harmony and contour which will enable him to supply a missing part, having as data his observation of the remaining physical characteristics of the individual so far as the face and physique are concerned. This latter plan is undoubtedly the method of the master; it is the method of one who has cultivated that nice discrimination of contour and that nice quality of discernment which enables him, almost without taking second thought, to pick out the exact shape of teeth which should go in a given mouth, for example, or to know what particular mold number would supply the proper form. For the most of us it is, I fear, not quite so simple a process. That skill which enables a prosthetist to make restorations by this method comes, probably, first from an innate artistic sense, an inborn sense of harmony and appreciation of proportion, coupled with which must go a large experience. However artistic one may be, unless one is familiar with the details of the field in which that particular artistic labor is done, he of course would not be able to measure up to the requirements of the case, and so observation and experience must certainly supplement that inborn artistic sense. I fear that this, although it be a most satisfactory method of doing prosthetic dentistry, is not the method which is available for the teaching of the greenhorn. He must have certain concrete facts, a certain amount of teaching—a certain amount of dogmatic teaching, in fact—as foundational to the development of his later judgment. We all recognize how very few men become skilled along this line, and yet there are a good many who, by fairly well following certain foundational principles, are able to accomplish better results than if we simply turned them loose with their own judgment. That is quite easily brought to view by reference to the fact that the average lay patient, if allowed to select teeth which were exactly like the ones he has lost, would invariably provide himself with pearly white, small teeth. That is perhaps an exaggerated view of the dental student's judgment, and indeed I am not subscribing to it fully. Nevertheless, I do feel, to conclude these remarks, that a certain amount of dogmatic teaching must be given to him as a basis for the judgment which he must eventually cultivate himself.

I feel sure that Dr. Wilson and I are perfectly in accord in our estimate of the desirability for some better classification of mankind than the temperamental one, and it is probable that in the field of anthropology some such classification may be worked out which will be available for our use.

I can only say in conclusion that, if Dr. Wilson will give us the recipe for producing the beautiful results which I have seen in his office and at other places as the products of his hand, and with which all of us are probably more or less familiar, by some method which will be available to us, we will acclaim him a little louder than we do now—and we certainly consider him now as one of the masters of his craft.

Dr. I. N. Broomell. It has been my pleasant privilege to follow the teachings and the work of Dr. Wilson for a good many years, and very long ago I regarded him in the light of his proper merits, viz, as one of the foremost contributors to prosthetic literature. Dr. Wilson appears to have the happy faculty of being able to describe and combine mechanics with science, and at the same time he has always been able to throw in just enough of the esthetic to make his writings very interesting, leaving his readers to believe that prosthetic dentistry is really a fine art rather than a trade or business. Considering these facts it seems to me almost out of order that I should be called upon to discuss this paper. The few remarks which I shall make, however, will concern the preservation of the facial contour and the failure of proper recognition of temperamental characteristics. I use the expression *preservation* of the facial contour in preference to *restoration,* because I think the former is much more important than the latter. It is very much simpler to preserve the facial contour than to attempt successfully to restore it after it has once been lost, and this can only be done by prompt prosthetic restoration. We all know the value of each tooth in the dental arch, and what the loss of one tooth means, viz, the beginning of the breaking down of the dental mechanism, and, if it were a practical possibility to introduce one tooth in the place of one which is lost, that would be the first step in the way of preserving the facial contour.

I may perhaps make myself clearer if I compare what is known as the permanent artificial denture with the temporary artificial denture. In former times—and not so very long ago—it was frequently suggested that patients go without teeth for a certain period of time, possibly a year, in order that absorption might fully take place. This I believe was a mistaken idea. Instead of doing that, many dentists would suggest a temporary denture, which is the right idea, and one favoring the preservation of the facial contour. I fully believe that many of the disfiguring facial lines which we see, most of which are attributed to approaching old age, are the result of loss of dental structure. I may, if you will pardon me, refer to my own case. While I am yet a young man, the wrinkles about my mouth would tend to make one think that I was rather old. I am free to admit that the result is due to the fact that my teeth have worn down so that the bite is perhaps one-eighth of an inch shorter than it was twenty-five years ago, and as a result these facial lines [demonstrating] are more prominently shown. If I had taken care of this gradual wear on the occlusal surfaces of the molars and at the same time the cutting edges of the incisors, I am sure that I would not appear quite so old as I now do. My plea, therefore, in this respect is one for preserving the natural organs, and replacing the lost parts just as soon as possible without deferring it for after-consideration.

I was pleased to hear Dr. Wilson speak of the characteristics of the lips, because these certainly must be taken into consideration in prosthetic work. Nothing is of more importance, and I fear that many times little attention is given to this factor. Dr. Wilson intimated that he thought too much stress was being laid on temperamental characteristics. I cannot agree with his argument in this respect. I do not believe, of course, that we can place all persons under these four basal temperaments, but I do believe that in a majority of instances much is gained by a consideration of this classification. Perhaps the question of tooth form and arch form are of greatest importance in this respect. I am sure that in my studies of students' mouths which I make every year, I can in nine out of ten cases tell very nearly the shape of the dental arch simply by looking at the student's face. I know by the contour of the face that there is a corresponding contour in the arch of the teeth, and it is for this reason particularly that I believe we should give full consideration to the temperamental characteristics.

Dr. Wilson has thrown on the screen a number of drawings which appear to me to be a description of the various temperaments. He has shown one which is characteristically nervous, another bilious, another lymphatic, and another sanguine, and I cannot understand why he is not fully in accord with the idea of using these as a basis of work; in fact, he does not claim that he is not in accord with this idea, but in a general way he seems to think that we should treat each subject individually.

With reference to functional worth in the arrangement of the artificial teeth, I should say that they should be arranged according to temperamental characteristics, according to the movements of the mandible, and I believe the movements of the mandible are controlled almost entirely by the shape of the teeth. I mean by this that in the nervous type, where we have the teeth interlocking, a pronounced overbite, and deeply penetrating cusps, we find a certain type of condyle. In that temperament the condyle is so shaped that the movements of the jaw are almost directly up and down. In the other extreme, where we have cusp formation almost wanting, we will find a condyle so shaped that there is a lateral or rotary motion. My argument, therefore, is this: If, in a mouth in which the chief movement of the mandible is lateral, we place teeth that lock every time they are brought into occlusion, the result will be a tendency to force the teeth out of position. On the other hand, if in a mouth where the bite is directly up and down we place teeth that do not lock, the results will not be so disastrous, but a smaller amount of functional worth will be obtained from teeth arranged in that way. I have here the last work of Dr. Bonwill. He came to my office a few evenings before he was stricken with his last illness, and there "ground up" —to use his own statement—a full upper and lower set of teeth. Dr. Bonwill never gave any thought to temperamental conditions, and ground all teeth alike. I took exception to this, saying that humanity was not alike in all cases. "Then we will make them all alike," he said, "simply by forcing the individual to wear teeth ground in this way."

Dr. S. H. Guilford. It has been my pleasure to be acquainted with Dr. Wilson for many years, and to know him intimately as a teacher, lecturer, and author, and his success in life has been shown better, probably, by the book he has published than in any other way. He has given us, I believe, the best book on dental prosthesis ever published for the dental profession. I say this not to flatter him or to compliment him at all, but because I believe this to be actually true, and because a great majority of those I have spoken to on this subject seem to be of the same opinion. I was very glad indeed to learn that he was to be our essayist tonight. I wanted to know what new ideas he had to present in regard to esthetics in prosthetic dentistry, and I must confess that I have been greatly edified. At the same time I cannot agree with him in some points, at least in the extent to which he carries the matter of classification of temperaments. We have taught this subject of temperaments for the last forty or fifty years as an aid to the proper selection of artificial teeth and facial restoration. Probably his classification is scientifically correct, yet I do not believe that we can follow it very closely, as the last speaker has said. We all need to know the various temperamental characteristics, yet at the same time the real way to learn esthetic prosthetic dentistry is by actual practice. The student comes to college with little idea on that subject, and he goes away with very little more of an idea on it, simply because we are not capable of teaching him what we would like to. We cannot teach him all that we have learned from practice, but, if we can lay the foundation and give him a little idea of what we want him to know, we expect him to build upon that. By talking of temperaments and laying down rules in regard to the way in which the student should make artificial dentures, we cannot possibly make our instructions so exact and so true that the individual student following them would get the results we desire him to obtain. We can only teach the merest outline of the fundamentals. Take, for instance, the student of art; he may know little when he begins and he must have definite rules and principles to follow during his student days, but these studies are simply intended to prepare him for future work. Nobody could hope, by teaching certain rules of art and drawing and the mixing of colors, to make a successful painter. After all, it is largely an education of the eye, and the one who becomes successful in art is the one who has the power of training the eye so that it will tell him what is accurate and harmonious and what is not. So it is with the practice of this branch of dentistry. The selection of the teeth, the grinding of the forms, etc., enter into it, but these factors alone will not suffice. We have to study the individual characteristics of the patient; that is to say, in addition to doing the best we can in the arrangement and selection of the teeth, we must see these teeth in the mouth and see their effect, and our sense of harmony must tell us whether or not what we have done is correct.

Dr. Wilson has spoken of the dentist who selects teeth, takes the bite, and then sends the case to the laboratory to be finished there. I think the most careful dentist today will do as much on a denture as he can in his office, and allow the prosthetic man to do as little as possible. After the teeth are arranged on the temporary base, they should be placed in the mouth and inspected by the dentist. He can better tell then than at any other time whether there is harmony or not. He can tell not only in regard to the size and shade of the teeth, the fulness of the lips, the removal of lines caused by the loss of tissue, but also the facial expression. So that in order to be an esthetic prosthetic dentist careful self-training on the part of the individual and the development of his talent in that direction are required. Some men have more talent in this direction than others.

I was sorry that Dr. Wilson did not say something about the other side of prosthetic dentistry—that is, its usefulness to the patient; but, of course, he could not cover the whole subject. For what he has told us I wish to thank him, and am only glad to have the opportunity of listening to his paper and receiving the inspiration which always emanates from an earnest seeker after truth.

Dr. Wilson (closing the discussion). I wish to thank the society for the courteous consideration accorded to my paper. I am very glad to know your mind regarding the extensive temperamental classification. I am convinced that you are not ready to discard the elaborate classification of our text-books, but as you think of it I am sure you will become imbued with the idea that it is wrong. I must confess that I am at the point where I cannot accept the elaborate classification of temperaments, because I cannot conceive of it as being founded upon truth.

We know that the latest classification of temperaments has drifted away from certain ideas of the old classification, and that the old classification was founded upon assumptions and not facts. In the early days of medicine, the temperaments were considered as expressions of the conditions brought about by four fluids of the body; later, two of these four conditions were found to be abnormal. Is it justifiable to assume that in a few hundred years the abnormal conditions of man will produce types of form and color of teeth that should be placed in the same category with the normal conformation? Then again, many of the later students of the subject will not accept this classification at all; they have a new one, which consists of the motive, vital, and mental temperaments, that they consider preferable to the old classification. In this they are possibly correct—at least I believe that the new classification is based upon a foundation better than the old for studying the individual. We have considered the vaults and arches as being the best indicators of the temperaments of the individuals. I wonder how many men who have given attention to orthodontia would be willing to accept the idea that either the vault or the arch having the appearance of the nervous temperament —that is, the triangular form—is normal! Would they not consider it the result of disease conditions, and say that the face had been distorted from its normal form? Orthodontists tell us that a very large percentage of mouths are not in normal condition so far as the shapes of the vault and arch are concerned. If that is the case, what value is the shape of the mouth in that respect to us in the study of temperaments? I feel that we are loading our students down with a lot of false material. We may teach the student that these names in the dental classification of temperaments represent the ideals that will aid in the study of the individual case.

I would like to call attention to the slides Dr. Broomell presented of the condyle and the glenoid fossa, because the dry bones are deceptive. In life there is a large amount of ligamentous tissue in the joint that in conjunction with the muscular action produces a very different movement from that produced by manipulating the dry bones.

There is another point to which I wish to call your attention, and which I think has been misrepresented, viz, in regard to the alignment of the teeth in the dental arch. We have been led to believe that the distal portion of the upper first molar is elevated. If you will study the specimens that were upon the screen and all well-arranged dentures you will find that the distal cusp of the upper first molar is in straight line with the mesial cusp and the cusps of the bicuspids and canine, and the compensating curve is found in the second and third molars only. Therefore the long curve as taught by Dr. Bonwill was neither anatomically nor mechanically correct. As force is exerted at right angles to the surface from which it emanates, it follows that, if the force of mastication is brought upon teeth in a horizontal position, artificial dentures will be more stable than if they are arranged on an inclined plane. Hence the inclination given to the second molar is intended for balancing purposes, and should be as slight as the individual case will permit.

The meeting then adjourned.

Annual Meeting.

THE annual meeting of the Academy of Stomatology was held on Tuesday, December 17, 1912, at the College of Physicians and Surgeons, Philadelphia, Pa., at 8 o'clock.

The first order of business for the session was the election of officers for the ensuing year, which resulted as follows: Dr. Joseph Huggins, president; Dr. J. V. Mershon, vice-president; Dr. Norman L. Jameson, secretary; Dr. A. E. Bassett, treasurer; Dr. W. A. Jaquette, librarian; Dr. F. R. Stathers, editor.

The literary feature of the evening was a discussion on Silicate Cements.

EDITORIAL DEPARTMENT.

THE CHAPIN A. HARRIS MEMORIAL.

IN the DENTAL COSMOS for January 1912, a committee appointed by the Maryland State Dental Association for the purpose published an appeal for contributions to a fund to be utilized in the creation of a suitable memorial to Dr. Chapin A. Harris—"to commemorate in a suitable manner the sense of appreciation felt by the dental profession for the services rendered by this distinguished man in the effort to elevate the profession of dentistry." The appeal made by the Harris Memorial Committee has met with a financial response now aggregating about $1000, and this after one year's activity by the committee.

In his admirable history of Chapin A. Harris, Dr. Burton Lee Thorpe states that, shortly after the death of Dr. Harris, which occurred September 29, 1860, "A memorial meeting was called in New York, October 8, 1860, at which fifty prominent dentists attended, and a public subscription—known as the 'Harris Testimonial Fund'—was started for the relief of his family. A committee was appointed for this purpose, with Dr. Eleazar Parmly as treasurer of the fund. After canvassing the profession for some months, at much expense, the committee reported that nearly $1000 had been subscribed, but that about $900 had been expended in collecting it; the balance of $85 was sent, with a note from Dr. Parmly explaining it, to Mrs. Harris—Dr. E. Parmly Brown, then a young man, being the messenger, who says she read the note, and when handed the gold exclaimed, 'My God!—and is this the gratitude of the dental profession for Chapin A. Harris, who laid down his life in its behalf?'"

No student of dental history can read the account of the life-work of Chapin A. Harris without definitely realizing the fact that to him, more than any other single individual, the dental fraternity owes the largest debt for having lifted dentistry from the level of a mechanical art to that of an organized profession. It is quite true that other great leaders took part in the movement which eventuated in the establishment of the three principal factors which are the foundation stones upon which the dental profession rests—indeed upon which any profession must rest—viz, the school, the journal, the association; but, in the study of the activities which led to the practical establishment of these three fundamental factors, and great as were the men who were associated with Chapin A. Harris in the achievement, his activities stand out in such a way as to prominently mark him as the guiding genius, the seer whose intelligence, greatness of mind, and untiring energies brought the movement to a successful culmination. We should make no mistake in determining to whom the honor belongs in this connection, nor can we honestly shift the responsibility of paying our debt of gratitude to the memory of Harris by the unctuous excuse that if he had not done his great work someone else would have ultimately accomplished the same end. Assuming that to be true, then as a profession it would simply be the shifting of our debt of gratitude to another individual, but the debt would remain the same in either instance.

The words herein quoted from Mrs. Harris, whether a literally correct record of her utterance or not, are, nevertheless, unquestionably true as to the facts. Chapin A. Harris labored indefatigably and continuously for the cause in which his whole life's activities were engrossed—viz, the placing of dentistry upon a professional basis. He was, incidently, a citizen of Baltimore, Md., in which city the greater work of his later years was accomplished. He was born in Pompey, Onondago county, N. Y. He had traveled and practiced extensively over a large portion of the more populous area of the United States, and by reason not only of his extensive travels, but especially by reason of his successful labors in behalf of the whole dental profession, he cannot properly be claimed as belonging to any geographical location, but rather as belonging to the whole dental profession.

Various efforts have been made at various times to awaken a genuine sense of appreciation and gratitude upon the part of the members of the dental profession toward those who have been great in its service. Such efforts in the past have not met with a large material response. Volumes of oratory have been expended in extolling the virtues and achievements of those whom the profession "delights to honor," but it has been mainly oratory, much of it undertaken for the self-aggrandizement of the orators rather than as a sincere expression of gratitude upon the part of those who have participated therein. The kind of gratitude that is genuine and sincere is the gratitude that is willing to express itself in terms of sacrifice. An old deacon in the congregation of an eminent and learned Baptist divine, now deceased, once made the boast that in connection with a certain charity he could give as much as ten dollars and not feel it, whereupon the learned clergyman, knowing the somewhat miserly instincts of the deacon, replied, "Well, brother, if that is the case, just give twenty dollars and feel it." It is necessary, in order to be a measure of real gratitude, that our giving should be of such character and magnitude as to cause us to feel it.

According to the record, it appears that on a previous occasion prominent representatives of the dental profession expressed their emotion of gratitude on the one hand and of sorrow on the other for the almost destitute financial condition of the surviving family of Chapin A. Harris to the extent of about $85. That, according to the record, was in 1860, a time which according to other records was one of considerable general financial stress. It can hardly be considered otherwise than unfortunate that the representative memorial meeting at that time permitted such a record to be created.

In the more than half a century that has since elapsed, mighty changes have been wrought in the world's history, in the history of the dental profession, and in the altruistic attitude of man's mind toward this kind of manifest duty. The sum subscribed by the dentists of the world to create a memorial to the late Prof. Willoughby D. Miller has reached a total amount of which the dental profession may well feel proud, and the time has come and the occasion is ripe when the dental profession can wipe out the stain of its earlier effort to express what it thought was its gratitude to the memory of Chapin A. Harris on an $85 basis, and now do something commensurate with the bigness of the man himself and his great work for dentistry, and more in harmony with the broadmindedness and real generosity of the dental profession of today.

The chairman of the committee having in charge the Chapin A. Harris Memorial is Dr. W. G. Foster, 9 Franklin st., Baltimore, Md. It is proposed to erect a memorial that shall consist of a bronze statue of Dr. Harris, mounted upon a granite base, the whole to cost in the neighborhood of $8000. The city of Baltimore has agreed, through its governing officials, to donate an appropriate site for the erection of the memorial. It will require but a little earnest work, and a generous response to their request for contributions, to bring this professional privilege and duty to a successful issue.

Review of Current Dental Literature.

IONIC MEDICATION IN ULCERATIONS OF THE ORAL CAVITY AND PYORRHEA ALVEOLARIS. By Dr. H. L. Jones, London.

Before the Section of Electro-Therapeutics and Radiology of the British Medical Society, at its annual meeting at Liverpool in July 1912, Dr. Jones spoke on ionic medication in ulcerations of the buccal cavity as follows: In a patient suffering from disseminated sclerosis, who had a chronic ulcer of the cheek and gum, he had observed rapid healing from zinc ionization, and in another case, with ulceration of the inside of the cheek of tuberculous nature, healing was obtained, though not very rapidly.

In pyorrhea alveolaris, some very satisfactory results have been obtained, the zinc ion being decidedly superior to the other ions tried. Success in the treatment of this disease needs a high grade of skill in dental work, as it is all-important to know the character of the suppurating pockets and the best means of bringing the zinc ions into all parts of these tiny sinuses. E. Sturridge had found zinc, copper, and iodin ions most effective in the treatment of pyorrhea alveolaris, many forms of gingivitis, and chronic alveolar abscesses. Bad cases of pyorrhea yielded almost immediately to treatment with zinc ions, which should be introduced into the affected pericemental membrane by passing a small spear-shaped electrode of zinc or platinum into the pockets and interstices of the teeth with a five per cent. solution of zinc chlorid. The strength of current necessary was from three to five milliampères, which most patients tolerated, and the penetration of ions with an electrode of such small area and cross-section was very great. Iodin ions introduced with a platinum cathode were also very effective in treating pyorrhea. This method has been used for a number of years, and has been found very reliable for curing the disease. It is not to be understood, however, that ionization alone would cure pyorrhea; there are many other details of treatment of purely dental nature which are just as essential.

[*New York Medical Journal*, New York, June 22, 1912.]

THE RELATIONS OF DENTISTRY TO MEDICINE: MISCELLANY.

The following article is an interesting comment on a question most vital to the dentist, though he may not fully coincide with the point of view taken:

A leading article in the June issue of the *Old Dominion Medical Journal*, edited by Dr. Beverley R. Tucker, reopens the discussion of the relations between dentistry and medicine which was begun in the April issue. The writer says: In our editorial in the April issue of the *Old Dominion Medical Journal*, we called attention to the close relationship, or the inseparableness, of medicine and dentistry. Since that writing several things have come to our notice which seem to us to strengthen our argument that dentistry should be placed upon a higher plane and made a part and parcel of medicine itself. We cannot but hope that the medical profession and the dental profession will take up this matter until it is pushed to a consummation that will amalgamate the two.

In the April issue of the *Archives of Internal Medicine*, than which no medical journal of higher standard is published in this country, we find an article by Thomas L. Gilmer, M.D., on "Chronic Oral Infection." Gilmer calls attention to the fact that in most mouths may be found tubercle bacilli among other dangerous bacteria. He also draws attention to the fact that deep pockets which harbor bacteria are found in the crowns and bridges made as substitutes for lost teeth, and to their faulty adjustment. He also states that he thinks it is a safe estimate to say that one-fourth of the human jaws have suppurating cavities, and quotes Odenthal, who found glandular swellings in ninety-nine per cent. of all children who suffered from badly decayed teeth; and he makes a strong insinuation that chronic alveolar abscess, though without the pain, swelling, rigors, or fever which are found in acute abscesses, is the more dangerous of the two. He calls attention to the marked general improvement in health which follows proper attention to the teeth in many cases, and quotes Osler as saying that in twenty cases of pernicious anemia, pyorrhea alveolaris was present in more than one-half. Certain types of nephritis are also believed to be due to oral infection.

In the same number of the same journal Frank Billings, M.D., of Chicago, in a paper entitled "Chronic Focal Infections and their Etiological Relations to Arthritis and Nephritis," states that abscesses of the gums and alveolar sockets, pyorrhea alveolaris, and septic types of gingivitis may cause systemic diseases of various types, and advises skilled attention in arthritic and nephritic cases.

In the May issue of the *Old Dominion Medical Journal*, La Roque has to say that Daland is very sure that the condition of the teeth and mouth among other things has immediate causative relation to gastro-enteric disorders, and quotes Osler as saying that more deaths are caused in the United States by unhealthy mouths than by alcohol.

Thus we are awakening to the importance of the mouth cavity as the cause of both medical and surgical disease, and the sooner we dignify the profession of dentistry, which treats these diseases primarily, the sooner we shall get better results in preventive medicine and in preventive surgery. We hope that this question of making dentistry a part of medicine will be actively taken up. We suggest that a committee from the American Medical Association confer with a committee from the National Dental Association with this end in view.

[*Deutsche Zahnaerztliche Zeitung*, Berlin, October 1912.]

PSYCHIC DISTURBANCES AFTER TOOTH EXTRACTIONS. By H. Woelke, Berlin.

Psychic disturbances are not necessarily caused by constitutional diseases or heredity; in fact, psychoses of the most serious nature are often due to apparently insignificant causes. While normal persons are able to tolerate pain of a most severe degree, or become unconscious when the pain is no longer bearable, nervous and especially hysteric persons perceive every impression, no matter how light, in a grossly exaggerated measure, and since the irritated condition of their nervous system will not permit of unconsciousness when pain becomes severe, a serious permanent psychic disturbance is created.

These contentions are borne out by the author's report of two practical cases. In the first of these the patient, a married woman, was anesthetized by her family physician with ethyl bromid for the extraction of several roots. During the anesthesia, she was tortured, according to her subsequent statements, by hideous dreams and dreadful mental anguish, and, although she seemed to recover fully after the operation, the memory of her agonies during the anesthesia was so vivid at times that she cried aloud, jumped up, and collapsed in a crying spasm. Her fear of people soon assumed the character of delusion of persecution, and she was obliged to undergo treatment in a sanatorium, and it was only two years after the extraction that her condition began to improve gradually.

In the second case, the patient, an elderly woman, had all the teeth remaining in her mouth extracted in one sitting without an anesthetic. The severe surgical insult impressed itself so indelibly upon her mind that she became subject to chronic spasms of fear, during which she uttered pitiful cries, and gradually became harmlessly, though hopelessly, insane.

The medico-legal aspect of such cases is of great practical interest. If all the usual precautions are taken in an extraction, it would be difficult for a patient to obtain a verdict for damages. On the other hand, the cases cited impress the necessity of great care in painful operations on nervous or hysterical patients.

[*British Dental Journal*, London, October 15, 1912.]

THE REMUNERATION OF SCHOOL DENTISTS. Editorial.

In view of the not infrequent attempts of local authorities to obtain school dentists at inadequate salaries, it is expedient to draw attention to what has been agreed upon by the British Dental Association and the School Dentists Society as reasonable minimum salaries for "part-time" and for "full-time" dentists respectively.

In the case of part-time officers, the sum in question is not less than £1 for each half-day's work, and it is highly important that members of our profession should bear this in mind, not only for their own benefit, but also for the benefit of their professional brethren.

In cases in which the work to be done has to be carried out in an institution far removed from the ordinary means of communication, it is well that dentists before accepting such appointments should see that due consideration is given to the amount of expense to be incurred in "going and returning," and also to bear in mind that, where no instruments or materials are provided, a proportionate allowance must be made to cover their cost.

There are cases in which a dentist has to make a journey of nearly two hours in order to reach a particular school, added to which the children may be epileptics or imbeciles, and as such specially trying when undergoing dental treatment, even at the hands of one possessed of the patience of Job.

With regard to "full-time" appointments, the salary to be offered should certainly not be less than £250 per annum to commence with, and it is well that education authorities should realize that it is more than likely that none but recently qualified and therefore comparatively inexperienced dentists would apply even at this standard of remuneration.

With regard to the insertion of advertisements of such appointments in our Journal, it may become necessary to follow the example of our medical contemporaries, the *British Medical Journal* and the *Lancet*, who decline to insert advertisements offering salaries of an inadequate character.

There is little doubt that if local authorities find their advertisements refused they will soon find it worth their while to offer adequate salaries, otherwise they will discover that the only applicants for their appointments come from the lower grades of the profession, and not from those public-spirited men who are willing to accept a moderate fee for the good of the rising generation of school children.

There is no branch of dentistry that calls for more tact, diplomacy, and patience than the treatment of the teeth of school children, and local authorities would be wise to see to it that the dentists they engage are such as are endowed with these qualities, and not merely persons who are ready to undersell their professional brethren.

[*Schweizerische Vierteljahrsschrift fuer Zahnheilkunde*, Zurich, No. 3, 1912.]

THE TRANSVERSE (COMPENSATING) BAR IN UPPER AND LOWER BRIDGE WORK, AND THE EFFECTS OF STRESS IN BRIDGE WORK. BY O. RIECHELMANN, STRASSBURG.

The author complains justly at the outset that in the construction of bridge work too much is based on pure empiricism and unscientific and unmethodical guesswork. In preparing the abutments a great many operators hesitate to devitalize or to grind the teeth sufficiently; others, again, allow themselves to be influenced by the patients' unreasonable wishes. After censuring a few mistakes that are frequently made in the construction of bridge work, the writer devotes special attention to the conditions of masticatory stresses and strains to be considered. His deductions are an amplification of Godon's theories on the same subject, although, considering the multiplicity of factors which enter into play in the act of incision or mastication, it seems entirely impractical to figure out in cold figures just how much strain or stress each portion of the bridge to be constructed will have to bear. Nevertheless, it is through such painstaking studies and experiments that greater clearness in regard to this important factor in bridge work will ultimately be brought about.

The author offers a generous number of examples of removable bridge work with transverse bars for the partial compensation of stress, explaining in each case the calculation, rationale, and technique for his procedure, and illustrating his theories regarding the distribution of stress, especially in large bridges.

Periscope.

A Serviceable Bench Block.—A door-bumper may be screwed into the laboratory bench. The rubber tip prevents the plate from slipping.—W. I. Prime, *Dental Digest.*

Making Gutta-percha Points More Rigid.—If difficulty is found in placing long, thin gutta-percha points in position because they are limber, they should be placed for a few moments in ice-water. Thus chilled they become more rigid.—A. J. Cottrell, *Dental Brief.*

Repairing Gum-section Dentures.—In repairing gum-section dentures in which one or more teeth are fractured, the porcelain is ground with a small engine stone for the insertion of single teeth, making a close joint. This saves a new block and time.—W. I. Prime, *Dental Digest.*

Cleaning Glass.—If the fountain cuspidor or other office glassware becomes coated with a white deposit from hard water, a few drops of nitric acid will dissolve the coating and leave the glass sparkling and bright. The acid may be easily applied with a pellet of cotton held in tweezers.—*Western Dental Journal.*

Staining Artificial Teeth to Match Natural Teeth in the Mouth.—A most artistic effect can be produced by painting thin lines of porcelain enamel, of suitable shade, longitudinally or transversely across the artificial tooth or teeth and baking in a small electric furnace. Such lines entirely remove the artificial appearance of the tooth or teeth, and from an esthetic point of view leave nothing to be desired.—*Ash's Monthly.*

Removing Gold from Arkansas Stones.—When Arkansas stones or points become covered with gold from reducing gold fillings, their cutting quality is much impaired. The gold may be quickly and effectively removed from the stones by taking a little moistened fine pumice between the finger and thumb of the left hand, and revolving the engine stones between them. The gold will at once be removed, and the stones be left clean.—G. C. Nicholson, *Commonwealth Dental Review.*

Protecting Metal Plates During Vulcanizing.—When a base-plate of aluminum or Watts metal, cast or swaged, is used in plate work, it may become tarnished by the sulfur escaping in vulcanizing, rendering it difficult to restore its luster. This may be avoided by painting the exposed metal surfaces with shellac or sandarac, which will protect the metal from the sulfur, and will greatly facilitate the polishing of the metal part.—M. L. Schmitz, *Dental Review.*

Advantages of Platinum Collars in Crowns.—One of the many advantages of platinum collars is that the thin platinum which almost entirely forms the edge of the collar admits of the most accurate and close adaptation to the cervix of a root or crown. This is due to the fact that platinum, being a very tenacious metal, can be trimmed down to form an extremely thin edge, which will not be destroyed by fusing in any subsequent part of the work.—G. Evans, *Items of Interest.*

Hints on Melting Zinc.—Zinc which has been fused repeatedly will be very slow in melting. This can be remedied by the addition of a trace of aluminum. Overheating of zinc is to be avoided. In order to gage the heat applied, a piece of dry pine wood is held into the molten metal. If the wood chars considerably, or even ignites, the cast should not be poured. Slight brown discoloration of the wood indicates the correct degree of heat of the metal.—*Archiv fuer Zahnheilkunde.*

Obtaining Correct Occlusion in Cast Gold Inlays in Occlusal Surfaces.—Gold inlays in occlusal surfaces of teeth, even if care be taken in regard to articulation, generally require some trimming after cementation. A good method for avoiding this consists in placing a piece of 60-gage tin foil between the wax pattern and the opposing tooth or teeth, and requesting the patient to bite. This method renders subsequent trimming or adjusting unnecessary.—H. C. Moxham, *Commonwealth Dental Review.*

Significance of Pus in the Maxillary Sinus.—When pus is found in the antrum, it can be accounted for in one of four ways: (1) It may be due to an extension of infectious material through the ostium from the middle meatus; (2) it may be due to infection reaching the cavity from the root of a diseased tooth; (3) it may be a secondary infection of a non-purulent accumulation of fluid, or (4) the antrum may be acting as a drip cup for the discharge from diseased areas higher up in the nose.—*Detroit Medical Journal* per *Amer. Journ. of Surgery.*

Sèvres Porcelain Teeth.—According to the Paris correspondent of the *Chemist and Druggist,* the well-known state porcelain factory at Sèvres, near Paris, appears to be in a fair way of adding a new and interesting branch to its business. It is announced that an inventor has obtained permission to make experiments in manufacturing artificial teeth with the ingredients of the famous Sèvres porcelain. The prospects are said to be promising, and if the dental branch proves satisfactory, the French government is likely to have a prominent place in the campaign for assisting in national dental aid.—*British Dental Journal.*

Lanolin for the Hands.—Lanolin is an excellent emollient for the hands. Its occasional use will keep the skin smooth and supple; for this purpose it is better than glycerin. Glycerin tends to draw the moisture from the skin, and at times it is irritating, while lanolin is soothing and healing. If scented with a delicate perfume and well rubbed into the skin after washing, it will keep the hands in good order. It is not at all expensive, and a little goes a long way. It is especially useful when the hands become chapped, and as a soothing application to the skin-cracks so annoying to some during frosty weather.—J. H. Grumm, *Dental Brief.*

Warnings in Regard to Bridge Abutments.—Do not place bridges upon abutments that have not been first made, through prophylactic measures, as healthy as it is possible to make them.

Do not place gold-shell crowns upon vital teeth unless thoroughly conversant with methods for removing enough of the enamel to straighten the sides.

Do not use unnecessary facings upon bridges used for masticatory purposes only.

Do not cement a bridge to place which draws or causes the teeth upon which they are placed to feel uncomfortable, because it is less trouble to saw it apart and place the parts in position and resolder than it is to lose a good patient and a couple of good teeth. —J. M. Thompson, *Dental Summary.*

Indications and Contra-indications for Bridge Work.—A careful choice of cases should be made for fixed bridges, bearing in mind the general health of the patient, and the special indications in the mouth. Not every gap which exists should be filled or spanned by a bridge. In mouths where chronic suppurative pericementitis exists, bridge work is contra-indicated. Probably the only crown by which marginal gingival irritation is entirely avoided is the bandless face-to-face crown, for in my mind the prevalence of gum diseases, especially of the type of chronic suppurative pericementitis, largely synchronizes with the too universal and indiscriminate employment of banded crowns and their multiple extension known as bridge work.—A. A. Forty, *British Dental Journal.*

To Prevent Porosity in Thick, Heavy Lower Vulcanite Dentures.—In making thick, heavy lower dentures, it is important, when flasking the case, to avoid using oil as a separating medium, as it has a detrimental effect upon the rubber during the vulcanizing process. Either a syrupy solution of soap or one of the many separating fluids which are sold for the purpose should be used —oil never.

Further, when packing the rubber in thick, heavy lower dentures, the center should be loaded with small pieces of old vulcanized rubber; then the temperature of the vulcanizer is raised very slowly to 315° F., and the case vulcanized for fully seventy-five minutes at this temperature, when a hard, dense vulcanite plate, entirely free from porosity, will be the result.—*Ash's Monthly.*

Bridge Attachment with the Aid of Accurately Cast Gold Inlays and Gold Mesh. —An accurately cast inlay to be used for an abutment for a bridge can best be obtained by reinforcing the wax pattern with gold mesh. Gold mesh, used as a framework and not as a matrix, controls both the shrinkage and warpage in the wax patterns in a vast majority of cases, and is a very distinct aid in making cast bases for crowns and in compound inlays for the bicuspid or molar. In bridge work it greatly facilitates the arrangement of the dummies, enabling the operator to carry the wax just where it is wanted, and lending strength to shallow wax patterns. In the casting of removable bases, it has been found a very great aid. In making bicuspid and molar crowns with cast cusps it is a splendid substance for placing the wax pattern upon, and in the mold it apparently fuses perfectly with molten gold.—G. F. Burke, *Dental Summary.*

A Simple and Definite Method of Marking Dental Instruments for Their Proper Arrangement and Placing.—By turning, at the extremity of the back end of an instrument, any special shape, such as a ball, or a cone, or an inverted cone, or a pear shape, etc., the instruments will be marked for their own drawer; that is, those terminating in a ball will belong in one drawer, while those terminating in a cone will belong in another drawer, and so on, each end-mark deciding the drawer in which the instrument belongs.

To mark the instrument so as to denote its place in the drawer, a narrow groove is turned around the back end of the instrument, cutting it on the first instrument close to its drawer mark, and cutting each instrument a trifle higher, so that when all the instruments in one drawer are laid down in their respective places these cuts or marks will form a diagonal line, thereby defining for each instrument its place in the drawer. By wider grooves cut around the handles in places where they do not interfere with the diagonal mark, the instruments can also be marked in pairs, each pair having either one, two, three, or more groves.—E. M. S. Fernandez, *Dental Brief.*

Changes in Leaf Metals as a Result of Surface Tensions During Heating.—The author has made experiments on the effect of heating leaf metals (0.087 to 2.9 microns in thickness) at temperatures up to 970° C. Gold leaf (97 per cent. Au, 3 per cent. Cu) becomes wrinkled at 350-400° C. and shrinks markedly between 440° and 500° C. The temperatures of the various changes increase with increasing thickness. In hydrogen and nitrogen the changes take place at much higher temperatures, but no powdering occurs even at 800° C. To explain these phenomena the existence of surface tensions in the crystal elements counteracting the forces of orientation is assumed. The latter forces diminish more rapidly as the temperature rises, with the result that they are ultimately overcome, when a deformation of thin metal layers is to be expected owing to contraction of the crystalline lamellæ. Experiments made with a view of determining the magnitude of the surface tension showed that the ultimate strength per square millimeter of thin sheets is less than that of thicker sheets, which can be partially traced to the fact that the effect of surface tension in thin foils manifests itself by reducing the strength. It is therefore maintained that in mechanically-deformed metals surface tensions are so concentrated as to bring about recrystallization in proportion to their magnitude.—H. Chattky, *Gescll. Wiss. Göttinger* per *British Dental Journal.*

Conservation of the Dental Pulp.—In filling operations we may take chances that are not advisable in crowning or extensive inlay operations, and especially not in the use of teeth as abutments for bridge work. In cases of extensive caries, verging on exposure of the pulp, the dentin, especially the portion overlying the pulp, if it is decayed or semi-decayed, should be sterilized. This is best done by placing and sealing sterilizing agents in the cavity, to remain at least two days. Non-coagulants are most suitable for this purpose, as they are more readily diffused through infected, decomposed, or semi-decomposed dentin. Ordinarily I use a saturated solution of aristol in oil of cloves, eucalyptus, or cassia. I prefer the clove solution when a sedative effect is desirable. When I desire to leave sterilizing agents in position for a considerable length of time, as in cases of pulpitis or where caries closely verges on exposure of the pulp, I place in the cavity a pellet of a paste made of chalk, carbolic acid, oil of cloves, and aristol, sealed in with a gutta-percha temporary filling.

In cases where I leave a portion of carious dentin over the pulp in order to avoid its exposure in excavation, I spread a thin layer of the paste over the carious portion, leaving it to remain permanently, and cover and partly fill the cavity with oxyphosphate cement.—G. Evans, *Journ. of the Allied Societies.*

Prevention of Dental Caries.—Food often sticks about the teeth after eating; it then decomposes and acts upon these organs, causing them to decay. It is the starchy and sugary foods that are the chief offenders. If food can be prevented from sticking to the teeth, there will be no caries. To prevent caries the following rules should be observed:

(1) As soon as an infant needs food other than milk (from eight to nine months), give it in a solid form requiring mastication, such as crusty bread, twice-baked bread, or crisp toast. In this way good teeth are likely to

grow, and good habits of mastication will be formed. Never give bread soaked in milk, or flour added to milk, or other soft starchy foods, such as most patent foods.

(2) As the child grows up, he should still be given most of his food in a hard form, compelling mastication. Food should rarely be taken in a liquid form, or soaked in liquid, or minced. Bread should not be eaten when fresh, and it should have plenty of firm crust.

(3) Drinking between each mouthful is very injurious; liquids should be taken principally at the end of a meal.

(4) Sweets should never be taken between meals, nor as the last course in a meal, but only along with food requiring mastication.

(5) A meal should always be finished with a cleansing food. It is very desirable that fresh fruit should be eaten freely, particularly at the end of a meal. This is most important with regard to the last meal of the day.

(6) Mouth-breathing in children should always be corrected, and, if it be persistent, medical advice should be obtained.—W. RUSHTON, *Dental Record.*

Porcelain Inlay Reinforced with Gold. —In incisors or canines, where a porcelain inlay coming to the occlusal edge might be broken, I have in a few cases performed successfully the operation of reinforcing with a gold tip, which furthermore helps to hold the inlay in place.

The inlay is inserted as ordinarily; then, after the end has been ground away somewhat, a gold filling is carried along the end of the tooth and malleted across the end of the inlay, serving as a buffer. This prevents the inlay from breaking, and if due care be observed so to grind the end of the inlay as to have the mass of gold toward the lingual surface, very little gold will show. The inlay is cemented in place before the operation with gold is begun.

This operation requires, of course, a degree of thickness of the end of the tooth to allow of grooving for the gold. The gold must be very carefully anchored, since no dependence for retention can be placed on the porcelain. If the porcelain be beveled slightly so as to allow the gold to exercise a retaining influence on it, so much the better.

It would seem hazardous to mallet gold upon an inlay, but I have found it unnecessary to use more than ordinary care.

The same operation may be employed, I presume, in a silicate cement filling. I have not tried it, but the five or six cases in which I have operated with porcelain as described, are, after from two to four years, apparently doing well.

The filling of gold may be replaced with a gold inlay, which, however, requires to be well anchored. I prefer filling after the usual way, as it affords better opportunity for firm anchorage.—F. W. SAGE, *Dental Summary.*

Regrettable Carelessness in Dental Nomenclature: "Ulcerated Teeth"; "Nerve."—"Ulcerated teeth" is an expression which our patients sometimes use. This is not a very serious mistake, but one which keeps our profession from being quite exact. Patients often try to get us to subscribe to their error by asking us the direct question after we have made an examination, "Doctor, is it ulcerated?" In almost all cases it may be answered truthfully, without giving offense, in something like the following language: "There is a condition here which is sometimes called 'ulcerated,' but not quite properly so; an 'abscess' is a better word for it." For when we consider the definition of an ulcer as "a suppurating surface," and an abscess as "a circumscribed cavity containing pus," we see at once that what they *usually* mean is an alveolar abscess. I say *usually*, for they sometimes mean a bad case of pyorrhea with the inner surface of the socket suppurating. Even then the tooth is not "ulcerated."

This is not written with the thought that the members of this association do not know better than to use the term "ulcerated tooth," but merely to remind us that our duty as teachers requires that we be a little more exact and take a little time to explain the difference between an abscess and an ulcer. When we hear physicians and sometimes even dentists using the term, we cannot blame the public from feeling encouraged—even justified—in using it also.

Another little error, which is not serious, is the habit some of us have of calling the "pulp" the "nerve." I can remember learning in the public school when quite young the different parts of a tooth as the enamel, dentin, cementum, and pulp. I did not learn the word "nerve" in this sense until years afterward. Then I learned it from a dentist, and several years later learned it to a greater extent in a dental school.

While the mistake is not a very serious one, it certainly seems to indicate a state of retrogression. It seems humiliating to the dental profession to know that seventh and eighth grade pupils in the public schools, or even pupils in the fifth and sixth grades, have a more exact word for anything pertaining to our profession than some of us put into common use every day.

We lack something of making dentistry an exact science when we allow a loose nomenclature.—V. W. LAUGHLIN, *Items of Interest.*

Welded Gold Bands in Crown and Bridge Work.—In crown work, welded gold bands have many advantages over the usual soldered bands which are so generally used, in that, when properly sweated, bands are much stronger at the seam than at any other part, and no matter how many times they are put through the fire, they never come undone. Also, when the ledge formed by the overlapping band is filed away, the usual line which would be present if solder were used is absent, as the karat is not lowered by the addition of solder, and the color is the same throughout.

By this method a whole crown may be made without the use of solder, provided perfect contact be obtained with cusp and band, and the cusp be filled with the same karat gold as the band. Twenty-two-karat gold will weld very nicely, but coin gold works very much more smoothly, and is better by far for this work, as the copper in the alloy helps its flowing qualities.

In welding a band, the two edges are not brought together as in soldering, but one edge overlaps the other a fraction of an inch, the under edge being sharply beveled, and perfect contact being obtained with a pair of pliers. A little liquid flux is now allowed to run the length of the joint, the band is placed upon a charcoal block, and the flame applied. At first the whole band is heated to a red glow; then the blue flame is centered at the lower edge—or the edge nearest the worker—and when this begins to fuse the flame is moved rapidly up the seam. This may be done several times, depending upon how heavy the welding is desired, or if the contact is affected by the heat. A brush flame does almost as well as the blue flame; operators, in fact, prefer it. As the flame is moved up the seam, a dark line may be seen to follow the seam; this indicates fusion. This is also a guide when sweating a crown.

The portion of the band burned where fusion starts may be filed out and used for the mesial or distal festoon.—R. L. WHELESS, *Texas Dental Journal.*

HINTS, QUERIES, AND COMMENTS.

SOLDER *VS.* SEPARATION.

THE value of the contact point has long been realized by the closely observant, and the attitude of the profession toward the question of oral hygiene has intensified interest therein. The cast inlay offers splendid inducements to seek perfection in its formation. It seems that most of those who endeavor to secure good contact resort to separation of the teeth to permit such forming of the wax model as will insure proper contact when the teeth have recovered from the separation.

In many instances the operator fails to judge, with precision, the extent of the separation, the resultant condition being either a failure to secure contact or a too extensive "contour," the former favoring the impaction of food and the latter causing derangement of the articulation. The evil consequences of such impaction and derangement are among the great lessons that are taught us by oral hygiene and orthodontia.

In those cases in which the teeth have not left their normal positions, the wax model should be made so that the finished inlay will present a flat facet at the position of the base of the eminence which is to constitute the contact point. In most cases, a piece of solder flowed over this surface will make a contact point, but there are some inlays in which the necessary building-out is too extensive to be readily done with solder. In such cases the facet is brightened by burnishing, and the contact point made by building out with plastic gold and flowing solder over this.

In those cases in which loss of structure has permitted the teeth to move toward each other, separation is necessary, of course, but its extent should be only sufficient to allow the teeth to return to their normal positions, after which the inlay may be made as indicated above. Thus may we make contact points and at the same time preserve or obtain normal articulation, with accuracy, ease, and dispatch.

Montgomery, Ala.

MAKING-OVER REFUSE WAX.

Refuse wax can be easily remade by the following mode:

Place the old wax in a bag made of two thicknesses of cheese-cloth—the finer the better—and tie the bag securely. Place the bag and wax in a metallic pail about two-thirds full of boiling water, which should be kept hot until the wax is melted. When melted, churn it with a metal rod—smooth at the end, so the bag will not be torn—and finally press the bag to the bottom of the pail, holding it with the rod, and allow to cool. Punch holes in the wax and allow the water to drain off. Heat the sides of the pail to loosen the wax, remove it from the pail, and take out the bag, which contains all the sediment, but no wax. Should, however, a small amount of wax remain in the bag, it can be peeled out and put into the wax-drawer to be used at the next melting.

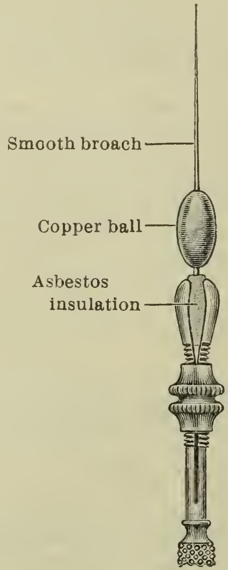
Re-heat the wax in the pail with water, and allow to cool almost to the congealing point. Have ready a slab of plaster of Paris about one-quarter inch thick dipped in cold water, and make the wax sheet, by dipping. Repeated dipping will make thicker sheets. When a sheet of sufficient thickness is attained, drag one edge and one end of the slab over the rim of the pail and place in cold water. The wax sheet will loosen, and the slab—now cooled—can be re-used. It is best to have two slabs, using one while the other is cooling.

To make the slabs, stretch a piece of rubber dam upon a flat board and pin it to place. Then, having ready four pieces of pine about one-quarter inch square, tack them to the rubber and pour in the plaster, stroking off the surplus with a straight-edge. When hard, remove from the board by loosening the pieces of wood.

Dr. James H. Beebee.
Rochester, N. Y.

A HOME-MADE INSTRUMENT FOR INSERTING PRINZ' PARAFFIN COMPOUND IN ROOT-CANAL FILLINGS.

The instrument suggested is devised for drying root-canals, which, according to Dr. H. Prinz, is the *sine qua non* of a successful paraffin root-canal filling (see "Filling Root-canals with an Improved Paraffin Compound,"



Dental Cosmos, October 1912, p. 1081), and for inserting the paraffin itself. The principle of its construction is that embodied in Dr. G. Evans' root-drier. A hole is drilled in an oval copper ball, and a tapering, smooth iridio-platinum broach is inserted into this hole and jammed fast. Enough of the broach is allowed to protrude at the shank to permit of its being wrapped with a double or triple layer of asbestos paper. This insulated end is then inserted in a pulp-broach-holder with wide jaws. Broaches of various sizes may be kept in stock. Instead of the iridio-platinum, silver or copper may be employed for these broaches.

Not every dentist has facilities for electrically heated and regulated points, which Dr. Prinz considers as the best, but the point of the instrument described, after the copper ball has been heated to a temperature slightly higher than that at which the paraffin compound will melt—viz, about 60° C. (140° F.)—will retain its heat for a considerable length of time, as the asbestos insulation prevents loss of heat by radiation into the handle of the instrument. It can be easily sterilized, and its convenient size, which allows of manipulation in the same way as a pulp-canal broach in its holder, greatly facilitates the correct introduction of the paraffin compound, which in every respect seems the best root-canal filling material thus far suggested.

Philadelphia, Pa.

OBITUARY.

DR. EDWIN CHEW.

DIED, at his home in Salem, N. J., January 10, 1913, EDWIN CHEW, in his eighty-first year.

Dr. Chew and Dr. Charles S. Stockton, who died in September of last year, were the last two surviving charter members of the New Jersey State Dental Society. Dr. Chew had been failing in health for some time, though he continued in a measure in active practice until a week before his death, when he contracted grippe.

He was born in Salem, N. J., May 17, 1832, where he received his education. In 1858 he entered the office of Dr. Samuel C. Herbert as a student, and later bought the practice of his preceptor.

Dr. Chew belonged to a generation of dentists who, lacking the facilities of our modern supply houses, were often compelled to make both materials and implements.

In reference to the development of dentistry at that period, he writes in a letter of three years ago—"At that time it was very hard to find anyone that could carve teeth, but I seemed to have the talent for it, and, not being satisfied with that alone, wanted to learn all I could of the materials that went into the body enamels and frits. I still have quite a supply of porcelains I made, using Delaware spar, which I selected from the quarries, and silex that I found in a sand hole near my home."

Dr. Chew's skill as a dentist was recognized by a large *clientèle* as well as by the members of his profession. As a citizen, he was much respected, his high sense of honor commanding the admiration of all who knew him.

Four married daughters survive him.

"IN MEMORIAM" RESOLUTIONS.

Dr. Wilbur F. Litch.

AT a meeting of the Pennsylvania Association of Dental Surgeons, the following resolutions were adopted:

Whereas, it is our sad duty to record the death, December 25, 1912, of our fellow member, Dr. Wilbur F. Litch; and

Whereas, throughout his long, busy, and honorable life, Dr. Litch has ever been a patriotic citizen. His scholarly attainments, his ability as a writer, editor, and teacher, his skill as a practitioner, and his keen interest in professional affairs have placed him foremost among the eminent men who have graced the dental profession; therefore be it

RESOLVED, That we, the members of the Pennsylvania Association of Dental Surgeons, feeling deeply the loss we have sustained, hereby express our appreciation and our sorrow over the close of a noble career; and be it

RESOLVED, That these resolutions be spread upon our minutes, and a copy be sent to his widow and to the professional journals for publication.

WILLIAM H. TRUEMAN,
J. FREDERICK WESSELS,
J. CLARENCE SALVAS,
Committee.

At a meeting of the Eastern Dental Society of Philadelphia, the following resolutions on the death of Dr. Wilbur F. Litch were adopted:

Whereas, death has removed from our midst our beloved teacher and friend, Dr. Wilbur F. Litch; and

Whereas, the Eastern Dental Society of Philadelphia wishes to express its sorrow at the loss of an esteemed teacher and friend, under whose guidance most of the members have received their professional training; therefore be it

Resolved, That we, the members of the Eastern Dental Society, do express our deep sorrow at the death of Dr. Wilbur F. Litch, the loss of whom will be keenly felt by the dental profession, and whose loving, kind treatment and beneficent influence cannot be forgotten by those who were fortunate enough to come in contact with him; and be it further

Resolved, That a copy of these resolutions be spread upon the minutes of the society, and that copies be sent to the journals for publication.

Charles B. Shupack,
David Feldman,
Committee.

Legal Decisions.

STATE OF RHODE ISLAND *VS.* EVAN B. ROSENKRANS.

CONSTITUTIONALITY OF STATE DENTAL LAW PASSED UPON BY THE UNITED STATES SUPREME COURT.

By PERCY W. GARDNER, Esq.,
Of Wilson, Gardner & Churchill, General Counsel for the State Board of Registration in Dentistry of the State of Rhode Island.

[This is the first case to be passed upon by the Supreme Court of the United States determining the constitutionality of a law regulating the practice of dentistry.]

While a number of the final courts of appeal in the various states have held that a law regulating the practice of dentistry and creating a board of examiners in dentistry is constitutional, the first case to be passed upon by the Supreme Court of the United States is that of State *vs.* Rosenkrans, decided by the Supreme Court on June 7, 1912. This case, which had been fought through the courts of Rhode Island and in the federal courts for over three years, and in which almost every possible constitutional question concerning the practice of dentistry was raised, will be of interest both to the members of the dental profession and to counsel for boards of dentistry throughout the country.

On August 12, 1909, Harry L. Grant, secretary of the Board of Registration in Dentistry of the State of Rhode Island, swore out a complaint in the district court of the sixth judicial district of that state, against one Evan B. Rosenkrans, alleging that he did practice and attempt to practice dentistry without having first received a certificate from the Board of Registration in Dentistry that he had passed a satisfactory examination with reference to his knowledge and skill in dentistry. This complaint was brought by Dr. Grant upon the strength of the following statutes:

Section 4 of Chap. 181 of the General Laws of Rhode Island, 1909, which is an enactment of Public Laws 470, May 21, 1897, provides that all persons who hereafter intend to enter the practice of dentistry in this state shall appear before said board and be examined with reference to their knowledge and skill in dentistry, and to such as pass a satisfactory examination certificates to that effect signed by the president and secretary of the board shall be issued, and thereupon the names of such persons receiving certificates as aforesaid shall be registered with said board.

Section 7 of the same chapter makes the practicing without first obtaining such a certificate a misdemeanor.

Section 9 of this chapter permits members of the Board of Registration in Dentistry to swear out complaints.

The defendant was tried in the district court, convicted, and took an appeal to the Superior Court.

In the Superior Court the defendant filed, on October 12, 1909, a special plea in bar alleging that he had held a certificate from the State Board of Registration in Dentistry of the State of New Hampshire and a certificate from the State Dental Commissioners of the State of Connecticut, certifying that he was competent and fit to practice dentistry, which certificates he received from said boards several years before the time alleged in said complaint and warrant, and that he held licenses to practice dentistry in both of said states, and that he had further been in the continuous and successful practice of dentistry for the period of about twenty-six years prior to the bringing of the complaint; that evidence of the existence of such certificates and of the length of time that the defendant had practiced was presented to the State Board of Dentistry for the State of Rhode Island by the defendant in the form of a sworn petition, demanding a license, before said complaint was sworn out, and that he was practicing dentistry in Rhode Island before there was any legislation in the state regulating the practice of dentistry therein. To this special plea the complainant demurred on the ground that such pleas were not sufficient in law to preclude the complainant from having an action against the respondent. Upon argument this demurrer was sustained by the Superior Court.

The respondent was then permitted before trial to file certain constitutional questions, and which constitutional questions were certified under statutory powers to the Supreme Court for the State of Rhode Island, the court of last resort in that state, for determination. The seven questions thus raised and certified were in effect as follows:

Questions 1 and 2. Is this statute in conflict with Sect. 10 of Art. I of the Constitution of Rhode Island, and Sect. 1 of Art. IV of the Constitution of the United States, in that it deprives the defendant of the right to continue to practice dentistry in the state of Rhode Island, which right of property he enjoyed before the enactment of the statute?

Question 3. Whether this statute is in conflict with Sect. 2 of Art. IV of the state constitution vesting all legislative power in the general assembly, whereas the general assembly has granted legislative power to the examining board?

Question 4. Is this statute in conflict with Sect. 2 of Art. IV of the Constitution of the United States, in that it denies to citizens of another state coming into this state the privilege and immunities of citizens of this state?

Question 5. Is it in conflict with Sect. 1 of Art. XIV of the Constitution of the United States, in that the defendant is deprived of the privilege or immunity as a citizen of the United States which he enjoyed before the passage of this act?

Question 6. Is it in conflict with Sect. 1 of Art. IV of the Constitution of the United States, in that it denies to each and every state the full faith and credit required to be given to public acts of each state?

Question 7. This question was a restatement of Question 2.

In the opinion handed down March 9, 1910 (see 30 R. I. 374) written by Mr. Chief Justice Dubois, and which discusses each of these questions in a full and exhaustive manner, each of these questions was answered in the negative, thus sustaining the constitutionality of this statute as far as the state courts were concerned.

Pursuant to the decision on the constitutional questions, the case was remitted to the Superior Court for the State of Rhode Island for trial. The defendant was tried and found guilty. A motion for a new trial was made and denied.

The case was then taken to the Supreme Court on exceptions raised during the trial and exceptions to the denial of the motion for a new trial, all of which exceptions were overruled and the case remitted to the Superior Court for sentence.

The defendant then filed with the United

States Supreme Court a petition for writ of error, which petition was granted by Mr. Justice Holmes on June 5, 1911, and was served upon a justice of the Superior Court on the day on which the defendant was brought before the court for sentence. This writ of error carried the entire record of the case to the United States Supreme Court, and placed before that court the questions involving the constitutionality of the state statutes as far as they were in conflict with the Constitution of the United States.

The complainant's attorneys, during the October term, 1911, of the Supreme Court of the United States, filed a motion to dismiss the case for want of jurisdiction and to affirm the judgment of the state court. This motion raised two questions—namely, whether the writ of error was prematurely or improperly brought, and secondly, whether the federal questions involved were frivolous, and therefore the judgment of the state court should be affirmed without further hearing in the United States Supreme Court.

As above stated, this motion was granted by the United States Supreme Court on June 7th, thereby determining that the constitutional questions involved were frivolous and that the judgment of the lower court should be affirmed.

The opinion written by Mr. Chief Justice Dubois in the state court, analyzes with great care the entire statute, and all of the constitutional questions, and should form a valuable precedent for any state having a similar statute, where the constitutionality of the statute is raised, and, since the case was carried to the United States Supreme Court on the constitutional grounds above enumerated, the possibility of a successful appeal in any other state having a similar statute has been finally disposed of.

SOCIETY NOTES AND ANNOUNCEMENTS.

DENTAL SOCIETY MEETINGS: March, April, and May.

MARCH.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA. Philadelphia. March 25th.

AMERICAN DENTAL SOCIETY OF EUROPE. Florence, Italy. At Easter.

OKLAHOMA STATE DENTAL ASSOCIATION. Oklahoma City. Six days: March 24th to 29th.

APRIL.

ARKANSAS STATE DENTAL ASSOCIATION. Little Rock. Five days: April 7th to 11th.

CONNECTICUT STATE DENTAL ASSOCIATION. Waterbury. Two days: April 15th and 16th.

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES. Boston, Mass. Two days: April 22d and 23d.

FIFTH DISTRICT (N. Y.) DENTAL SOCIETY. Syracuse. Three days: April 3d to 5th.

MAY.

DENTAL SOCIETY OF THE STATE OF NEW YORK. Albany. Three days: May 8th to 10th.

INDIANA STATE DENTAL ASSOCIATION. Indianapolis. Three days: May 20th to 22d.

IOWA STATE DENTAL SOCIETY. Davenport. Three days: May 6th to 8th.

KENTUCKY STATE DENTAL ASSOCIATION. Lexington. Three days: May 26th to 28th.

LAKE ERIE (PA.) DENTAL ASSOCIATION. Cambridge Springs. Three days: May 15th to 17th.

MASSACHUSETTS DENTAL SOCIETY. Three days: May 8th to 10th.

NEBRASKA STATE DENTAL SOCIETY. Omaha. Four days: May 12th to 15th.

NORTH DAKOTA DENTAL ASSOCIATION. Fargo. Two days: May 13th and 14th.

TEXAS STATE DENTAL ASSOCIATION. Temple. Three days: May 15th to 17th.

VERMONT STATE DENTAL SOCIETY. Burlington. Three days: May 21st to 23d.

Examiners' Meetings.

ARKANSAS BOARD OF EXAMINERS. Little Rock. April 7th and 8th.

ILLINOIS BOARD OF EXAMINERS. Chicago. June 4th.

MASSACHUSETTS BOARD OF REGISTRATION. Boston. March 5th to 7th.

WASHINGTON STATE BOARD OF EXAMINERS. Seattle. May 22d.

READING (PA.) DENTAL SOCIETY—

Its Work in the Public Schools.

AT a recent meeting of the Reading Dental Society a copy of the appended resolutions, passed by a committee of the teachers of the public schools, was received, and on motion the secretary was instructed to send a copy to the DENTAL COSMOS for publication.

OTTO J. SPECKER, *Sec'y.*

Resolutions.

Whereas, the city of Reading and the school children of the city have been benefited beyond measure by the Reading Dental Society's gratuitous dental inspection of the children in the grades; and

Whereas, we, the teachers of the schools, knowing of the marvelous improvement in the health and physical development of these children through their magnanimity; therefore be it

RESOLVED, That we, the teachers of the city, in institute assembled, do express to the Reading Dental Society our sincere thanks, and in this way show our earnest appreciation and full realization of the great amount of good they have done; and be it further

RESOLVED, That a copy of these resolutions be sent to the secretary of the society.

[Signed] GEORGE BEGGS, *Chairman*, MARY H. MAYER, ESTHER M. EVANS, EMMA C. HOUDER, ELIZABETH PIPER, ANNA FINK, JOSEPHINE MURRAY, CARRIE LOTZ, MARTHA GOODENOUGH, MARGARET GOSSLER, *Committee on Resolutions.*

SOCIÉTÉ BELGE D'ODONTOLOGIE.

AT the annual meeting of the Société Belge d'Odontologie, held at Brussels on December 15, 1912, the following officers were newly elected: Dr. Pitot, president; Mr. Emile Huet, vice-president; Mr. Groth, librarian. No changes were made in the remaining offices.

DR. GEORGE FAY, *President.*

AMERICAN DENTAL SOCIETY OF EUROPE.

THE fortieth annual meeting of the American Dental Society of Europe will be held at Easter, in Florence, Italy. All members of the profession are cordially invited to be present. Florence is one of the most interesting cities of Europe, and Easter is the most favorable time of the year for seeing Italy.

GEORGE H. WATSON, *Sec'y,*
Pariser Platz 7, Berlin, Germany.

THE PANAMA PACIFIC DENTAL CONGRESS.

As one of the attractions of the Panama Pacific International Exposition, a dental congress, international in character, to be known as the Panama Pacific Dental Congress, is to be held in San Francisco, California, beginning on the last Monday in August 1915, and continuing for ten days.

A Committee of Organization has been perfected, including representatives from the Pacific Coast states—California, Oregon, Washington, Utah, Idaho, Colorado, and Arizona.

This committee is now actively engaged in perfecting the work of organization, including the establishment of executive committees in every state of the United States and in every foreign country where dental organizations are known to exist, which will be empowered to promote the business of the congress by bringing it to the attention of their national, state, and local societies, and securing memberships and contributions to the program.

The American Society of Orthodontists and the National Dental Association, of the United States of America, have already made arrangements to meet in San Francisco in 1915 as part of the congress, and invitations will be extended to other dental societies to take similar action.

The Panama Pacific Dental Congress is the first organization to apply to the Exposition management for space for exhibits, and to ask that a definite time be set aside for its meeting.

Manufacturers of dental goods have signified their intentions to maintain during the congress the greatest exhibition of dental supplies ever held. Ample space for this purpose has already been promised by the Exposition authorities, and we are assured of their hearty co-operation in all things pertaining to the success of the congress.

The membership fee has been fixed at ten dollars, and the finances of the congress are being cared for by a corporation, formed within the Committee of Organization, and known as the "Pacific Dental Congress Commission of 1915."

Over $8000 has already been subscribed for promotion purposes by the dentists and dental societies of the Pacific Coast states, and this fund will be increased by many thousands of dollars before the congress meets.

Ample funds for promotion of the congress are assured, and in due time Committees on Local Arrangements, Transportation, Exhibits, Clinics, Program, etc., will be appointed, and everything possible will be done to insure the success of the congress and make it in attendance and scientific and professional interest the greatest dental congress ever held.

The whole world is coming to San Francisco in 1915 to participate in and enjoy the Panama Pacific International Exposition, which will commemorate the completion of the world's engineering masterpiece, the Panama Canal.

Never in the history of the profession has there been so auspicious a time for holding a great dental congress, and the Panama Pacific International Exposition Company and the Committee of Organization of the Panama Pacific Dental Congress unite in a cordial invitation to the members of the dental profession to come to San Francisco in 1915 to attend the congress and view the wonders of the Exposition and the Pacific Coast of the United States of America.

Frank L. Platt, *Ch'man,*
Committee of Organization.

NEW SOUTH WALES DENTAL BOARD.

The following gentlemen have been reappointed members of the Dental Board of New South Wales: Mr. Donald Smith, president; Mr. P. A. Ash, D.D.S., Mr. A. Burne, D.D.S., Mr. A. W. Cleary, Dr. A. M. Gledden, and Dr. J. J. Kelly.

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

The next annual meeting of the Dental Faculties Association of American Universities will be held at Harvard Dental School, Longwood ave., Boston, Mass., April 22 and 23, 1913. The meeting will be called to order on the morning of April 22d, at 11 o'clock.

Edward C. Kirk, *Sec'y-Treasurer.*

INSTITUTE OF DENTAL PEDAGOGICS.

At the annual meeting of the Institute of Dental Pedagogics, held at Pittsburgh, Pa., January 28, 29, and 30, 1913, the following officers were elected for the ensuing year: D. H. Squire, Buffalo, N. Y., president; Fred W. Gethro, Chicago, Ill., vice-president; J. F. Biddle, 517 Arch st., N. S., Pittsburgh, Pa., secretary-treasurer. Executive Board—Dr. H. M. Semans, Columbus, Ohio, S. W. Bowles, Washington, D. C., and A. W. Thornton, Toronto, Canada.

The next annual meeting will be held in Buffalo, N. Y., during the last week of January 1914.

J. F. Biddle, *Sec'y.*

OKLAHOMA STATE DENTAL ASSOCIATION.

The Oklahoma State Dental Association will hold its sixth annual meeting in Oklahoma City, Okla., March 24 to 29, 1913, inclusive. Headquarters Skirvin Hotel; rates $1 to $2.50 per day.

This will be the second postgraduate course given by the society for the dentists of Oklahoma and adjoining states. The course will be conducted the same as last year, except that more suitable arrangements will be made for the clinics. Lecturers and demonstrators: Dr. Thos. P. Hinman, Atlanta, Ga.; Dr. J. V. Conzett, Dubuque, Iowa, and Dr. Martin Dewey, Kansas City, Mo.

The course will consist of about eighteen lectures and many practical demonstrations in operative dentistry, prosthetic dentistry, crown and bridge work and orthodontia. All ethical dentists are eligible to take the course, and dentists from other states are cordially invited to the meeting, but will be expected to pay a membership fee of five dollars. For any information address C. R. Lawrence, Enid, Okla.

The next issue of the *Bulletin* of the society will contain an outline of the program. A copy will be mailed to all out-of-state practitioners who will notify the undersigned that they desire same.

A. L. Walters, *Sec'y*,
Checotah, Okla.

FIFTH DISTRICT (N. Y.) DENTAL SOCIETY.

The forty-fifth annual meeting of the Fifth District Dental Society of the State of New York will be held at the Onondaga Hotel, Syracuse, N. Y., April 3, 4, and 5, 1913. Papers and clinics of unusual merit have been secured, and it is confidently expected that this will be the largest and most instructive meeting ever held by the society. A most cordial invitation is extended to all ethical practitioners.

J. N. Garlinghouse, *Sec'y*.

CONNECTICUT STATE DENTAL ASSOCIATION.

The next annual meeting of the Connecticut State Dental Association will be held in Waterbury, April 15 and 16, 1913.

A. V. Prentis, *Sec'y*,
New London, Conn.

ST. LOUIS DENTAL COLLEGE.

Mid-year Commencement.

The commencement exercises of the St. Louis Dental College (Dental Department of St. Louis University) were held in St. Louis, Mo., on January 30, 1913.

The commencement address was delivered by Dr. Martin Fischer, professor of physiology in the University of Cincinnati, Ohio.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Sylvester Baker, Missouri.
Louis J. Dicks, Missouri.
Charlie Gilliland, Missouri.
Nicholas T. Hoxmeier, Missouri.
Harry M. Stamm, Missouri.
George J. Vandas, Missouri.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

The regular meeting of the Academy of Stomatology of Philadelphia will be held on Tuesday, March 25, 1913, at the College of Physicians, Twenty-second st. above Chestnut, Philadelphia, Pa., at 8 P.M. Dr. Clarence J. Grieves of Baltimore, Md., will give a lantern talk on the "Comparative Vulnerability of Cavo-surface Margins in Contact Fillings and Inlays."

All members of the dental profession are invited to attend.

Norman L. Jameson, *Sec'y*.

ARKANSAS STATE DENTAL ASSOCIATION.

The Arkansas State Dental Association, instead of having papers and clinics by its own members as heretofore, will hold a post-graduate Course in Little Rock, Ark., April 7 to 11 inclusive, 1913.

This course will be under the direction of Drs. John P. Buckley, Hart J. Goslee, and J. H. Prothero of Chicago. All ethical dentists are eligible, and a membership fee will be charged.

For further information address

I. M. Sternberg, *Sec'y*,
Fort Smith, Ark.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

The forty-fifth annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May 8, 9, and 10, 1913. There will be the usual reduced railroad rates on the certificate plan.

The first session will open on Thursday at 10.30 A.M. The literary program of the meeting will be rendered in the auditorium of the Educational Building. Headquarters will be at the Hotel Ten Eyck, where the exhibits and clinics will be held.

A cordial invitation is extended to all ethical dentists in New York and sister states. Exhibitors wishing to engage space please address Dr. O. J. Gross, Schenectady, N. Y.

A. P. Burkhart, *Sec'y*,
52 Genesee st., Auburn, N. Y.

VERMONT STATE DENTAL SOCIETY.

The next meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 21, 22, and 23, 1913.

P. M. Williams, *Sec'y*,
Rutland, Vt.

NORTH DAKOTA DENTAL ASSOCIATION.

The eighth annual meeting of the North Dakota Dental Association will be held at Fargo, N. D., May 13 and 14, 1913.

E. N. Hegge, *Sec'y*,
Hatton, N. D.

KENTUCKY STATE DENTAL ASSOCIATION.

The forty-fourth annual meeting of the Kentucky State Dental Association will be held at the Phoenix Hotel, in Lexington, Ky., on May 26, 27, and 28, 1913. All ethical dentists are invited to attend.

C. R. Shacklette, *Sec'y*.

LAKE ERIE (PA.) DENTAL ASSOCIATION.

The fiftieth annual meeting of the Lake Erie Dental Association will be held at Hotel Bartlett, Cambridge Springs, Pa., May 15, 16, and 17, 1913. This meeting celebrates the "golden anniversary" of this society, and the Program Committee have arranged for the best meeting ever held. Entertainment for the ladies; come, and bring them.

C. L. Mead, *Sec'y*,
Union City, Pa.

INDIANA STATE DENTAL ASSOCIATION.

The fifty-fifth annual session of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, May 20, 21, and 22, 1913.

The officers of the association recently met at Indianapolis and perfected plans for a three-day "Postgraduate Course." The very best instructors and specialists are being secured for each day. The course will be as follows: Tuesday—"Humanitarian Dentistry." Wednesday—"Preventive Dentistry." Thursday, A.M.—"Prosthodontia"; P.M., a great table clinic. The clinic will also be held in the hotel.

No tuition fee for the members of the association, or visitors from outside the state who are in good standing in their state associations, but all others desiring to take this course must arrange their tuition fees with the secretary.

Otto U. King, *Sec'y*,
Huntington, Ind.

NEBRASKA STATE DENTAL SOCIETY.

The Nebraska State Dental Society will hold its thirty-seventh annual meeting at Omaha, Nebr., May 12, 13, 14, and 15, 1913. Several special men have been secured from without the state, besides the usual array of home talent.

E. H. Bruening, *President*,
Wm. A McHenry, *Sec'y*.

IOWA STATE DENTAL SOCIETY.

The fifty-first annual meeting of the Iowa State Dental Society will convene at Davenport, Iowa, May 6, 7, and 8, 1913, beginning Tuesday, May 6th, at 9 A.M. Elaborate clinics and lectures and a large exhibit will be presented.

Further information will be furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

Exhibitors desiring space should apply to Dr. Wm. Finn, Cedar Rapids, Iowa.

C. M. Kennedy, *Sec'y*,
Des Moines, Iowa.

MISSISSIPPI DENTAL ASSOCIATION.

The thirty-eighth annual session of the Mississippi Dental Association will be held at the Great Southern Hotel, Meridian, Miss., June 24, 25, and 26, 1913.

A determined effort is being put forth to make this meeting our best. There will be a fine clinic, excellent papers, a banquet, and a fine exhibit.

L. B. Price, *Sec'y*,
Corinth, Miss.

TEXAS STATE DENTAL ASSOCIATION.

The thirty-third annual meeting of the Texas State Dental Association will be held at Temple, Texas, May 15, 16, and 17, 1913.

The clinics will be in charge of Dr. J. O. Hall, Waco, Texas, who will furnish any information relative to same. Exhibitors desiring space will please address Dr. J. M. Murphy, Temple, Texas. All ethical practitioners are cordially invited to attend the meeting.

Any other information will be cheerfully furnished by

J. G. Fife, *Sec'y*,
Dallas, Tex.

RHODE ISLAND DENTAL SOCIETY.

At the annual meeting of the Rhode Island Dental Society, held at Providence, R. I., on January 9, 1913, the following officers were elected: W. R. McIntire, president; T. F. McHale, vice-president; W. B. Rogers, secretary; D. J. Fisher, treasurer; F. P. Gleason, librarian. Executive Committee—C. N. Williams, chairman; F. P. Duffy, and A. G. Midgley.

W. B. Rogers, *Sec'y*.

EASTERN DENTAL SOCIETY OF THE CITY OF NEW YORK.

The January meeting of the Eastern Dental Society was held at Café Boulevard, 156 Second ave., New York City, the president, Dr. Wm. J. Lederer, presiding.

A paper—"What the General Practitioner Should Know About Orthodontia"—was read by Dr. Robert Elster of New York, and discussed. Study classes in crown and bridge, inlay, and casting work, for members in good standing, have been organized, to begin on January 15, 1913.

A. LeWitter, *Sec'y*.

WASHINGTON STATE BOARD OF EXAMINERS.

The Washington State Board of Dental Examiners will meet in Seattle, Wash., on May 22, 1913, for the purpose of holding the spring examination.

L. B. Manchester, *Sec'y*,
Wenatchee, Wash.

MASSACHUSETTS BOARD OF REGISTRATION.

A meeting of the Massachusetts Board of Registration in Dentistry for the examination of candidates will be held in Boston, Mass., March 5, 6, and 7, 1913. For application blanks and other information apply to

Dr. G. E. Mitchell, *Sec'y*,
14 Water st., Haverhill, Mass.

ARKANSAS BOARD OF EXAMINERS.

The next meeting of the Arkansas Board of Dental Examiners will be held in Little Rock, Ark., April 7 and 8, 1913. All applicants are required to pass an examination to obtain a certificate. Examination fee $15.

For application blanks apply to

E. H. Johnson, *Sec'y and Treas.*,
305 Citizen's Bank Bldg., Pine Bluff, Ark.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending January 18, 1913:

Wm. A. Squires, act.d.s., January 7th, returned to Fort D. A. Russell, Wyo., from leave.

For the week ending January 25th:

B. C. Warfield, act.d.s., left Fort H. G. Wright, N. Y., January 22d, for temporary duty at Fort Terry; arrived January 23d.

For the week ending February 1st:

A. T. Knoderer, act.d.s., arrived at Fort Crockett, Texas, January 17th, for temporary duty; arrived at Jackson Barracks, January 23d, for temporary duty.

First Lieut. E. P. Tignor left Fort Du Pont, Del., January 29th, for temporary duty at Fort Howard; arrived January 29th.

First Lieut. F. P. Stone arrived at Fort Williams, Me., January 29th, for temporary duty.

A. T. Knoderer, act.d.s., ordered to Fort Oglethorpe from temporary duty at Key West Barracks; granted leave of absence for twenty-two days about April 6th.

First Lieut. F. F. Wing left Fort D. A. Russell, January 25th, on leave of absence for one month.

J. F. Feely, act.d.s., left Fort Hamilton January 31st, on leave of absence.

For the week ending February 8th:

C. E. Sherwood, ACT.D.S., arrived at Fort Barry, Cal., January 28th, for temporary duty.

W. A. Squires, ACT.D.S., left Fort D. A. Russell, February 1st, *en route* to Philippine Islands; sailed February 5th.

A. T. Knoderer, ACT.D.S., left Jackson Barracks, La., February 1st, on temporary duty at Fort Morgan, Ala.

EXAMINATION OF DENTISTS FOR THE U. S. ARMY.

THE Surgeon-general of the army announces that examinations for the appointment of acting dental surgeons will be held at Fort Slocum, N. Y.; Columbus Barracks, Ohio; Jefferson Barracks, Mo.; Fort Logan, Colo., and Fort McDowell, Cal., on Monday, April 7, 1913.

Application blanks and full information concerning these examinations can be procured by addressing the Surgeon-general, U. S. Army, Washington, D. C.

The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-one and twenty-seven years of age, a graduate of a dental school legally authorized to confer the degree of D.D.S., and shall be of good moral character and habits.

Acting dental surgeons are employed under a three years' contract, at the rate of $150 per month. They are entitled to traveling allowances in obeying their first orders, in changing stations, and in returning to their homes at termination of service. They also have the privilege of purchasing certain supplies at the army commissary. After three years' service, if found qualified, they are promoted to the grade of dental surgeon, with the rank of first lieutenant, and receive thereafter the pay and allowances appertaining to that rank.

In order to perfect all necessary arrangements for examination, applications must be in the possession of the Surgeon-general at least two weeks before the date of examination. Early attention is therefore enjoined upon all intending applicants. There are at present a large number of vacancies to be filled.

UNITED STATES PATENTS

PERTAINING OR APPLICABLE TO DENTISTRY

ISSUED DURING JANUARY 1913.

January 7.

No. 1,049,654, to WILLIAM O. BLOOM. Sanitary tooth-brush holder.

January 14.

No. 1,050,178, to WESLEY L. SMITH. Antiseptic waste-cotton receiver.

No. 1,050,282, to HUGH T. LIPSCOMB. Rotary tooth-brush.

No. 1,050,469, to FOREST O. KIEFER. Dental appliance.

No. 1,050,560, to GEORGE MOORE. Dentifrice and floss dispenser.

No. 1,050,561, to JOHN MOORE. Pad for artificial teeth.

No. 1,050,620, to WILLIAM H. DE FORD. Mouth-inhaler.

No. 1,050,621, to WILLIAM H. DE FORD. Inhaler.

No. 1,050,672, to JAMES H. B. MACINTOSH. Dental wall bracket.

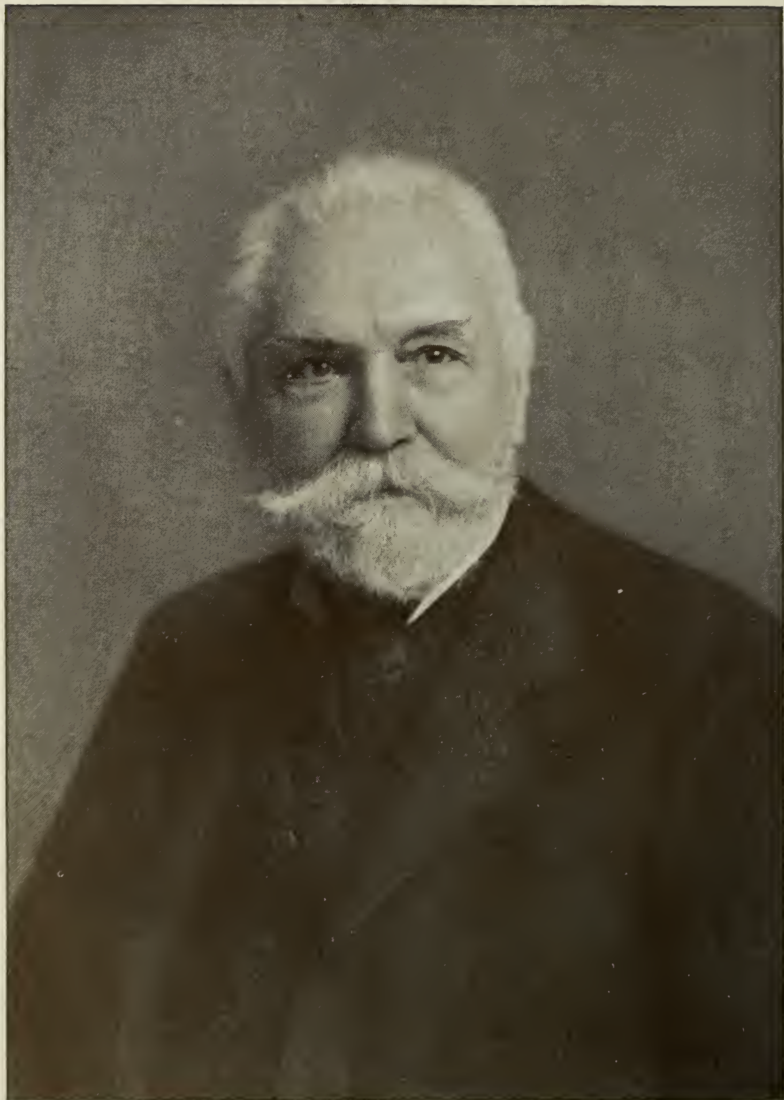
January 21.

No. 1,050,864, to WESLEY L. SMITH. Tooth-brush holder.

No. 1,050,933, to WILLIAM W. EVANS. Attachment for dental articulators.

January 28.

No. 1,051,433, to G. C. MOSELEY and A. C. CAMERON. Tooth-brush holder and sterilizer.



DR. NORMAN W. KINGSLEY.

THE

DENTAL COSMOS.

VOL. LV. APRIL 1913. No. 4.

ORIGINAL COMMUNICATIONS.

DIAGNOSIS AND TREATMENT OF IMPORTANT DISEASES OF THE DENTAL PULP.

By J. F. BIDDLE, D.D.S., Pittsburgh, Pa.

(Read before Section III of the National Dental Association, at its sixteenth annual meeting, Washington, D. C., September 11, 1912.)

THE rational diagnosis and treatment of pathological conditions of the dental pulp is one of the fundamental branches of modern dental practice. While the profession has had its several spasms of enthusiasm over various operative procedures in recent years, we must recognize the fact that the success of any of these operations is absolutely dependent upon the healthy condition of the tooth-root. In view of the marvelous strides that have been made in the restoration of tooth structure, operations which a few years ago would have been deemed impossible, it is apparent that more definite and exact methods of pulp treatment must be devised, if this important division of our work is to rank with the more purely mechanical.

From the pulp and its disorders arise many pathological conditions, due, no doubt, to the fact that the pulp is one of the few tissues in the body that have retained the original, embryonic form. It is soft and gelatinous, and therefore easily attacked by the micro-organisms of the oral cavity, which may be transmitted to it through the dentinal tubuli, the apical tissues, or by direct exposure. In order to diagnose and treat intelligently diseases of this delicate and important tissue, one cannot emphasize too strongly the value of a comprehensive knowledge of anatomy, physiology, histology, and pathology, and its conscientious application to each case that comes under our observation. How often one is prone to treat mechanically, rather than thoughtfully and logically, the individual needs of his patients.

The diseases of the dental pulp that we shall consider are hyperemia, inflammation of the pulp, suppuration, and chronic inflammation.

HYPEREMIA.

Hyperemia is divided into two classes, active and passive. The many circulatory and infective diseases of the pulp are attributable, no doubt, to its lack of lymphatics, and the peculiar character of its structure. For this reason any irritation of the pulp often produces hyperemia, with a distension of the arteries, capillaries, and veins, and if the apical foramen be small, the pressure of the enlarged arteries upon the weaker veins prevents the free circulation of the blood, thus resulting in a passive as well as an active hyperemia. Of the active hyperemic cases, such only will be considered as relate to the destruction of the pulp, as this paper deals with destruction, not conservation, of the dental pulp. In the diagnosis of such cases let us consider causes, viz—

Direct. The irritation of the pulp through thermal stimuli, due to defective enamel or dentin, or the presence of a large metallic filling in close proximity to the pulp.

Indirect. Injury or disease of the apical tissue. A blow or other injury to the teeth.

In cases where a sharp, acute pain is produced by contact with hot or cold substances, recurring only in response to direct stimuli, the symptoms are favorable under proper treatment. Paroxysms of sharp pain, varying from a few seconds to a few minutes, are indicative of a serious disturbance of the circulatory vessels of the pulp. The pain from a hyperemic pulp is not always referred to the affected tissue, but is often reflected to the ear, temple, infraorbital foramen, the malar prominence, the angle of the lower jaw, the side of the neck, or other remote part of the affected side. Cold water applied to the offending tooth will usually produce an aggravation of the reflex neuralgic pain, as well as pains in the affected tooth. For relief, the cavity is rinsed with warm water, the carious dentin, as far as possible, is removed, and an anodyne treatment of oil of cloves and chloroform, equal parts, applied for a few minutes, repeating if necessary. The pulp when exposed usually presents a purplish hue, and on account of the enlargement of its vessels immediately protrudes slightly through the opening. Phenol is now applied and the pulp is punctured with a sharp probe, permitting the escape of blood for some time, after which it is destroyed. In diagnosis of hyperemia, one must bear in mind that the severity of the disorder depends upon the vascular disturbance, hence is often simply a matter of differentiation, distinguished mainly by therapeutic tests, on account of which one must discriminate carefully between this disturbance and other pulp disorders. The location of a hyperemic pulp is not always indicative of its cause, as the following example will demonstrate: A partially impacted lower left third molar was removed from the jaw of a woman about thirty-two years of age. It was necessary to bur and chisel away the occlusal half of the process before attempting the extraction of the tooth, which was accomplished only after great difficulty. Two days later the patient returned, complaining of the condition of the first molar, which was highly sensitive to thermal changes. A careful examination revealed a hyperemia in this tooth, due to no apparent cause, except possibly to a reflex pain from the third molar region. The tooth was isolated, washed with alcohol, and received several coats of resinous varnish, usually used as a cavity lining. Next a loose-fitting band of exceedingly thin German silver, filled with gutta-percha to form a crown, was pushed into place, and the patient instructed to remove a partial upper plate which occluded with the offending tooth. The gutta-percha cap was removed after five days, during which time the socket that had contained the third molar was irrigated daily with warm, normal salt solution. Thermal tests were applied to the first molar, which was found to be in normal condition, the irrigation of the third molar socket having relieved the irritation due to the reflex action of its torn circulatory vessels.

INFLAMMATION OF THE PULP.

By its symptoms only, inflammation of the pulp cannot be differentiated, positively, from hyperemia, for the reason that inflammation usually involves hyperemic conditions, although in inflammation the pain is more lasting, frequently occurs without apparent cause, and is greater after exertion, mastication, and lying down. During the first stages of inflammation the pain is dull and heavy, with uneasiness about the jaws and inordinate response to thermal stimuli, particularly to heat; while in the latter stages the pain is of a severe, continuous nature, the pericemental membrane becomes somewhat hyperemic, and the tooth responds to percussion. Reflex pains also are noted. In making a diagnosis one must remember that there is seldom true inflammation of the pulp without its exposure, although extensive bacterial invasion may occur by the micro-organisms or their products through the dentinal tubuli. The causes should be carefully considered, whether they be extrinsic, such as are due to the pulp's exposure by decay, deep-seated cavities, the action of irritating drugs, large metal fillings, mechanical violence in the form of accidents or dental operations, an abscess on an approximating tooth, pyorrhea pockets, or impacted teeth. The intrinsic or direct causes may be pulp nodules, injury to the vessels at the apex of the root, thrombosis, etc. If there be any doubt regarding the identity of the affected tooth, each tooth of the affected side should be isolated and thoroughly tested. The electric mouth-lamp and the X ray are often valuable diagnostic aids. The prognosis in pulpitis is bad; invariably the pulp should be removed.

Treatment. Excavate the cavity of decay as thoroughly as possible. Apply an anodyne treatment, repeating if necessary, after which arsenic may be introduced. One must be sure pulpitis has subsided before the introduction of arsenic, otherwise it acts as an irritant instead of promptly devitalizing. If danger of further irritation seems imminent an opening should be made in another part of the tooth for the introduction of arsenic through healthy tissue for the pulp's devitalization. Simultaneously the pulp may be quieted by sedative applications in the cavity of decay. In inflammation without decided hyperemia, the pulp may become inflamed, and go on to suppuration and final destruction of the organ without producing any symptoms whatever of inflammation or of hyperemia. Occasionally such trouble cannot be dissipated by the anodyne treatment, nor will it be quieted by cocain or arsenic. The writer has in mind one case which would not yield to treatment, and it was necessary to give the patient an anesthetic in order to remove the pulp. Two years later he returned with another tooth in the same condition, and which would respond to no known treatment. This time nitrous oxid and oxygen were administered for the operation.

SUPPURATION.

Suppuration of the pulp usually occurs from infection through the dentin, but bacteria or their products may enter the pulp through the circulation, if the systemic resistance be lessened during a period of bacterial invasion of any other part of the body. In ulceration of the pulp there is usually little if any response to cold, the discomfort being a dull, gnawing pain if the cavity of decay be open, but if closed, so that the pus cannot escape, intense pain results. If the pulp chamber be opened, the probe may be passed in for some distance, depending upon the extent of suppuration, before any sensation be felt, unless it be a pulp abscess, when it may be necessary to pass a sharp, slender probe into the pulp tissue, resulting in a bead of pus and immediate relief. In pulp abscess the pain grows in intensity, and, in contrast to the other conditions of suppuration, is often relieved by a cold application. In most cases response to heat stimuli is very marked, while in others it may decrease to such an extent as to be almost imperceptible. In the latter stages of pulp suppuration the tooth may become sore, due to the action of bacterial products upon the pericementum. The symptoms of pericemental disturbance may assume proportions of incipient acute apical abscess, although considerably highly inflamed but vital apical tissue exists. The differential diagnosis of these two conditions is highly important with regard to the patient's comfort, particularly since the introduction of formocresol, the use of which over vital tissue will inaugurate excruciating pain. Many phases of this condition may exist, as will be demonstrated presently by radiographs. Case 1 is an instance of a mesial root of a lower molar containing an abscess with apical involvements plainly discernible; secondary dentin had completely severed the pulp, entirely filling the body of the pulp chamber, while the distal root contained a vital pulp.

CHRONIC INFLAMMATION.

Chronic inflammation may result either in a sclerosis or an hypertrophy of the pulp. The hypertrophy is often of much greater bulk than the original pulp, and is composed of an inferior type of granulated tissue, hence it bleeds readily, and the absence of nerves permits the easy removal of its bulbous portion, thus permitting confirmation of the diagnosis that it is pulp, rather than gum tissue grown in through a cavity or through a perforation. The importance of correct diagnosis is apparent when one considers the matter of devitalization.

Pulp nodules are usually found in the coronal portion, although they may be found in any part of the pulp tissue, and may produce either hyperemia or inflammation. In the majority of cases they can be detected by the X ray, but their pathological significance is not such that it is wise to devitalize the pulp without confirmatory diagnosis by other means.

EXTIRPATION OF THE PULP.

The *modus operandi* of destroying a pulp is dependent upon existing conditions. If the pulp be suppurative, devitalization by arsenic is preferable, as its use sterilizes the contents of the canal simultaneously with its destruction of the pulp; but if non-suppurative, cocain or some form of cocain extirpation should be employed. Clinical observations have shown that infections frequently follow pulp extirpations with cocain, and have led to the conclusion that the principal cause was the indiscriminate use of the extirpation method. If the operator be in doubt as to the reasonably healthy condition of the pulp, he should invariably use arsenic, the after-results of which have proved uniformly satisfactory. The methods employed in the use of cocain are too well known to receive more than passing notice. They are—

(1) Cocain pressure with base-plate gutta-percha, usually deemed best for cases of direct exposure.

(2) Cocain with high-pressure syringe where the tooth be sound or the pulp be covered with considerable dentin.

(3) The method of injecting through the gum tissue in close proximity to the periosteum and anesthetizing the apical tissue is sometimes used. This method is the least desirable.

DEVITALIZATION BY ARSENIC.

The greatest objection of most practitioners to the use of arsenic is its production of pain. While arsenic is recognized as an irritant of pulp tissue, the writer believes that the greater part of the pain produced is due to faulty technique in cavity preparation and in the application of the agent. Very satisfactory results may be obtained by the preparatory use of an anodyne treatment from five to fifteen minutes immediately preceding the insertion of the arsenical paste. In a record of more than fifty cases which has been carefully kept, four had slight, intermittent pain during the first few hours, and two had severe pain—not sufficient, however, to necessitate the removal of the application. The arsenic should be left from one to three days, where there is an exposure or nearly so, and will very rarely require removal on account of pain. Occasionally an obstinate case presents which will not respond to the anodyne treatment, or devitalization, or to the extirpation method, and can be removed only after resorting to the use of a general anesthetic.

It may be of interest to say a word here regarding the introduction of arsenic into teeth not fully formed. Recently such a case came to your essayist's notice. The patient was a boy fourteen years of age. The lower right first molar had been removed when the child was seven years of age, the second molar moving forward and occupying the exact position of the first molar. There was an exposure in an occlusal cavity, and the dentist, after a superficial examination of the supposed first molar, decided that the roots were sufficiently formed to insert arsenic with safety for forty-eight hours. Four days later the patient presented with the buccal and lingual sides of the gum showing a deep purplish color, the teeth exceedingly loose, the glands and side of the neck and face swollen. The tooth was immediately removed (Fig. 1), also the infected hard and soft tissue for a considerable distance; then the infected area was irrigated with normal salt solution and swabbed with 10 per cent. iodin. The patient was seen every day for a week. The glands and tissues returned quickly to normal condition with no further treatment except daily irrigation with warm, normal salt solution.

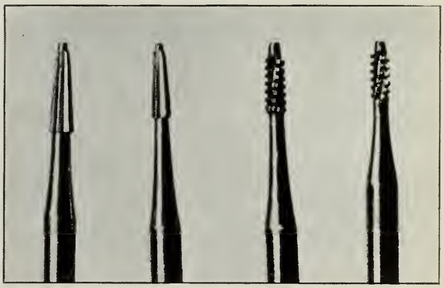
FIG. 1.

Lower second molar of boy of fourteen, in which arsenic has been used.

ROOT-CANAL TREATMENT.

For successful root-canal treatment it is essential that the pulp chamber be correctly opened in order to accomplish its thorough mechanical cleansing, observing the following rule: "The walls of the cavity, pulp chamber, and canals should be continuous, but not necessarily parallel or on the same plane." The pulp chamber is first opened with a round bur. The opening is enlarged with a small fissure bur, the end blades of which—and sometimes the edges of the side blades also—are removed, thus making it capable of enlarging the walls of the pulp chamber of a bicuspid or of a molar without marring the floor (Fig. 2) and changing the angle of approach of one wall of an incisor or of a cuspid without making pits in the opposite walls. In no case should the removal of the pulp be attempted until the cavity and the pulp chamber be thoroughly cleansed of all débris. The incisors and cuspids more frequently than the other teeth are insufficiently opened, their ideal opening being through the center of their lingual surfaces; but as their cavities are generally on the approximal surfaces, the canal is usually opened from that angle. To facilitate the removal of the pulp, the "orifice of the exposure should be extended to the gingival wall and the full breadth of the chamber," frequently cutting a lingual extension, which will admit of free access of a broach to the lingual of the incisal edge. For the extension of the canal the small specially prepared fissure bur (Fig. 2) previously mentioned is used. The canal is approached from the same direction as a broach would be introduced, passing the bur into the canal, where its lateral cutting broadens

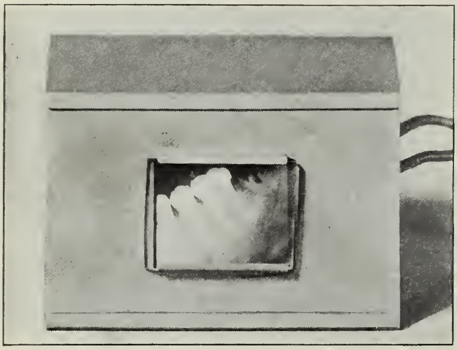
FIG. 2.



Specially prepared fissure burs for opening pulp chamber.

the canal in such a direction as will straighten its approach, using great care to prevent the cutting of the opposite wall and the consequent roughening—which would result in making the canal impassable to the broach. In bicuspids the orifice should be made through the center of the roof of the pulp chamber, and then broadened bucco-lingually to expose the horns of the pulp, which in these teeth diverge toward the points of the cusps. Their root-canals are given

FIG. 3.



Author's illuminating box in operation.

off from buccal and lingual extremities of the pulp chamber, hence the cutting must be sufficiently wide to permit the insertion of an instrument. The radiograph has been found to be one of the greatest aids in the treatment and enlargement of root-canals. In difficult cases the writer places the film in an illuminating box, and keeps it before him on the bracket table during the entire operation, so that it may be referred to at all times without handling. This box has a shield for both horizontal and vertical films. (See Figs. 3 and 4.)

SUMMARY OF ESSENTIALS OF ROOT-CANAL TREATMENT.

To sum up, the essentials of root-canal treatment are—

(1) To establish and maintain an aseptic field of operation.

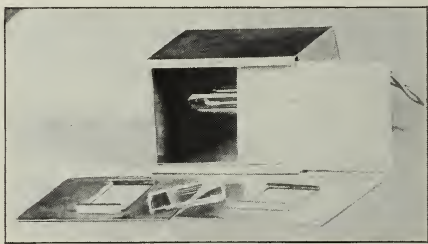
(2) Never to attempt the removal of a pulp until all cutting be done and débris removed.

(3) Instruments that have been used in the cavity of decay should never be used for the removal of the pulp.

(4) Instruments used in the canal of one tooth of a patient should never be used in the canal of another tooth of the same patient without their being sterilized.

(5) Instruments used in a canal of a multi-rooted, infected tooth should

FIG. 4.



Parts of author's illuminating box.

never be used in other canals of the same tooth.

(6) Burs and drills should never be used to open root-canals.

PRIME IMPORTANCE OF REMOVAL OF ALL PARTICLES OF PULP TISSUE.

Before the advent of the X ray it was taken for granted that in the filling of a root-canal, when the patient felt pressure at the end of the root, the ideal result had been accomplished. This pressure is analogous to the action of the hyperdermic syringe. If one's finger be placed over the orifice of the syringe and pressure be created on its piston, the compression of the air in the syringe will produce pressure on the finger covering the opening. The same result occurs in the root, the apical tissue corresponding to the finger and the gutta-percha or other filling material to the piston of the syringe. The X ray has revealed roots two-thirds filled, or less, the filling of which was attended with slight or in some cases acute apical pain.

The filling material introduced, matters little, provided all particles of pulp be removed and the canal rendered sterile to the apex of the root. Judging from experience with the radiograph, the writer believes that thorough cleansing of the canal is much more essential than the filling of the root to its apex, although one should of course endeavor to do this also. However, contrary to all that has been said on the subject, your essayist has as yet failed to radiograph a single case—wherein the removal of all organic matter had been accomplished

Fig. 5.

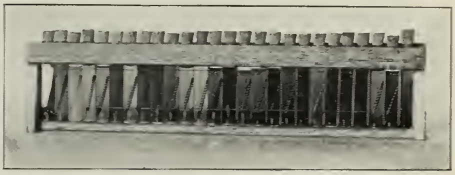
Author's sterilizing dish for root-canal instruments.

—that revealed any abscess, even though the roots had not been perfectly filled. But in cases where small quantities of organic matter remained, or where mummifying paste had been used, many blind abscesses were revealed.

STERILIZATION OF ROOT-CANAL INSTRUMENTS.

The testing and sterilization of all instruments entering a root-canal is one of the most important details in their treatment. For the purpose of sterilizing instruments, the writer uses a small glass dish divided lengthwise into three compartments. (See Fig. 5.) One of these parts is subdivided, thus making in all four compartments, two long and two short ones. Of the two longer compartments, one is used for smooth and barbed broaches and long-shanked reamers, the other for straight handpiece burs. One of the smaller compartments is used for right-angle burs and the other for short reamers with handles. This sterilizing dish is kept on the cabinet at all times. It has a dustproof, airtight cover, and does not permit the escape of the sterilizing agent, a 10 per cent. lysol solution, which is a saponified product of coal-tar. Lysol is a clear, brown, oily liquid containing 50 per cent. of comparatively pure cresols. Its effects are simi-

Fig. 6.



Lysol test as described in paper.

lar to phenol, but it is five times stronger and eight times less poisonous. Instruments will not rust or corrode in lysol solution from 2 per cent. up. The writer has made some lysol tests which have been standing since last December. (Fig. 6.) The first tube contains simply water, and shows considerable rust of the bur; the second tube holds 1 per cent. lysol, and there is very little rust; while in the remaining tubes, containing 2 to 25 per cent. lysol, no rust is present. The sediment in the tubes is due to the fact that unfiltered city water was used, thus causing the lime to be precipitated by the soap in the lysol. All instruments to be used in opening or penetrating the root-canals are placed in this sterilizing dish and allowed to remain until ready for use, when they are removed with pliers, placed in a watch-glass containing alcohol with which to rinse off the lysol, and then in a holder ready for use. After using them they are mechanically cleansed and replaced in the sterilizing dish, not to be removed until again needed.

USE OF THE X RAY IN DIAGNOSIS.

The X ray is of inestimable diagnostic value in dentistry, but in the past its use has been confined more to the discovery of chronic involvements of the apical tissue than to acute destructive conditions. While its value for these latter conditions has increased wonderfully, it still has decided limitations, and requires also a more exact technique, as the accompanying radiographs will illustrate.

Fig. 7.

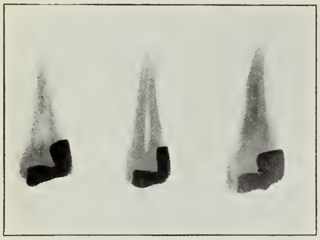


Fig. 8.

Fig. 9.

In Fig. 7 the radiograph in the center depicts the filling practically the same size as the original, while the ones on each side were taken with the tooth lying in exactly the same position, but the tube was moved first three and one-half inches to the right, then three and one-half inches to the left, respectively, of the original position, and focused so that the rays from the tube were oblique to the bucco-lingual axial plane, not parallel with it as in the first instance, hence the distortion of the filling.

In the next illustration (Fig. 8), will be noted the distortion of the length of the tooth; the central figure, where the focus was direct or perpendicular to the mesio-distal plane, reproduces the tooth of the same length as the original, while the oblique rays reproduce a distortion in the length of the tooth similar to that noticed in the filling.

Fig. 9 shows the correct opening of the canal of the cuspid, the easy insertion of a broach, and the canal filled.

Some of the most important uses of the X ray in this field of dentistry are found in the diagnosis of the following:

(1) Diseases of the pulp due to the presence of large metallic fillings.

(2) The presence of invisible cavities.

(3) The presence of pulp nodules.

(4) Diseases of the pulp due to the presence of impacted teeth.

(5) Deposits of secondary dentin.

(6) Abscesses on one root of a tooth, with vital pulp in others.

(7) To locate the number, position, and curvature of the canals of a tooth.

(8) To show the length of roots.

(9) To show success or failure of an operation in insertion of a root-filling.

Besides the foregoing, the X ray has at least fifty other uses in dentistry, the enumeration of which, time and the subject of this paper will not permit.

Fig. 10.

PRACTICAL CASES.

There will be thrown upon the screen a number of views illustrative of cases mentioned.

Case 1. The patient, a woman, fifty-five years of age, with a lower left first molar which exhibited slight soreness upon occlusion, also an occasional discomfort which the patient could not describe as pain but simply as an "uneasiness." Upon the removal of a large amalgam filling, it was found that the body of the pulp chamber was filled with secondary dentin, the removal of which, followed by the insertion of a broach in the distal canal, brought forth a protest from the patient, and a drop of pus from the mesial canals. A radiograph (Fig. 10) revealed an apical abscess on the mesial root of the first molar, a pericemental abscess on the vital bicuspid, also partially filled roots of the second molar with resorption of the apical portion of the root.

Case 2. The patient, a man of thirty-five years of age, ten years before presenting had had a crown with a facing attached to it placed on the bicuspid. Seven years later, the patient noticed that the central and lateral responded to thermal stimuli. His dentist advised him that this condition would pass away, which it eventually did, but the result is apparent. About a month prior to the time when the radiograph was taken, a slight swelling appeared. An examination revealed a sinus between the first bicuspid and lateral incisor on the labial surface (Fig. 11, *a* and *b*). A radiograph was taken, after which the central, lateral, and impacted cuspid, with surrounding structure, were removed. Had the case been correctly diagnosed at the beginning of the hyperemic condition, doubtless both incisors could have been saved.

Case 3. The patient, a young woman of twenty, was suffering with spasmodic pains of about an hour's duration once

FIG. 11.

a

b

FIG. 12.

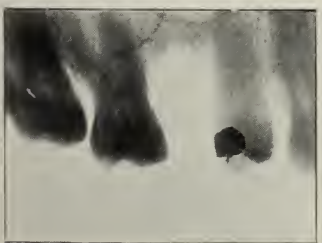

FIG. 13.

FIG. 14.

or twice every twenty-four hours. The second bicuspid was badly broken down and was removed, but the pain continued. Thinking that possibly there might be some loose bone in the socket, as the process was splintered in the extraction of the tooth, the case was referred for a radiograph. The film (Fig. 12) reveals pulp nodules in both molars. With this discovery as a clue, the thermal tests were applied, with just sufficient response to confine the diagnosis to the first molar.

Fig. 15.

Fig. 16.

Fig. 17.

a

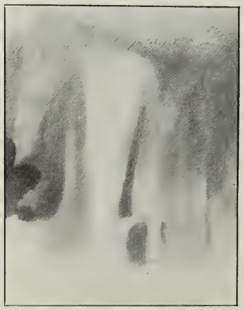
Fig. 18.



a

b

Case 4. The patient, a man of

twenty-eight, had a chronic abscess on the central and lateral incisors, with inflammation of the lateral, which is not surprising when one considers the extent of the abscess tract. (Fig. 13.)

Case 5. The radiograph shown in Fig. 14, which was taken in a woman of twenty-six, is of peculiar interest, owing to the fact that it shows a deciduous molar with deposits of calculus (only the occlusal surface is visible through the gum); also an exposed, inflamed pulp, which the dentist was unable to locate, attributing the trouble to the supposedly partly erupted first permanent molar.

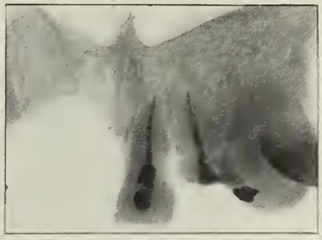
Case 6. The patient, a man thirty-five years of age, with an inflammation of the lower molars. The second molar contained a large contour amalgam filling of some years' standing; the third molar, a large approximo-occlusal cavity. Both teeth gave equal response to tests. The radiograph (Fig. 15) revealed the trouble to be due to the amalgam filling, which was removed. The pulp was devitalized and the root and tooth filled.

Case 7. The only manifestation of trouble in this patient, a woman of thirty-eight, was a swelling of the left side of the upper lip and the lower portion of the nose, which an examination showed to be due to a large deposit of bone. The X ray (Fig. 16) revealed the cause to be an abscess involving the central and lateral incisors, which when opened were found to contain cotton root-canal fillings.

The next two cases are instances in which it was necessary to resect the roots in order to save the teeth.

Case 8. This case, that of a woman of forty, involved abscesses on both centrals, as well as the left lateral and left supernumerary, there being also three sinuses. The centrals were treated successfully with quick response, then the X ray (Fig. 17, *a*) revealed the condition of the lateral. The results ten months later are noted also (Fig. 17, *b*); the cavity was then filled with bony tissue, with the exception of a small particle of bismuth, which is not as yet absorbed.

FIG. 19.



Case 9. This shows the longest section of root that the writer has ever removed with the hope that the tooth will eventually recover. The band surrounding the crown is so placed as to hold the tooth firmly until the cavity in the bone is filled, and the tissues (Fig. 18, *a* and *b*) are readjusted.

Case 10. This is illustrative of the proper root-filling of a central and a lateral incisor. (Fig. 19.)

Some of these examples are not within the scope of this paper, yet are indicative of the grave results of careless diagnosis and treatment of the dental pulp, hence should serve as an incentive to more careful and rational methods of investigation and diagnosis.

IMPLANTATION OF ARTIFICIAL CROWN AND BRIDGE ABUTMENTS.

By E. J. GREENFIELD, D.D.S., Wichita, Kans.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, Tuesday, January 28, 1913.)

IN this age of achievement and progress, when it is not at all uncommon for the miraculous to become the actual, when people no longer gasp at the definite accomplishment of ideas which at first glance or consideration are seemingly impossible, it is not at all surprising that prosthetic dentistry should keep pace with the notable achievements in other fields of science.

This great and vitally useful branch of our profession, which is concerned with the mechanical restoration of the organs of mastication, has been both the producing agent and the beneficiary of wonderful developments during the last few years. Consequently our study of the implantation of artificial roots should be considered of the utmost importance by all dentists who are anxious to keep abreast of the times, and should be of intense interest to all who wish to be in the van of progress—in short, to each and every man who desires to be a leader in his particular vocation in his community.

IMPERFECTIONS OF NATURAL TOOTH IMPLANTATION.

For several years the countless attempts to replace natural teeth after extraction have met with only a fair measure of success. Every practicing oral surgeon has probably implanted quite a number of natural teeth, and knows how unsatisfactory this operation is. He finds that five years is a long life for the majority of implanted natural teeth. It is a matter of rather general experience that the implanted natural root fails, viz, simply disappears, because nature absorbs it, just as she does the deciduous tooth.

Like all my brothers in the profession, I have continually been confronted with the very serious problem of just what to do for patients with one tooth missing, or with the posterior teeth all lost. And this problem has been of such intense interest and so vitally important that I have spent every spare moment during the past eight years trying to devise a means of making implantation a permanent operation. I believe my success in this work, the perfection of the process which I shall describe, and the instruments used in it, will be of the same interest to you as they have been to me.

SERIOUS SEARCH FOR A SUBSTITUTE.

Through much study and extensive experimenting, I was early convinced that, even with the most careful work, the implanted tooth could never meet the demands of the profession. Though searching constantly for a substitute, and though having at my beck and call all of the advantages, facilities, and equipment of modern dentistry, my actual discovery of artificial root implantation was somewhat due to chance. One night a few years ago I happened to be present at a very difficult operation. I watched the surgeon reduce a fracture in which he used a silver-wire suture; then and there came the problem-solving query—If a surgeon can use metals in bone, why cannot a dentist do the same?

THE MISSING LINK IN DENTISTRY.

Inspired by this thought, I set to work with increased energy, and it seems to me that the activity resulting from that chance observation of a surgical operation has produced a process which is perhaps as audacious and revolutionizing in prosthetic dentistry as were the discovery and use of wireless telegraphy, radium, and the X rays in their particular fields of science. For this discovery in actual concrete form is an artificial root that is permanent. I have tested and proved it repeatedly, with continued success, and have demonstrated before clinics in all parts of the country that artificial roots can be put into the human mouth to stay.

This new process of implantation is no less than the making of a few circular incisions in the jaw-bone of an edentulous mouth, inserting properly prepared artificial roots of iridio-platinum, and mounting on each a base or anchorage, to which can be attached a full set of permanent, natural-appearing teeth, capable of rendering as good and efficient service as those endowed by nature at her best.

NO SPLINTS NECESSARY.

Perhaps the greatest convenience to dentists in this new process is the fact that the splint is unnecessary. For filling the vacancy caused by the loss of a single tooth, what better method could be employed? No splint will be needed, and the adjacent teeth will not have to be mutilated in order to serve as anchorages or abutments; the artificial root eliminates all that. Besides, the mechanical phase of this wonderful process is so utterly simple that it will be readily understood, and proficiency in its use will be quickly acquired by all who desire to use it.

The permanence of the operation is its chief value. At a clinic in Wichita, Kans., Dr. F. O. Hetrick, now president of the National Dental Association, asked the question, "How long will this platinum root last?" And such was and is my confidence in the permanence of this process that I answered honestly, "I do not expect to live long enough to answer that question." And what is more, though the tooth in question was not a spectacular case in any way, it still does not show any signs of deterioration in its enduring qualities.

THE PROCESS AND THE INSTRUMENTS.

The artificial root used for this process is a hollow, latticed cylinder of

FIG. 1.

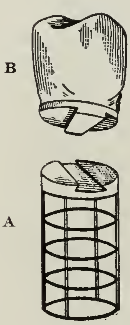

FIG. 2.

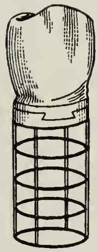

FIG. 3.

iridio-platinum, No. 24 gage, soldered with 24-karat gold. It is impervious to acids, and does not injure the tissue which grows about it. The disk-shaped cast base with groove or slot (Fig. 1, A), in which the crown attachment (Fig. 1, B) is inserted, is made of 22-karat gold, and is soldered to the metal frame of the root.

Special machinery is necessary for cutting and shaping these roots. Absolute accuracy is essential, for the artificial root must fit exactly the circular incision or socket made for it in the jaw-bone of the patient.

These roots are made in three different sizes or diameters, 3/16, 5/16, and 7/16 of an inch respectively, and are ½ inch in length. As a rule, the 7/16-inch size can be used for supporting a molar, while the two smaller sizes are employed for bicuspids and anterior teeth. The character of the ridge, however, in which the roots are to be implanted must serve as the ultimate guide in the selection of the proper size of the root to be used in the operation. In a small, narrow ridge the small root is used for a molar as well as a front tooth. The length of the root—½ inch—is ample for any case. Often it will be necessary to shorten the root a little by removing a layer of the crate-like root-frame.

Of course, thorough sterilization of these roots and of the instruments used always precedes the operation of implantation. When everything is ready and the patient has been put under an anesthetic—either general or local—the gum is cleansed with ether and then painted with tincture of iodin. Next the tubular knife (Fig. 3) is employed in the dental engine for removing the gum tissue.

The remainder of the operation is performed with a cylindrically shaped drill or trephine (Fig. 4), which is made in the same three widths as are the roots; likewise the selection of the drill for any particular operation is determined by the character of the ridge in which the trephinement is to be accomplished.

The trephine is first used with the center rod (Fig. 4, A) in place, for the sake of guiding the instrument in position as it starts the socket in the jaw. After the socket is started, the trephine is removed for a moment and the center rod is taken out. Then the excavation is continued to about ⅜ of an inch depth in the alveolar process or bony structure which supports the teeth. In the absence of alveolar process, a socket is trephined in the jawbone to a depth of ¼ inch plus whatever depth is necessary, if any, to permit the tooth-supporting base of the root to be evenly embedded in the gum tissue (Fig. 6).

Fig. 4.

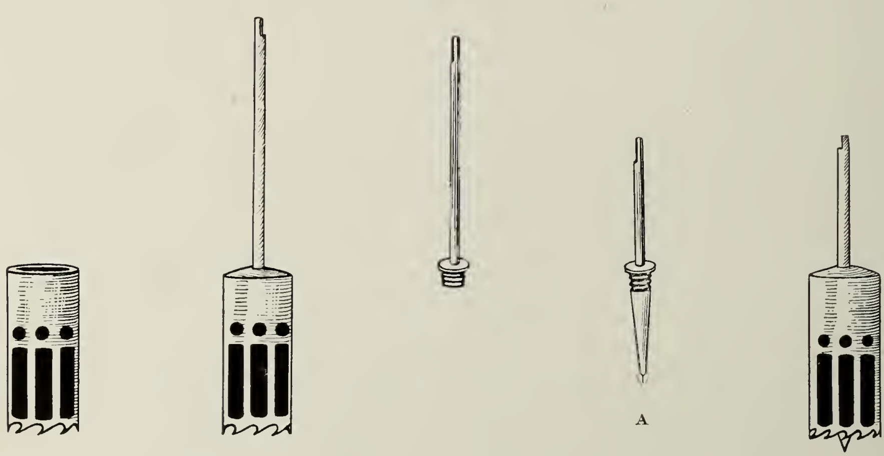

Fig. 5.

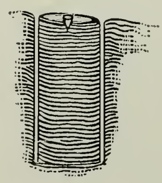

Fig. 6.

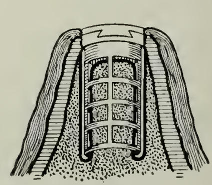


From the above, it will be observed that it is absolutely essential to excavate the root-socket (Fig. 5) to exactly the right depth. Conditions determining this depth may vary, but in any event the attachment for the crown of the root, when in position, must be on a level with the outer surface of the gum tissue (Fig. 6). It should be noted that a row of holes is punched through the cylindrical wall of the trephine around its center, to serve as a guide to the depth to be attained in trephining.

Thus far the operation should have consumed about five minutes' time. The circular socket in the jaw-bone (Fig. 5) is now finished, and the patient, if he has been subjected to general anesthesia, can be allowed to regain consciousness.

The root-socket should now be filled with bismuth paste, the formula for which is as follows: Bismuth subnitrate

FIG. 7.*

30.0, white wax 5.0, soft paraffin 5.0, vaselin 60.0 parts by weight; mix while boiling. Then the thoroughly sterilized artificial root is placed in position (Fig. 6), *i.e.* sunk down around the bony core or center of the root-socket.

When once in place, the artificial root should not be removed; but if for any reason there is absolute necessity for its removal, care should be taken not to rotate the root as it is taken out, for in doing so, the core of the socket might be fractured or pulled out entirely.

In the course of a week or ten days after operating, sensitiveness has largely abated, and in six weeks' time—rarely longer, the bony tissues of the jaw have united through the latticed root-structure, and a positive anchorage is provided for the attachment of the artificial denture.

FIG. 8.

FIG. 9.

HISTOLOGIC REASONS FOR SUCCESS OF OPERATION.

By means of the bony core which the trephine produces in making the incision or root-socket, the artificial root,

*[The radiographs here presented were not shown at the time of the reading of the paper.]

after being placed in position, will be held firmly until a sufficient deposit of bone cells has filled the spaces in the root-frame. Thus the artificial root becomes solidly embedded in the jaw.

This bony center of the root-socket is one of the chief factors in the success of this process of implantation. It assures the fit of the artificial root in the socket trephined for it, and an absolutely accurate and certain fit is decidedly essential to permanence and endurance.

Without this core or center, splints would be necessary, also there would be no possibility of operating on an edentulous jaw; but with it, there are practically no limits to the prosthetic appliances available. It is this feature of the process which makes it so inviting and interesting to all members of the profession, especially when the results accomplished are compared with the results of the implantation of natural teeth. The implanted natural tooth fails because of the rarefying inflammation which occurs at the seat of implantation.

The end results can readily be demonstrated by experimentation. It can, also, be proved that in the implanting of new bone in osseous tissue the grafts naturally die, and are gradually replaced by the formation of new bone. In the dead bone or grafts we find a more rapid dissolution, and the defect becomes filled with connective tissue, with latent osteosclerosis or condensation. By analogy, the same process must take place in the implantation of natural teeth.

To go into the minute embryological formation of cartilage and its replacement by bone is a matter too remote for this discussion. Suffice it to state that bone tissue is developed from the mesoblastic layer of the embryo, or the mesoderm, as is all connective tissue. But an understanding of the process of formation of new bone is a necessity in the implantation of artificial teeth, for it is with this knowledge alone that we are able to understand the process, and to gain a clear conception of what we are doing.

When an artificial root is implanted in either jaw, a cellulo-plastic exudation forms around and between the mesh-work of iridio-platinum wire, and is soon converted into granulation tissue, and inasmuch as the constituent cells are derived from bone, they early manifest a bone-forming or osteoblastic function. The periosteum becomes thickened and more vascular, and is slightly loosened for a short distance by an exudation of plasma, which is soon followed by a new deposit of spongy bone on the surface as the result of the irritation.

The granulation tissue from the periosteum unites with that from the bone, forming what might be called the provisional or ensheathing callus. The transformation of this callus into bone starts from the periosteum by the multiplication of the osteoblastic cells and their invasion of the granulation tissue or callus, the cells being derived from the osteogenetic layer of the periosteum.

It will thus be obvious that the continuity of the bone is restored long before the act of repair is completed, and that the end result depends on the ossification of the ensheathing callus. The time necessary for the removal of the clot and the formation of the granulation tissue is about a week or ten days, and new bone formation commences about the first week. By the fourth or sixth week, according to the size of the cavity, the degree of immobilization of the root, and the recuperating power of the individual, the union will be completed, and all tissues consolidated.

APPLICATION IN EDENTULOUS CASES.

In cases of entire loss of the teeth, incisions are made in each jaw at points so selected as to insure sufficient anchorage for the proposed restoration. I have made as many as eight incisions in either jaw for artificial abutments for bridge work.

The danger of these operations may be thought greater, possibly, than the benefits to be derived from them. But such is not the case if attention is given to the prevention of infection by keeping everything sanitary and sterile—a precaution every dental surgeon should exercise in performing any operation.

CONSTRUCTION OF A BRIDGE.

I have found that a great many dentists are confused as to the setting of a bridge on artificial roots. The impression often prevails that the bridge must be soldered to the caps and then made to slide into the grooves on the roots. This, of course, would be impossible.

One practical way of making a full bridge is as follows: First, a heavy platinum pin is soldered to the gold cap or crown-supporting base of the ordinary artificial root (Fig. 1, B); then the caps are placed in position on the roots. The pins are covered with tin foil so that the plaster will not pull too hard on the roots. Next an impression is taken, and the caps are removed and placed in the impression. Care should be taken to keep them in order. Then the model is poured, the bite taken, and the case mounted on an articulator.

Next, inlay wax is pressed over the post or pin. The tooth is placed in position and the wax is carved as it is to appear when finished in gold. This should be continued until all the teeth are in proper position; then the teeth are removed and the casting is made.

If parts are cast separately, it will be necessary to replace them in position, invest, and solder, care to be taken not to solder the caps to the bridge. Finally the caps should be replaced on the roots, and the bridge cemented in place.

A bridge made in this manner can be made removable by drilling a hole in the pins and castings, threading them, and placing screws in them to hold the bridge.

POSSIBLE LIMITATIONS ARE FEW.

The conditions limiting the success of this process of implantation are decidedly few in number, and inconsequential as to effect. The physical condition of the patient must, of course, be taken into consideration as in any other operation. If the patient's condition is anywhere near normal, little trouble should be encountered in implanting an artificial root.

The nature of the maxilla or the alveolar process in which the intended implantation is to be made also has somewhat to do with the success of the operation. The subsequent solidity of the implanted root depends largely on the amount of the area—the width and depth—of the ridge available for the operation.

This operation must not be placed in the same class as all other implantations, nor should it be anticipated that this process comes to the same end as do all other implantations. No fear is to be entertained that infection will occur. If a solid body is inserted in the maxilla there would be room for infection to set in around it, but in this operation a cage-like, hollow cylinder is inserted in a circular socket in the maxilla. This root is open all the way up, clear to the gum, and the circulation carries away any bacteria which might otherwise be destructive. This is one of the main features in the success of this process of artificial root implantation. If the root were a solid body or even simply perforated, it would be thrown off, as nature would not tolerate it, and there would be room for infection.

Another factor which limits the conditions of failure is the simplicity of the operation, which is neither difficult nor complicated, and can be performed in a few minutes.

Another advantage is the immovability of the root. When once implanted, this artificial root is solid and stationary, the bony core in the center of the socket assuring solidity.

I have implanted both natural teeth and these artificial ones, so I speak from experience when I say that the absorption which takes place after a few years and absolutely destroys implanted natural teeth is entirely avoided by this process, which provides for the anchoring in the jaw of good, solid, imperishable artificial roots.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE POST-OPERATIVE TREATMENT OF PYORRHEA.

By THOMAS B. HARTZELL, D.M.D., M.D., Minneapolis, Minn.;
PROFESSOR OF CLINICAL PATHOLOGY AND THERAPEUTICS AND OF ORAL SURGERY, COLLEGE OF DENTISTRY, UNIVERSITY OF MINNESOTA.

(Read before the National Dental Association, Section III, at its sixteenth annual meeting, Washington, D. C., September 11, 1912.)

IN this short paper the writer desires to discuss the most effective methods of treating our pyorrhea cases after surgical treatment has been successfully accomplished, and when the cure seems perfect.

PYORRHEA ALVEOLARIS CURABLE.

The surgical treatment of pyorrhea is now so firmly established that it is needless to discuss it in this connection, for it is proved by a multitude of case records that the destruction of the bony process commonly noted in pyorrhea can be absolutely stopped, and the gums be made to resume normal tint and normal resistance. Unfortunately for both patient and operator, many cases are allowed to pass from observation without further care or instruction to the patients, and in the course of a few months such cases show recurrence of inflammation. The patient is therefore discouraged, perhaps goes to some other dentist, who probably does not believe that pyorrhea can be cured, and who frankly informs the patient that the disease is incurable, and promptly advises the extraction of teeth which, under proper care and treatment, could be easily rendered serviceable to the patient for a long term of years.

EFFECTS OF SURGICAL TREATMENT, AND RECURRENCE OF GINGIVITIS.

It is illogical to suppose that teeth which have lost any part of the bony process which nature built around them are as good as teeth which have never lost this supporting process, because the result of such a loss is infection of the root-surface. This infection promptly induces a deeper cellulitis of the gum margins than obtained in the original gingivitis which initiated the inflammation; the clinical picture, therefore, shows the gums swollen and perhaps a trifle higher around the necks of the teeth than normal. The first effect of surgical treatment induces just the opposite condition, namely, the recession of swelling, and because the bony socket has been reduced in height, this recession of swelling of the gingiva lays bare the neck of the tooth below the enamel margins, exposing this surface to the fluids of the mouth and to the attack of caries; then, by reason of the loss of the interproximal bone, the interproximal gum sinks, and crevices are opened to the impaction of foodstuffs, which are very difficult for the patient to remove. The decomposition of such materials brings on caries, and possibly recurrent gingivitis.

THE PATIENT'S USE OF DISCLOSING SOLUTION IN HIS DENTAL TOILET.

In order to prevent this first step in a recurrent attack of pyorrhea, it is the duty of every conscientious operator thoroughly to explain to the patient the absolute necessity for extreme care in keeping the necks of the teeth free from all foreign matter, and to supply him with some method or means of knowing, beyond any shadow of doubt, whether or not his teeth are being kept clean. To this end the patient should be instructed in the use of a revealing stain, than which there is none better than a combination of zinc iodin 15 gr., potassium iodid 15 gr., iodin crystals 15 gr., with glycerin 4 dr., water 4 dr., carefully triturated together in such a manner as to lose absolutely none of the solid material in the mortar when decanting the same in the bottle. This disclosing solution sponged lightly upon the tooth surface by wrapping cotton on a toothpick or orange-wood stick instantly reveals to the eye fermentative materials which are otherwise transparent, and puts the patient at once upon his guard, so that he may remove these damaging substances.

PROPHYLACTIC OUTFIT FOR THE PATIENT.

The patient should be supplied also with the proper outfit for the removal of the irritating matter revealed by the stain. This outfit should consist of a properly shaped tooth-brush, flat silk, mouth-mirror, and wood-point carrier, together with suitable polishing materials, and the patient should be instructed in its use. There is a certain proportion of people who will gladly follow directions implicitly, and the time required to keep the teeth clean by this method is cheerfully spent by these individuals.

PROPHYLACTIC SILVER NITRATE TREATMENT.

For those who will not care for their own teeth, the monthly prophylaxis treatment by the dentist is the only remedy. In addition to the care of the teeth themselves, as outlined in the foregoing paragraphs, it is very wise and sometimes absolutely necessary to flush the necks of the teeth with a 10 per cent. solution of silver nitrate for the restraint of caries, or to rub a 40 per cent. solution of silver nitrate into the roots by means of a wood point held in a carrier, by first drying the necks of the teeth with cotton and hot air, then applying the strong solution of silver nitrate by vigorous rubbing, and drying it in with warm air. This treatment administered three or four times a year by the dentist himself is a vigorous prophylactic measure not only against caries but also against recurrent infection of the gum margins. The gums contiguous to the teeth themselves should be next to receive attention.

IMPORTANCE OF INTEGRITY OF GUMS.

It is the writer's belief that a hard, elastic, pink gum is, beyond any shadow of doubt, the best guarantee of freedom from infection, both local and constitutional. The inner, raw surface of the cuff or sleeve of the gum which surrounds the neck or root of a tooth whence the bony process has dissolved is a serious menace to the life and health of any individual—because it is easily possible that in an ordinary case of pyorrhea, involving perhaps the loss of an average depth of one-eighth of an inch of alveolar process, the equivalent of two square inches of ulcerating raw surface is open to infection. The bone itself, being exceedingly cancellous, renders the spread of infection in its substance from such an ulcerating surface extremely easy, and the penetration of micro-organisms into the cancellous structures of the body of the bone is made certain by the force of occlusion —amounting to thousands of tons of pressure in a year—and this force being applied to the tooth causes the latter to act much like the plunger of a powerful syringe, injecting bacteria and the fluids of decomposition directly into the cancellous substance of the bone and the bloodvessels and lymphatics of the surrounding tissues, thus producing deep inoculation by the bacteria that happen to be present in the pyorrhea pockets or apical abscess cavities.

MASSAGE TREATMENT FOR THE AVOIDANCE OF REINFECTION.

Among the bacteria with which the raw surfaces above described may become inoculated, and which are very commonly found in the mouth, are the pus-forming varieties, of which the streptococcus and staphylococcus are *always* present. The strepto-bacillus of arthritis deformans of Goadby, the pneumococcus of Fraenkel, and the tubercle bacillus and fusiform bacillus, accompanied by the spirillum of Vincent, are constantly found in these pockets, as well as many varieties of anaerobic bacteria of which the significance has not yet been determined. There is no doubt that "lumpy jaw," or *actinomycosis hominis,* is started by the same avenue. It is therefore obvious that in post-operative treatment we should look toward the closing of lesions constantly open to infection. To this end a method of treatment should be adopted which will speedily close these ulcerating lesions to further infection. This is best accomplished by rubbing the gums external to these surfaces as vigorously as possible with some medium which will not break the mucous membrane, at the same time applying as much force as possible to them. This massage promotes toughening of the mucous membrane and healing of the lesions beneath the membrane in the pockets.

The tooth-brush has been the chief implement in use for gum massage until recently, and, when kept clean, answers the purpose reasonably well; coarse linen finger-stalls have also been used with some success. More recently the heavy cotton roll, cut in short pieces three-quarters of an inch in length and held securely by hemostatic forceps or the Kurorus devised by Dr. Skinner, has come into use. These short, heavy cotton rolls held firmly and saturated with a vegetable astringent such as Azone—which is composed of alcohol, glycerin, and an astringent—serve this purpose best of all. The short cotton roll, after rubbing all the gum surfaces both inside and outside the arch vigorously for a few moments, is thrown away, and a new piece is taken for each treatment, thus avoiding the danger of reinfection with a dirty brush. The dense cotton roll, saturated with the alcoholic astringent and vigorously used on the gums as described, causes the gums speedily to harden and shrink, and the ulcerating surface is soon protected by the formation of a dense layer of elastic and fibrous connective tissue, thus closing the lesions to further infection, and affording a reasonable guarantee that reinfection will not occur.

SPLINTS AND REMOVABLE BRIDGE WORK FOR THE RETENTION OF TEETH AND ROOTS.

The next problem in post-operative treatment is that of retaining for useful service such teeth as have lost so much of their supporting bony structure that, even though infection has been stamped out, the teeth will be lost very soon, because there is not sufficient bone left to sustain them. In this type of cases it is necessary to supply some form of splint to compensate for the bone which has been lost. The cementing of fixed bridge work upon loose teeth is an impractical procedure, because it is impossible to keep them free from irritating matter, hence inflammation must recur. It therefore seems advisable that any form of bridge work or other prosthetic appliance be of such a nature that the patient can readily remove it, so that gum massage and thorough prophylactic work may easily be accomplished. After many years of observation the writer has reached the conclusion that removable bridges or other prosthetic appliances constitute without doubt the best practice in the after-treatment of pyorrhea. The fixed splint, such as advocated by Dr. Patterson of Kansas City, Dr. McDonagh of Toronto, and Dr. Logan of Chicago, answers admirably for small groups of teeth, as do the Case retaining appliances devised by Dr. Case for retaining teeth in proper alignment after regulation. When greater numbers of teeth have been loosened, the form of appliance which has given the author the greatest satisfaction is the combination removable splint bridge. In preparing loosened teeth for this type of retainer, it is necessary first to devitalize the teeth and cut them off at the gum margins. Then each tooth should be coped, and the cope must be made to fit the root-end so perfectly that it will not afford any irritation to the gum margin. The cope is made on practically the same lines as the cope for the Richmond crown. After all the copes are made and in position, they are removed in a plaster impression. The impression is then used to obtain a perfect model of the jaw and of the teeth upon which the copes properly belong. After this has been accomplished, the operator has the choice of two methods: (1) He may adjust on each cope a short metallic post slightly lingually to the center of the cope. All these posts are to be placed in perfect alignment, and each is fitted with a gold crown or a porcelain-faced crown, as the position of the tooth demands. After having been thus prepared, these crowns are united as in ordinary bridge work. The copes with their projecting short posts are cemented to the tooth root, and the bridge is placed upon the copes and pins in the lower arch without any retaining device whatever, the patient thus being able to lift the bridge off the root-ends at will, in order to cleanse the under surface of the bridge and to massage vigorously the gums about the root-ends. (2) If large groups of teeth are missing, it is advisable to insert a saddle in the bridge, allowing the saddle to rest firmly on the gum, thus aiding in the support of such roots as still remain in the arch. These saddles should not closely approximate the coped roots, in order to avoid irritation of the gum around the coped root. In the upper arch, or when it is necessary to obtain a greater degree of fixation than the aggregation of posts will afford, we can insert an occasional Roach attachment on the copes, hiding the spring within a molar or bicuspid dummy. When this is not advisable, we can cut a slot on the side of a post and fit a small slide in a dummy on either side of the mouth, placing it so that it will fit into the slot in the post. This slide or key, when in position, firmly locks the piece upon the root-ends. The patient, when desiring to remove such a piece, thrusts a small pin against the slide, driving it toward the lingual surface, thus releasing the bridge from the copes and pins, and thereby permitting the easy removal of the whole piece. In certain cases it is desirable to have the bridge work fastened to the teeth in such a manner that the patient cannot remove it himself, for occasionally we find individuals who dislike removable bridge work, though the great majority seem to prefer it, as it guarantees cleanliness and prevents recurrent inflammation.

SEMI-FIXED BRIDGE WORK.

In those individuals who dislike removable work, but in whose mouths it seems essential that the work allow of ready removal, the Corcoran attachment fitted to the copes can be used. With the Corcoran attachment the copes are made and fastened to the teeth. The piece is placed in position and retained by means of small, heavy screws, which the operator can readily remove, and upon the removal of which the whole bridge is lifted out of position, so that proper prophylactic measures can be instituted as often as the teeth and tissues demand. There is a vast advantage in having all appliances on pyorrheal teeth readily removable. Occasionally an infection may recur in a single tooth or a group of teeth. If we have fixed bridge work, the difficulty of overcoming such inflammation is very great. Removable bridge work may be taken off and any material which may have crept under the bridge removed, with the result that the inflammation rapidly recedes, and the bridge is easily put in place again. If a single root should abscess under a removable bridge, it is an easy matter to remove the bridge, extract the root, and, in the course of a few weeks, add a saddle resting on the gum in the space formerly occupied by the lost root.

COMBINATION BRIDGE AND PLATE WORK.

In cases in which only a small group of very loose teeth is left in the mouth, an artificial denture only hurries the loss of these teeth, because the plate will press upon and strip the gum tissue away from the roots. If, however, instead of fitting an artificial denture around such roots, we amputate the teeth at the gum margins, cope them, and unite them with a half-round bar, and, if desirable for purposes of retention, place one or two Roach attachments on the copes at either end of the group of teeth, we may build a removable denture to rest upon the root-ends with saddles resting upon the gums. The half-round wire which is used to connect these copes will permit the rise and fall of the saddles under the stress of mastication and at the same time enable the teeth to bear and share the work of the denture, without straining the teeth or the copes thereon in any way. Since the copes and the half-round wire have oval surfaces, the denture resting on them has free play, at the same time affording all the retention necessary to approximate natural teeth more nearly than is possible in any other way known to the writer, who in his practice has under observation a considerable number of the types of splints and dentures advocated in this paper.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE SPALTEHOLZ METHOD OF PREPARING TRANSPARENT ANIMAL BODIES.

By HERMANN PRINZ, A.M., M.D., D.D.S., St. Louis, Mo.

FROM THE RESEARCH LABORATORY OF WASHINGTON UNIVERSITY DENTAL SCHOOL.

IN the study of anatomy it has often been found a serious drawback that the internal structures of the various organs as a whole, or the relationship of the various organs to each other, can only be partially revealed by dissection, by the use of the Roentgen rays, or by making corrosions of existing cavities. In dissecting the cadaver with a scalpel, it is a common occurrence that some of the finer vessels are unintentionally cut, or that, under certain conditions, it is often impossible to isolate the minute structures. The X ray necessarily reveals only one phase of the object. The preparation of corrosions of cavities furnishes valuable aids for the study of the internal structure of the organs, but the preparation of a corrosion always means the more or less complete destruction of the original mold. In 1906, Prof. Werner Spalteholz of Leipzig, conceived the idea that it might be possible to make muscle tissue, skin with the underlying fascia, and even bone structure, transparent by subjecting the respective materials to a process which is analogous to the preparation of tissue for microscopical examination, *i.e.* to decalcify the bone, dehydrate the soft structure and clarify in oil of cloves, xylol, etc., and finally immerse it in Canada balsam for permanent preservation. After many laborious experiments, Spalteholz finally succeeded in devising an excellent method by which it is possible to produce perfectly transparent specimens of tissues. Not alone may thick sections of tissue be preserved permanently in this manner, but whole organs or even entire animals may be subjected to the process with equally good results.

THEORY OF PREPARING TRANSPARENT ANIMAL SPECIMENS.

The preparation of transparent animal specimens embodies a combination of specific chemical and physical processes. The chemical processes are of a preparatory nature; they are necessary to render the specimen receptive to the further physical procedures. The latter involve the application of an optical law to which the specimen and the medium with which it is surrounded has to conform. This optical law may be formulated as follows: An animal or vegetable object reflects the least light, and reaches the highest state of transparency, when it is saturated and surrounded by a medium which possesses an index of refraction which is equal to the medium index of refraction of the object under consideration. The light-rays, when striking an object, partially penetrate into its interior and partially are reflected at its surface. The proportion of reflected light reaches a minimum density and the light that penetrates into the interior a maximum density when the indices of refraction of the two substances—the object and the surrounding medium—are equal. The result of the equalization of the two indices of refraction corresponds to the maximum of transparency. A simple practical demonstration will materially assist in the ready comprehension of the above law. Glass, under ordinary conditions, is transparent; it allows the light-rays to pass into its interior. If this glass be ground it presents innumerable angles on its surface which reflect the majority of the light-rays, and, as a consequence, the glass becomes opaque. If we coat the ground surface of the glass with a medium which possesses an index of refraction equal to the glass, *i.e.* if we fill-in the innumerable angles, and thereby change the broken-up surface and the underlying solid surface into a homogeneous mass, the glass at once becomes transparent again. For example, we will take an electric-light globe with a partially ground surface. The light penetrates through the clear glass unhindered, while at its ground portion only a diffuse shadow of the light is visible. If we now coat the ground portion with artificial oil of wintergreen, for instance, that portion of the globe at once becomes transparent. This transparency is so perfect that at a distance of a few feet no line of demarcation between the ground and the clear portions of the globe can be observed. The removal of the oil will immediately restore the opaque surface. The same principle, in a modified degree, is involved in using an oil immersion in microscopic work.

In preparing histologic specimens it is common practice to "clear" the tissues after they have been dehydrated in graded alcohol. The fluids used for such purposes are the essential oils of cloves, bergamot, origanum, etc., or xylol, toluol, and similar substances with a comparatively high index of refraction. Thick sections of tissue or the whole organ may be subjected to this process with equal facility; in fact, there seems to be no limitation to the size of the object. However, for the permanent preservation of the specimen not all of the enumerated fluids are serviceable. Some are very inflammable, as xylol, benzol, and carbon disulfid, and others, especially the essential oils, become dark with age or when exposed to light. The latter fluids may ruin the specimens by discoloration or cause opaqueness. The primary important properties of any fluid used for the purpose of permanently preserving a specimen are to possess an index of refraction which must be equal or nearly so to that of the specimen, and it must not discolor the latter. Professor Spalteholz, in working with the above-enumerated substances and other compounds of a similar nature, reasoned that suitable fluids might possibly be found among the various synthetic compounds as used in perfumery, etc. By soliciting the aid of some prominent manufacturers of essential oils, he finally succeeded in obtaining a few synthetic compounds which apparently answered the demands made upon a fluid intended for the purpose in view. It was found that the methyl ester of salicylic acid, also known as methyl salicylate or artificial oil of wintergreen, has an index of refraction, 1.534–1.538; benzyl benzoate, which is the benzyl ester of benzoic acid, one of 1.568–1.570; and colorless iso-safrol, which represents the aromatic constituent of oil of sassafras, one of 1.577. By mixing these compounds in suitable proportions, a fluid may be obtained which closely corresponds to the index of refraction of the object under consideration. Later on, the benzyl benzoate was eliminated, as it was found that, in most instances, a mixture of five parts of methyl salicylate with three parts of iso-safrol was extremely serviceable as a "starter" in the preparation of the transparent specimens. Depending on the nature of the object, small quantities of either of the two compounds, usually of iso-safrol, have to be added until the greatest transparency of the specimen is obtained. No fixed formula which would answer all purposes equally well can be given for this mixture. The penetration of the specimen by the final preserving fluid requires considerable time—from two to ten weeks may be necessary. During this period, the jar should be kept loosely covered to allow the xylol or benzol to evaporate. Very small quantities of iso-safrol may now be added from time to time, if necessary, until complete transparency is obtained. Extreme care should be exercised in adding only very small quantities of the compound, as too much is very liable to materially affect the transparency of the specimen. The correct gaging of the respective quantities can only be acquired by experience; the beginner, especially, is apt to make mistakes.

To bring out the relationship of the blood and lymph vessels to the surrounding structure they may be injected with colored materials. It should be remembered that the materials used for such purposes must be insoluble in the fluids used in the preparation and final fixation of the specimen. Colored gelatin solutions answer this purpose well. In the preparation of bone specimens, the injection has to be made prior to the decalcification, and the gelatin injection has to be rendered insoluble by immersion in formaldehyd solution in the same manner as the gelatinous matrix of the bone itself is hardened. The gelatin mass is prepared as follows: A sufficient quantity of the best quality of French gelatin (silver label) is placed in distilled water for twelve hours or until thoroughly saturated. It is then pressed out by hand and melted in a porcelain dish on a water-bath. For coloring, carmin, cinnabar, Berlin blue, etc., may be employed as desired. The various details of preparing colored solutions for injection may be found in any good text-book on histologic technique. A gelatin-cinnabar mixture, which has been used by us with satisfactory results, is composed of gelatin solution 25 parts, cinnabar 5 parts. The freshly prepared mixture has to be injected while hot. A paraffin syringe with a hot-water jacket or an ordinary automobile grease-gun are best suited for this work. The successful injection of the specimen depends largely upon the alertness and dexterity of the operator.

EXPERIMENTAL WORK.

Our own experimental work has been solely confined to the preparation of transparent bone specimens, and primarily we have utilized the human jaw-bones for this purpose. While we have described the working method in detail under "the technique, etc.," a few additional items are here enumerated which may prove of some value, especially to the beginner. The thickness and the size of the bones have no bearing on the final results. We have successfully prepared various mandibles and a whole skull; dry or green bone may be used with equally satisfactory results. The bones must be thoroughly cleansed of adhering soft tissue and washed with soap, water, and brush before they are subjected to the treatment. In decalcifying a jaw with the teeth in position, the enamel of the teeth is naturally totally destroyed, while the organic matrix of the teeth and bone remain intact. If it is intended to preserve the enamel of the teeth, the crowns should be carefully coated with wax or paraffin before the preparation is subjected to the acid. The paraffin or wax will readily dissolve in the xylol or benzol which is used as a clearing fluid. Of course, it is understood that such remaining enamel cannot be made transparent. The pulps do not have to be removed from the teeth; they will be made perfectly transparent by the process. The injection of bones with colored materials usually offers difficulties to the beginner. The colored gelatin solution has to be made fresh for every case, and it has to be injected under pressure while hot. In the lower jaw the best place to insert the nozzle of the syringe is the mandibular foramen. The nozzle is wrapped with wet cotton to assist in making a watertight joint. As soon as the colored solution appears about the mental foramen, the opening is closed with the finger and the injection is continued. The alveoli from which the teeth have been removed are plugged with wet cotton, while those in which the teeth remain should not be touched. Superfluous material pressed out may be trimmed away, when set, with a sharp knife. If, for some reason, the injection is a failure, the gelatin solution may be immediately washed out with warm water. If the gelatin has set, its removal is accompanied by great difficulty. The injection of the various canals and the antra of the upper jaw may be readily accomplished by plugging with wet cotton all those cavities which are not intended to be filled. The starting-point of the injection is materially altered by the bone itself, *i.e.* it depends upon whether the maxilla is detached from the rest of the bones with which it normally articulates, or is a single detached bone. If the whole skull is prepared, the canals are best injected from the cranial cavity.

TECHNIQUE OF PREPARING THE SPECIMENS.

Fixing. The fixing of the object may be readily accomplished by using any of the well-known fixing fluids, such as alcohol, sublimate solution, formalin, etc. We have invariably employed a weak formaldehyd solution with good result. The official formaldehyd solution contains about 37 per cent. of the gas dissolved in water. A suitable solution is made by adding 10 parts of the formaldehyd solution to 90 parts of water. The object remains in the solution from two to five days, depending upon its size.

Decalcifying. As a decalcifying fluid, diluted hydrochloric acid is preferably employed. The process is started with a 2 per cent. solution and followed by a 1 per cent. solution until complete decalcification is accomplished. The acid should be used in quantities amounting to about forty to fifty times the volume of the object, and it must be changed daily. The official hydrochloric acid contains 31.9 per cent. by weight of absolute acid. A 2 per cent. solution is prepared by adding 20 parts of the pure acid to 219 parts of water. To test the progress of decalcification, a fine steel (sewing) needle is thrust into the bone at its thickest portion; if the needle readily passes through the bone, the process is completed. Too many punctures should be avoided.

Washing. After complete decalcification, the specimen is washed in running water for a few hours, and then remains immersed in water, with frequent changes, for two or three days, or until the water reacts neutral to blue litmus paper.

Bleaching. Occasionally it is advisable to bleach the specimen. The official hydrogen peroxid solution is satisfactorily employed for this purpose. It should be used undiluted, and the specimen completely immersed in it for one to two hours. After bleaching, the specimen is again washed in running water.

Dehydrating. The removal of water from the tissue cells is best accomplished by immersing the decalcified specimen successively in alcohol of various grades. The process is started by using a mixture of equal volumes of alcohol, 95 per cent., and distilled water. After twenty-four hours a mixture of two volumes of alcohol, 95 per cent., and one of water is used, which after twelve hours is replaced by pure alcohol. Finally the alcohol is changed to absolute alcohol and the specimen remains in it for twelve to twenty-four hours. A small quantity of dehydrated copper sulfate may be added to the absolute alcohol to take up traces of water. The alcohol incidentally hardens or "fixes" the soft gelatinous specimen.

Clearing. Of the various clearing fluids, benzol (benzene) or xylol (xylene) act equally well. Both are hydrocarbons, and are very inflammable; benzol is the cheaper of the two. The clearing fluid has to be changed twice; the specimen remains in the first bath for twenty-four hours, or until complete penetration is accomplished. The fluid is then removed and the specimen is immersed in the second bath, charged with fresh benzol or xylol for two or three days. The clearing fluid may be preserved for future use, but only for the first clearing; the second clearing always requires fresh benzol or xylol.

Permanent clearing and preserving fluid. The final solution in which the specimen is permanently preserved consists of a mixture of hydrocarbons whose index of refraction is equal, or nearly so, to that of the specimen. Methyl salicylate and colorless iso-safrol* are mixed in the proportion of 5 parts of the former to 3 parts of the latter. The specimen is transferred from the clearing fluid to this mixture as quickly as possible to prevent the air from entering into its cellular structure. If air-bubbles have formed in the specimen, they may be removed by carefully turning the specimen about in the final solution or by exhausting the air with a suction pump. The proportions of the two fluids have to be slightly modified for each individual specimen. A very small quantity of one or the other fluid, usually the iso-safrol, has to be added at times until the specimen shows the greatest transparency when viewed in direct light. It is a good plan to start with the original 5 : 3 mixture, and then add either of the fluids, according to need, instead of employing a modified mixture in the beginning.

After the specimen is placed in the final fluid the container is covered with a layer of cheesecloth to allow the benzol or xylol to evaporate and to keep out dust, etc. In from two to ten weeks, depending on the size of the specimen, complete penetration of the preservative solution has taken place.

Preserving jars. Specimen jars* must be made of perfectly clear glass, and have parallel sides. If possible, they should have polished fronts. Round jars will distort the light-rays and consequently disturb the image. The perfect sealing of the lid to the jar has offered many difficulties, as the ordinary sealing materials, which are more or less of a resinous character, will be dissolved by the preserving fluid. A concentrated solution of celluloid in acetone or in amyl acetate, in the proportion of 1 part of celluloid to 8 parts of the solvent, has given fair results. The edges of the glass must be scrupulously clean and dry before the sealing solution is applied; within a few hours it has sufficiently set to allow the jar to be handled.

To insure success, it is imperative that the various steps of the process be carefully followed in rotation, and we therefore recapitulate them briefly:

(1) Fixing of the dry or green specimen in a suitable solution.
(2) Decalcifying.
(3) Washing in running water.
(4) Bleaching.
(5) Second washing.
(6) Dehydrating in graded alcohol.
(7) Clearing in benzol or xylol.
(8) Permanent clearing in preserving fluid.
(9) Evaporating the benzol or xylol, and final sealing of the jar.

Professor Spalteholz has protected his invention for preparing transparent anatomical specimens by letters patent. He has very generously, however, allowed the unrestricted application of his invention for purely scientific purposes.

* Fritzsche Bros., of 82 Beekman st., New York, supply these various synthetic compounds.

* Suitable specimen jars may be obtained from Arthur H. Thomas Co., 1200 Walnut st., Philadelphia.

FINANCIALLY FIXED FOR LIFE.

By H. EVERTON HOSLEY, D.D.S., Springfield, Mass.

(Read at Worcester, Mass., December 16, 1912.)

I AM coming to you tonight on an errand of financial friendship and good fellowship; particularly, as one professional man to another.

So many good articles are being published on fees that it seems timely that we consider how to invest safely a part of our income, so as to eventually travel the road that leads to that haven of rest —"financially fixed for life."

I shall endeavor not to consider this subject in too much of an academic way, but to place it before you on a general practical basis, whereby you may gain knowledge for a distinct betterment of your financial condition.

LACK OF BUSINESS EXPERIENCE AMONG PROFESSIONAL MEN.

The apathy of the profession toward investments may be explained by a lack of financial investigation and education. It is your duty to have recourse to such knowledge as will make you do something worth while on this subject and justify the end in time, by being financially fixed for life.

Professional men of all kinds should be among the first to recognize the fact that, while they may be experts in their own work, yet, when it comes to transacting business of a different nature, they are not qualified to do so to the best advantage. They should not only be the first to admit this, but it is contended, furthermore, that there is no class of men who need to admit it more than professional men. They have specialized along certain lines, and have not had the time or the opportunity to acquire experience and training in other spheres of business activities. They unconsciously recognize this fact in matters of no vital importance, and involuntarily seek the services of others who are better qualified to perform the work in question; but with these small matters of business they stop, and in the important transactions, with so much more at stake, not only in money value but in other respects, they attempt transactions in which they have had no experience and for which, by reason of lack of training, they are not qualified. This is particularly true as regards finances. Few of us will admit that we are not perfectly qualified to manage and invest our money; and yet how few of us but can cite times in our lives, or in those of our friends, when losses in money matters would in all probability have been avoided had we recognized our inexperience in financial dealings and taken the advice of those who are specialists in that work, as we are in ours? We all feel that if we can make money, we can invest, care for, and keep it without the help and advice of others. This tendency is not assumed by all professional men, nor is it contended that it applies to that class alone, but it is true of many of us, and I believe it is more prevalent among professional than any other class. Specialization in one field seems to breed in us a conceit that gives assurance of capabilities in any line of work. Are we loath to admit, even to ourselves, that we cannot do anything equally as well as the work we are adepts in? But do not let professional egotism blind our common sense. We would not think much of the financial man who attempted his own dental work; why should we, then, attempt, unaided and unadvised, the handling and investing of money—work that others specialize in as we do in ours?

ADVANTAGE OF A FINANCIAL ADVISER.

In urging my *confrères* to seek outside help in such matters, it is unnecessary to tell them to get the best help, viz, that of men who have had the experience needed, which the ordinary professional man does not possess. They will not necessarily find such men among their friends, but will find them in the business world—men whose work consists in giving just what is wanted, trust companies which maintain special departments rendering service of this kind. Their very business existence and growth depend upon the value of the service they can give, and their acts, unlike those of many individuals, will be entirely disinterested. Their business consists in handling and investing the money and estates of those who are inexperienced in such matters, and for those who, though competent enough, do not have the time aside from their regular business to attend to financial matters with the greatest degree of advantage and safety, or for those who for a variety of reasons cannot or do not want to manage their own financial affairs. That they exist and thrive is evidence that many people feel unable for one reason or another to transact their financial affairs with the same degree of success and safety as others who make it their business. They recognize in themselves what I am urging my colleagues to see in themselves, namely, that there are those whose advice and services on financial affairs are available, with advantage and profit.

THE CARE OF AN ESTATE.

At this point, it will not be out of place to refer to a man's estate after his death. Assuming that one wishes to leave his affairs in the best possible shape and in the safest hands for the benefit and protection of his family, how is he going to do it? Many, probably, have never even given this a thought. If they have not, it is time they did. How many men know of friends or acquaintances who have died with their estates and family unprovided for, or of men whose estates have been eaten up with costly litigation, or embezzled by reason of having fallen into unreliable and irresponsible hands for management and settlement? How many know of inheritances squandered by heirs of improvident habits? There are ways of avoiding such results, if one will only take advantage of them. We professional men, more than ordinary individuals, should recognize the importance of availing ourselves of the opportunities offered nowadays for safeguarding our estates and families from financial losses. Every professional man should attend to this while he is alive, and not leave it to his family after his death. There are companies engaged in this work of caring for estates and trusts whose officers will gladly give any information wanted and needed, who will point out the ways of providing for and accomplishing the results wanted, and how to attain them in a legal way. No one should say that he has not enough of an estate to bother about, for it is all the more important that his family have that little undiminished by loss and expense.

It has been said that procrastination is the thief of time, but for the man who delays too long the making of proper provision for the protection of his estate and family often imposes expense, worry, and even downright hardship upon those he ought to protect and provide for in every possible way.

NECESSITY OF ADVICE IN REGARD TO INVESTMENTS.

I quote from a recent article bv Arthur B. Chapin, former banking commissioner of Massachusetts:

It has been estimated that over one hundred millions of dollars each year are taken from the public through these wild-cat schemes by those who dress up securities, so called, of mining, oil, rubber, land, and investment companies with attractive statements and the bait of large dividends or visions of wealth. Many of these schemes are frauds, and have no possibilities for the purchasers except loss of all that is invested.

An investigation of this subject in Massachusetts has been authorized by the legislature on my recommendation while bank commissioner. The report of the chief inspector of the Post-office department of the United States for the year ending June 30, 1911, says: "From the final reports submitted by inspectors, covering the arrests for the fiscal year, it has been ascertained that the promoters of these fraudulent schemes who have been put out of business completely during the past year have obtained approximately $77,000,000 from the public.

To the person who has no money to invest, the problem of selecting securities does not seem at all difficult, and the cutting of coupons from bonds appears as a kind of amusement, involving not the least particle of care or anxiety.

The investing of money, on the contrary, requires expert knowledge and sound judgment fully as much as does the accomplishment of any special work. If we wish to find out the law on any special subject, we go to someone who has carefully studied the subject, and is thus qualified to advise us correctly. If an illness overtakes us, we consult a doctor, who is an expert in medical matters. And so, if we have become possessed of some of that highly important article which is the medium of exchange, viz, money, and we desire to have it minister to our needs—bring us medical advice when we are sick, enable us to travel, or, most of all, bring us comforts when we are not able to work—then it is very necessary that we should not be induced to put our hard-earned savings into those securities which merely present a glistening surface for a short time, and then fail us when we need their help the most.

THREE FUNDAMENTAL REQUIREMENTS FOR A SAFE INVESTMENT.

Three fundamental requirements for the investment of money should be made, no matter whether one is able to obtain the benefit of expert advice or not. First, its safety; second, its availability, viz, its being placed so that it can be returned when desired; third, its earnings or interest.

Too many people reverse this order and look at the interest or dividend return, and neglect the principal. It is difficult to make a moderate investment today meet all these requirements and yield a satisfactory income, so the safest way is to diversify the investment of one's savings. Perhaps it would be well at first to eliminate certain classes from consideration for permanent investments.

SAVINGS-BANK DEPOSITS.

The income from the savings bank averages now very nearly four per cent., or forty dollars on each thousand, the limit of a deposit in Massachusetts being $1000. There are today nearly nine hundred millions of dollars in the Massachusetts savings banks alone, held in nearly two million accounts, which means in round numbers that two out of every three persons in Massachusetts have a savings-bank account. This shows how popular such a class of investments has become.

While a certain amount should be placed in a savings bank, provided there is proper state supervision, the amount that the law will allow must necessarily be rather limited, and the income less than that which can be realized on good bonds.

BONDS.

Bonds are the next in the list of investments. One not familiar with bonds should not invest in them without the advice of a reliable bond house, and great care should be taken in the selection of a house that has established a good reputation through its favorable dealings with its customers. The investor can secure from his banker the names and standing of those to whom it is safe to go for advice, or, if this be inconvenient, then a letter to the financial editor of one of the daily papers or one of the magazines may bring suggestions that will be of great assistance.

Even bonds should not be taken under consideration unless the management of the enterprise has demonstrated its ability to succeed, unless the enterprise itself has shown its value, or unless the future possibilities for success are determined.

All these and many other tests must be met before one should think of investing. Here is where the expert advice of a good bond house comes in, and their advice should be heeded. With their expert knowledge, they have, before purchasing, gone into the matter carefully to see that the bonds have merit and will be paid when due—for a reliable bond house cannot afford to sell bonds which are not first-class.

CORPORATION STOCKS.

Next in this class of investments are the stocks of standard corporations which have proved their value by going through a period of hard times, whose management is able, honest, and which are not subject to wide market fluctuations on account of legislation, the tariff, or the uncertainties arising from a conflict of labor and capital. Mining investments are always subject to great risks, and an investor dependent on the income from his investments should not allow himself to be tempted by glittering prospects to risk his principal. No woman should invest in mining securities, and only those who can afford to lose should take the risk.

It is usually true that when the interest or dividend return is very large, the risk is great also, so that the greater care should be exercised in investing in securities the income from which appears to be large. Occasionally, however, a bond house has an opportunity for a select high-yield investment which it can recommend highly.

The most conservative advisers are the safest to trust, and it is well to follow the suggestions of those whose experience has been such that their judgment is sound. The greatest care should be exercised in the making of investments, and the purchaser should be influenced chiefly by the character of the men who are managing a corporation, and the experience and honesty of those who are in charge of the house that is dealing in bonds. Then the lesson of conservatism is learned without bitter cost. Good judgment implies heeding the advice of a first-class investment house or of those who have had experience in making investments.

LIFE INSURANCE.

A dentist can make no better investment of a portion of his income than in life insurance. Like everybody else, the average dentist must use life insurance to protect his family; and, like many other men, there are plenty of dentists whose income is not large enough for investment and life insurance separately.

Endowment policies; advantages and disadvantages. That kind of life insurance which has most nearly the character of an investment, consists in the endowment policy. Under an endowment policy, the insurance is paid to the insured on a definite date, or to his beneficiary if he dies before that date. In a first-class company the amount paid to the insured under an endowment policy will equal the amount paid to the company in premiums, plus about 2 per cent. interest. This is not a high interest, of course, but the difference between that rate and the rate paid is the price the insured pays for life-insurance protection of his dependents during the time the policy was in force; had he died after having paid only one premium, the full amount of the policy would have been paid to his beneficiaries. The man who has an endowment policy will go out of his way to pay his premiums, the policy exercising a sort of gentle coercion upon him; he attends to its payments even though he lets almost every other obligation wait.

I have spoken about the endowment policy and its advantages. Let me now speak of two of its disadvantages. The first is that the premiums are larger than those of other forms of insurance, and consequently, if a man's chief aim is family protection, he should remember that a given amount of money will buy a smaller amount of such protection under this form than under other forms of policies. The other disadvantage is that the average endowment policy matures when a man has reached middle life; the policy is paid, and the insurance is ended. The chances are that he has a family and that they need insurance protection. There is, however, at that time of life, a grave liability that he cannot pass the medical examination that is a prerequisite to further insurance. Of course, he has his endowment money, but if he invests that and his investment turns out wrong, his family might be without provision in case of his death. For a young man who has not formed the saving habit, or for the man who has no dependents and is not likely to have any, the endowment policy is a splendid institution.

Life policies and their various forms. I will now speak of life insurance as an instrument of family protection and of support of a man's old age. It is not necesssary to call to mind that there is no similar economic institution. Nothing but life insurance will capitalize a man's mental worth or manual skill, and pay that capital to his wife or other dependent if he untimely dies. Life insurance does this, wholly or in part, according to the extent to which it is employed; or, to come closer to the average life, it may be said that no other human institution says to a man, "Pay us a stated small sum each year for a number of years or until you die, and we will pay your dependents a stated large sum, even though you die after having paid not more than one of these stated small payments." Life insurance cannot work financial miracles. It is a fixed science, based upon immutable laws of mathematics, and it therefore pays a man's dependents such a sum only as the money paid in by him entitles them to receive. But it does do that which the average man cannot. He cannot, by tomorrow or the next day or the day after, or in a month or in a year, lay aside enough money to protect his family from want or hardship should he die tomorrow or the next day or the day after, or in a month or in a year. Yet it is his aim and his duty to make as certain as possible his family's welfare after his death, if he can pay for a large enough policy.

The life policy is the most employed nowadays. It is payable at the death of the insured, whenever that may occur. It comes in three forms: Single premium policy, the ordinary life policy, and the limited payment life policy. Under the limited payment life form one may pay premiums for five years, or ten, or fifteen, or twenty, or some other period, at the end of which time the policy will be fully paid up. This does not, of course, mean that the policy then becomes payable; it simply means that the policy-holder has paid the insurance company all that it requires of him. The premium in this form of policy is somewhat larger than under the ordinary life form. The limited payment life plan has the advantage that the premium payments usually have all been made during the most productive period of a man's life, and they do not linger on to be a possible burden upon him in his declining years. Life-insurance policies have what is known as a cash surrender value, available at almost any time. Thus a man who is paying premiums is year by year building up a savings fund that can be used in his old age if the policy has not previously become a claim through his death. Life insurance, therefore, combines investment, protection, and savings.

The term plan of life insurance offers temporary protection only. Its premium is very small, and the policy expires at the end of a stated term. There is practically no cash surrender value, and consequently neither an investment nor a saving. If a man cannot pay for a life or an endowment policy, but must have family protection, the term plan can be used until he can afford something better. It is better than none, and only just better than none.

I have seen many dentists whose supreme need was a financial anchor to hold when all else failed, and have seen what life insurance has done for many of them, as an investment, as a medium of saving, and as a family protection.

CONCLUSION.

Professional men throughout the world should be brought together in closer relation with financial advisers, and in more sympathetic emulation to avoid error and arrive at ultimate truth. Method and precision are now coming to characterize our daily practice. Great has been our material, intellectual, and social progress, and now let us add to this progress financial stability.

It is pleasant to think of the growing numbers in our profession that are learning to make helpful deductions regarding their financial needs. A steady, guaranteed, if not a rising income has a strong influence on the happiness of mankind, with the increased power to lessen physical suffering.

I want to leave with my *confrères* this message of hope and encouragement. May it come true so that each will experience the happiness and contentment of living his declining years snugly housed and financially fixed for life!

THE SYSTEMIC RELATION OF SOME MOUTH INFECTIONS.

By FRANCIS ASHLEY FAUGHT, M.D., D.D.S., Philadelphia, Pa.

(Read before the West Philadelphia Odontographic Society, December 2, 1912.)

THE SPHYGMOMANOMETER IN DENTISTRY.

THE development of methods of refinement in the study of disease, particularly the employment of instruments of precision by both the medical and the dental practitioner, constitutes tangible evidence of the advances made in diagnosis during the past half-century.

It is praiseworthy that dentistry has been quick to take advantage of this progress by adapting to its use the clinical examination of the urine and the study of the composition of the blood.

ADVANTAGES OF THE STUDY OF ARTERIAL TENSION IN ORAL CONDITIONS.

It is my intention at this time to direct attention in a slightly different direction, and to show in a general way what practical information may be derived from a study of blood pressure or arterial tension in certain mouth conditions. At first mention it may not be entirely clear what bearing the state of the blood-vascular system has upon the daily practice of dentistry. This I will endeavor to explain.

Studies in pathology, particularly those of Talbot, have shed much light upon the underlying pathologic factors, especially the arterial changes active in the production of chronic inflammatory conditions in the mouth, particularly gingivitis and pyorrhea. It is now, I think, an accepted fact that in a great majority of cases we are dealing with a systemic, and not a local condition; one which demands for its arrest or cure measures directed chiefly toward systemic and constitutional disturbances, rather than to the manifestations in the mouth, which are in reality only local and purely secondary to organic disturbances in some distant organ or region. Talbot has referred to an obliterative endarteritis which occurs in different organs, particularly in the vessels of the alveolar process, and has actually produced this condition by artifically altering metabolism and by administering toxic agents to healthy dogs, in which he produced secondarily a true gingivitis and pyorrhea. In these experimental animals, the auto-intoxication caused arterial changes with accompanying increased blood pressure, thus proving experimentally what has long been suspected clinically, viz, the interrelation between arterial change, high blood pressure, and low-grade inflammation of the alveolus.

The same relation exists in other organs where a low-grade inflammation is set up by chronic changes in blood supply brought about by permanent elevation in blood pressure. The most significant point in this connection is that this permanent blood-pressure elevation precedes for a longer or shorter period the development of the diseases which it produces. It becomes, therefore, one of the earliest signs, often the first, of the condition, and being such, it may be used to great advantage in diagnosis.

Physicians are learning to appreciate this fact, viz, the blood-pressure elevation and its relation to chronic diseases of the heart, of the kidneys, and of the cerebral circulation, so that a systematic effort is now being made to prevent the development of its more serious consequences by regularly repeated physical examinations, directed principally toward the cardio-vascular and renal systems. By so doing, early departures from the normal are often detected at a time when the permanent injury is slight, and when measures directed toward their correction may be instituted with reasonable hope for success. The dental surgeon has an important part to play in this conservation of human life and efficiency. His frequently repeated examination of the mouth for detection of caries gives him almost an unlimited opportunity in this field. He sees a great number of individuals, apparently in good health, yet in whom there can often be found, when sought, evidences of organic change in the gingival margins and alveoli, which, if properly interpreted, will suggest the importance of special examinations, in an effort to detect the changes above referred to. Under such circumstances it is proper, often desirable, to recommend consultation with some medical man competent to carry out the several examinations necessary to establish the presence or absence of the condition suspected. Several joint studies of this character will often, after some practice, enable the dentist later to carry out these examinations for himself—which will redound much to his credit, and often greatly benefit the patient under consideration. This is particularly true of the blood-pressure test, which can be applied by anyone after a little practice, and which should, when properly used, yield brilliant results at his hands.

FAULTY METABOLISM AS REVEALED BY CHANGE IN BLOOD PRESSURE.

The general physical appearance of many patients is often a valuable clue, pointing toward the probable presence of some mouth inflammation or infection, as many patients presenting the early signs of gingival irritation and recession show signs of an unstable nervous mechanism, symptoms of irritability, introspection, lack of concentration, cold extremities, excitability, and attacks of drowsiness. Evidently these symptoms are dependent upon some general disturbance, the basis of which will be found in a faulty metabolism, auto-intoxications, a rheumatic or gouty diathesis—call it what you like.

Here examination into the state of the blood-vascular system and the urine may, in many of these cases, give evidence of definite kidney irritation and an increased arterial tonus, if not of actual permanent thickening, of the arterial walls.

To elaborate: In a fairly well developed case of hypertension, the urine will be found deficient in quantity, containing an excess of solids as shown by high specific gravity, a faint trace of albumin, and also—which is of particular importance—large amounts of indican and skatol, while the microscope will show oxalates and cylindroids. This is a picture of faulty metabolism and deficient nitrogen elimination, which explains the cause of the arterial change. Toxic materials, absorbed in the main from the intestinal canal, enter the circulation and are eliminated by the kidneys. During circulation they act as direct irritants to the vessel walls, causing them to contract and narrow their lumen, and while passing through the kidneys they cause a moderate degree of chronic irritation, resulting in the appearance of cylindroids and oxalates, and not infrequently of albumin in the urine. The effect of this general narrowing of the blood channels consists in a disturbance of the blood distribution throughout the body, which particularly affects certain organs, namely, the heart, the kidneys, the brain, and the alveoli, these several structures being all supplied by bloodvessels having no lateral anastomosis, *i.e.* they are end-arteries. It is thus seen that the vessels of the alveolar process are among the first to suffer from imperfect nutrition and reduced vital resistance, which permits of easy bacterial invasion, resulting in well-known pictures of gingivitis or pyorrhea. The earlier stages of vascular contraction or hypertonus may be manifested in the mouth as gradual recession or irregular attacks of gingivitis. This is where diagnosis is most valuable.

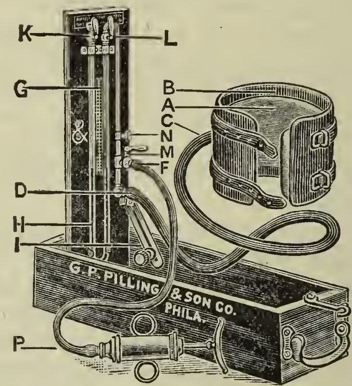
CLINICAL PICTURE OF ADVANCED STAGES OF ARTERIAL IRRITATON.

To follow the clinical picture to a more advanced stage, we may note the effect of this arterial irritation upon the contained blood and upon the vessel wall. As a primary effect of the toxic contraction of the whole arterial system, the outflow of blood from the great vessels is retarded to overcome this resistance; the heart must increase its force, and the inevitable result is increased general arterial blood pressure.

In the presence of general and continued high blood pressure, the vessels are called upon to withstand an increasing strain; consequently, besides augmenting their natural tone, they commence to hypertrophy and thicken, so that when this increased pressure exists for a long period, we have a definite and permanent thickening in the vessel wall. This is in many instances perfectly evident to the palpating finger either in the form of regular, smooth thickening, or as a beaded or nodular irregularity of the bloodvessel, and is known as arteriosclerosis.

We have now logically traced the pathologic sequence. Beginning with some disturbance of metabolism, there follow irritation of the vessel walls and contraction of the vessels. This calls upon the arteries for greater effort, and results in gradual permanent thickening. This primary and secondary alteration in the caliber of the vessels reduces the vital resistance, permits of retrograde tissue changes, and paves the way, among other things, for microbic infection and pyorrhea alveolaris.

Fig. 1.



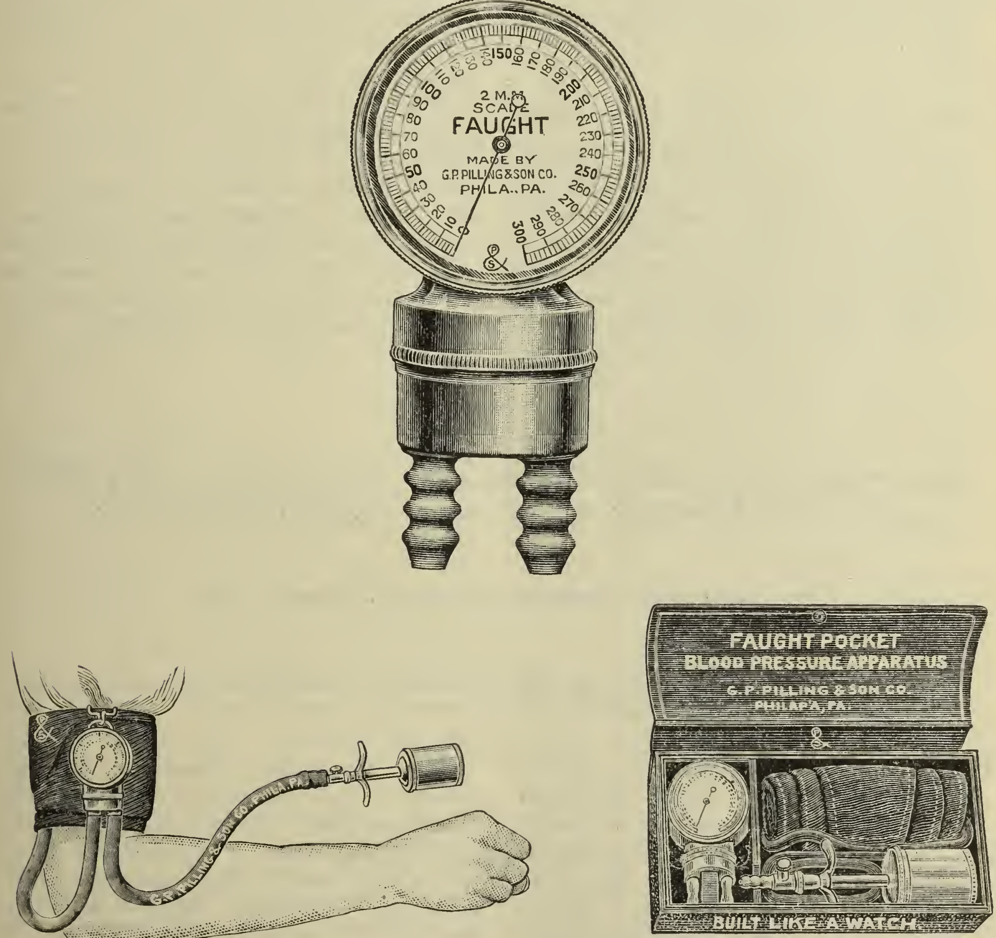
Author's standard sphygmomanometer or blood-pressure apparatus.

EFFECT OF BLOOD-PRESSURE TEST UPON METHOD OF TREATMENT.

If the practitioner takes pains to acquaint himself with the state of the urine and the state of the blood-vascular system in cases of the type above referred to, he will frequently come into possession of a triad of factors which are the key to the situation. These, in the order in which he usually finds them, are chronic alveolar inflammation, a pathologic urine and arterial hypertonus, or arteriosclerosis. Upon this triad a rational and usually successful superstructure of treatment may be erected.

The hygiene of the mouth is of course a preliminary necessity to all forms of treatment. This being accomplished, attention should be directed to the lifelong habits of the patient, in order to determine where the original fault occurred which has gradually resulted in the present abnormal pathologic state. The determination of this is usually not difficult, and when this has been once uncovered, rapid progress will follow the institution of appropriate treatment. Lest some become discouraged by the mention of special examinations, let me say that even if the primary cause is overlooked or cannot be found, very satisfactory results often follow the institution of treatment based upon a general knowledge of the usual causes.

Fig. 2.



Author's pocket sphygmomanometer or blood-pressure apparatus.

CONCLUSIONS.

To summarize:

(1) Alveolar inflammation is usually secondary to some general metabolic disturbance of long standing.

(2) Its true significance is usually appreciated only after careful general study of the patient. which includes—

(3) The past history and a general physical examination, urinalysis, and blood-pressure test.

(4) Early detection and general management play a very important part in effecting permanent arrest and cure.

(5) Local treatment should not be neglected.

DESCRIPTION OF SPHYGMOMANOMETER.

The instrument described in the foregoing article is one now generally employed by the medical profession for the determination of blood pressure, which study during the past ten years has become quite general, and is now employed in both medicine and surgery and in specialties. The instrument follows roughly two types, one on the mercury column (Fig. 1) which measures the pressure in mm.Hg, the other being a modified form of aneroid chambers, which is graduated to give readings in mm.Hg (Fig. 2). The larger of the two instruments shown in the accompanying illustrations is the more valuable when its use is confined to a stationary place, as in the consulting room or in hospital work, whereas the other instrument, which is contained in a case of pocket size, is very valuable on account of its portability. Space will not permit of a more detailed description of the method of application, which is but slightly more difficult than temperature reading or pulse examination, hence the instrument can easily be manipulated by anyone after simple instructions.

THE TREATMENT OF PYORRHEA BY BACTERIAL VACCINES, AND THE RESULTS OF ANIMAL EXPERIMENTATION.

By GEORGE B. HARRIS, Sc.M., D.D.S., Detroit, Mich.

(Read before the National Dental Association, Section I, at its sixteenth annual meeting, Washington, D. C., September 11, 1912.)

THE predisposing causes of pyorrhea have been laid to many conditions, the formation of calcarious deposits on the teeth being generally considered the chief of these. The fact that these calcium salts produce a local irritation, however, is no proof that their effects are local; nor is the fact that they are precipitated from the saliva any proof that they originated there. A superabundance of these salts in the saliva is the direct result of faulty metabolism, and is entirely preventable by the use of Epsom salts. If you doubt that, try it. The fact that pyorrhea entirely clears up after the teeth have been extracted is sometimes considered ample proof that it is purely local in all its phases. Certainly it clears up, but pyorrhea is not cured by removing the tissues involved. What is done is simply the bringing about of certain conditions which later would follow the ravages of pyorrhea. The underlying, predisposing causes still remain. Appendicitis can be cured by removing the appendix, but certainly the appendix is not cured by its removal. Neither does the removal of the appendix, followed by recovery from the attack of appendicitis, prove that the disorder was entirely local in effect, cause, and conditions. I am not attempting to belittle the local treatment for pyorrhea in any way, shape, or form. Local treatment is of vital importance in the treatment of this disease, but we have to get back of the effect of pyorrhea and attack it at its starting-point, if we hope to check and cure it in its later stages. The removal of calcarious deposits is of vital importance, and the gums must be kept from coming in contact with them at all times. Unless this is done, the gums cannot resume a healthy condition, and our best efforts in any other direction will be wasted. But while we are busily engaged in scaling the teeth and applying this or that mouth-wash, we must not lose sight of the fact that pyorrhea is an *infectious* disease, that the infection is generally located at a point which antiseptics cannot possibly reach, and that the entire removal of infectious material is impossible. Even if the removal of all infected tissue were practicable, pyorrhea would recur at once, if indeed it was ever cured. Time will not permit me to point out why this is so, but those interested may be referred to an article published in *Items of Interest*, entitled "Some Phases of Pyorrhea Alveolaris and Its Treatment by Bacterial Vaccines."* When tetanus follows an injury produced by a rusty nail, it might be considered to be of local origin. Tetanus cannot be cured, however, by treating the point of ingress of the tetanus bacillus. Just as tetanus is very plainly more than local in its effect, so pyorrhea certainly has a more far-reaching effect than a purely local one, regardless of the fact that we are a little slow to apprehend its true significance.

Can pyorrhea be cured by local treatment alone? I would answer that question by saying, That depends entirely on what one chooses to call pyorrhea. If a simple irritation surrounding the gums is to be considered as pyorrhea, or ulcers forming on the gums be pyorrhea, then I would say that those forms of the disease—if they are such—can be cured by local treatment. I do not choose to call these conditions pyorrhea, however.

By pyorrhea, I mean an infection of the alveolus producing pus; and these cases, I contend, cannot be cured by local treatment alone. To illustrate: Mr. C. was referred to me as suffering with pyorrhea. Upon examination I found that his gums were in a very bad condition, the upper one being simply one mass of ulcers. This case was cured by two applications of a 20 per cent. solution of silver nitrate—viz, cured by local treatment. That was not a case of pyorrhea, however, although it might have developed that disease later, or the patient may contract it at some later date; but he did not have it at that time. If his resistive powers should be raised, however, he would be in absolutely no danger of contracting it. The resistive powers to infection can be raised by vaccines, which prevent as well as overcome infection. Supposing an infection of the gums has been overcome by local treatment; what has been done to prevent another infection? By what means have the predisposing causes been altered in any way, so that reinfection will not bring about the same condition?

NEGLIGIBLE VALUE OF ANTISEPTICS.

Local treatment is important, but local treatment alone cannot remove infection or prevent it. Oral prophylaxis will do a great deal, and antiseptics may help a little, but if one pins his faith to antiseptics, he will be disappointed, because no antiseptic can be used strong enough or long enough to have any effect on the bacteria. The antiseptics generally used, if the truth be known, when they are diluted—as they have to be before they can be used in the oral cavity—hardly have an inhibitory action, let alone any antiseptic powers. The term antiseptic is the most abused term in all dental nomenclature. When it is applied to a mouth-wash, the idea is conveyed of a little boric or other acid, dissolved in water and alcohol, nicely colored and flavored, such a mouth-wash being supposed to give an alkaline reaction, though it seldom does. To this exceedingly useless concoction is added an astringent to make the mouth feel nice and cool—for a few minutes. Such substances as these are heralded

---

* See *Items of Interest* for February 1912, vol. xxxiv, p. 122.

by the manufacturers as preventives, cures, valuable adjuncts, etc., in pyorrhea. The manufacturers depend upon the color, taste, and the ignorance of the dentists for their sale. I do not say that all of these preparations are useless. I will say, however, that some are harmful, as every practitioner may test for himself.

PROBLEMATIC VALUE OF ORAL PROPHYLAXIS.

Oral prophylaxis will do a great deal of good if properly carried on by the patient. We are lucky, however, if we can get the patient to brush his teeth twice daily, in any old way. If he did practice oral prophylaxis as it should be done, reinfection would not be made anything like an impossibility. Indeed, the improper use of the tooth-brush plays an important part in the initial infection, as well as in its recurrence. Oral prophylaxis, then, lessens the danger of reinfection, but does not remove it. A high index toward the organisms with which the tissues are sure to come in contact is the only safe way to prevent a reinfection. Vaccines will do this.

EXPERIMENTAL PYORRHEA IN GUINEA-PIGS.

When the staphylococcus is introduced directly into the gums of a guinea-pig, one of two things will happen. Either the infection, instead of remaining local, will rapidly become general, resulting in the death of the pig, or else the infection is promptly checked and overcome by the leucocytes in the blood. Which of these two processes will happen depends upon the number of bacteria injected and upon the resistive powers of the pig, and this depends directly upon the power of the leucocytes to ingest the bacteria. The same process takes place in the oral cavity; either the resistive force is high enough to ward off the attack, or else an infection follows. The resistive powers in man, however, seldom reach an ebb so low that the staphylococcus is able to produce a general infection, as it often does in guinea-pigs. The best method of producing pyorrhea in a guinea-pig is an indirect one, preferably by means of a putrescent canal. Having produced a putrescent canal with staphylococcus infection, an irritation is produced by means of cement under the gums, preferably in the region of the infected canal, and pyorrhea will develop. It will develop far more rapidly, however, if the pig is constipated, and more quickly in old pigs than in younger ones, although it is possible to cultivate pronounced cases at any age. It is very difficult to produce pyorrhea in the guinea-pig by introducing the bacteria directly into the gums. I would not say that it is impossible to do so, but I have not succeeded in producing the disease in that way. The susceptibility of guinea-pigs to bacteria is the reason why this becomes so difficult, and experiments usually result in a general infection and the death of the pig.

EXPERIMENTS WITH VIRULENT AND ATTENUATED FORMS OF STAPHYLOCOCCUS ALBUS AND AUREUS.

At the meeting of the Northern Ohio Dental Association I made the statement that I did not believe pyorrhea to be caused by true albus or aureus, but rather by an attenuated form of these, and possibly other organisms. My belief is stronger today than it was then. Cultures obtained from acute abscesses and cases of true pyorrhea were incubated at the same time; clusters of each were then put in separate test tubes containing sterile water. They were then counted and diluted until each contained one million bacteria to the cubic centimeter. One-half of 1 cc. from one tube was then injected into a guinea-pig, and the same amount from the other tube into another pig of the same weight. The pig that received the injection from the tube containing the bacteria obtained from the abscess died twenty-four hours before the other. Repeated experiments gave the same result; the virulence of the one was found to be nearly one-third greater than that of the other. There is also a difference in the growth of the two strains: (1) The one is more rapid in growth, (2) it resists various antiseptic agents longer, and (3) cultures obtained from true cases of pyorrhea are much more difficult to separate from the agar, and it is more difficult to break up the clusters in the centrifugal machine.

COMPARATIVE RESULTS OF STOCK AND AUTOGENOUS VACCINES, AND LOCAL TREATMENT EMPLOYED IN EXPERIMENTAL ANIMALS.

Various means were employed in treating the guinea-pigs suffering from pyorrhea, which was produced in them in the manner described above. Stock vaccines were employed in some cases, while autogenous vaccines were used in others; in still others local treatment only was tried. Where local treatment was used, improvement seemed to take place slowly, but as soon as the treatment was discontinued, the condition became worse than it was before, leaving a larger area of involved tissue, which became reinfected at once. The extraction of the root only prevented the area from becoming infected so quickly. Although every effort was made to remove all infection, I do not believe this was accomplished, nor do I believe that it is possible to do so. The amount of pus produced soon became much greater than it had been formerly. When stock vaccines were used in conjunction with local treatment, the results varied. If a pure strain had been used in producing pyorrhea, a stock vaccine for that strain would break up the infection at once. If the infection was a mixed one, the result depended upon the luck I had in guessing the strains and the proportion of each.

TRANSMITTED INFECTION AND IMMUNITY BY VACCINES IN EXPERIMENTAL ANIMALS.

Four other guinea-pigs were infected, two with pure strains of albus, and two with pure aureus cultures. One infected with each organism was isolated; the other two were allowed to be together. Three weeks later an examination was made which showed that the two that were isolated were still infected with the same pure cultures, while the other two each showed mixed infection of the two, the original infection predominating in each case. Pigs not infected were then put with each of these. In every case they slowly became infected from their fellows. Still others, previously injected with vaccine, were put with the infected guinea-pigs, with the result that they showed immunity. In those cases where autogenous vaccines were employed, uniformly good results followed.

ADVANTAGES OF AUTOGENOUS VACCINES.

One strain may be the real cause of pyorrhea, and yet a pure strain vaccine will not produce the results expected. This is best explained by Dr. Schafer of California. He believes all acute and most chronic infections to be mixed infections. "While one species may predominate," he says, "the pathological process produced by it is intensified by other organisms, and while their numbers are either so comparatively small or their pathogenic rôle is insignificant in themselves, yet when brought in contact with other organisms whose pathogenic powers are much greater, they must be reckoned with in any successful scheme of therapeutics." In using the autogenous vaccines all the organisms playing this minor rôle which Dr. Schafer speaks of are made to play their corresponding part in producing beneficial results, which are obtainable in no other way.

CONCLUSION.

In conclusion, as a result of these and other experiments, I would say that—

(1) Pyorrhea is not a purely local condition, although it may be caused by local means.

(2) There are many predisposing causes, as

(*a*) Malnutrition producing constipation and faulty metabolism; (*b*) poor circulation of the alveolar tissue due to astringent mouth-washes and nervous disorders. These conditions cause malnutrition of the alveolar tissue, lowering greatly the force of resistance to invading bacteria.

(3) Pyorrhea may be caused by purely local conditions, as

(*a*) Putrescent canals, (*b*) alveolar abscesses, or (*c*) poorly fitting crowns. Any local condition producing an irritation of the alveolar tissue may so weaken the resistive force that infection becomes possible.

(4) Pyorrhea produces constitutional disorders that are far-reaching in effect, and may be the indirect cause of death.

(5) Pyorrhea is contagious.

(6) The resistive power of the leucocytes to invading bacteria is the main determining factor.

(7) Pyorrheal infection becomes impossible when the force of resistance to the involved bacteria is raised to a high point.

PREDENTAL EDUCATION.

By JOSEPH L. APPLETON, Jr., B.S., Philadelphia, Pa.,
JUNIOR STUDENT, DENTAL DEP'T, UNIV. PA.

THE problems of education are today receiving intense attention. A little less than two hundred years ago, Rousseau introduced the idea of utility into education. A trifle over one hundred years ago, Lamarck attempted to show that the organic world was determined by use and disuse. Malthus in pointing out the struggle for existence in human society implicitly emphasized the value of nurturing those characteristics, endowments, and resources which are of use to man. Darwin, impressed with the struggle for existence, demonstrated that the organic world was not "determined" in the Lamarckian sense, but was selected on the sole principle of utmost utility. Herbert Spencer applied natural selection to human society and institutions; and the part his work on "Education" played in gaining for the sciences their present supremacy was enormous. The refrain of that work was utility.

Now that the prophylactic idea has arisen, the finest future rôle of the branches of medicine will be to aid the human organism in adapting itself to the complex conditions of modern civilization. Hence the medical man will be an even more valuable member of society than at present, and his education must demand the most critical and sincere consideration.

ORGANIZATION IN EDUCATION.

Organization and systemization are absolutely necessary to the highest perfection of any subject. Recognition of this truth is here acknowledged in order that what follows may not be misunderstood. As in everything else, however, so in organization the pendulum may swing too far. The organization which was necessary for the establishment of something desirable, frequently becomes, later, when all else is ready for the next step, a hindrance.

Education in this country has been crystallized into the following divisions: The kindergarten, the primary and grammar schools, the secondary school, the college, and the professional or postgraduate school. The termination of any of these divisions is marked by a certificate, diploma, or degree.

DENTAL EDUCATIONAL SYSTEM AS ADVOCATED BY THE AUTHOR.

Until a few years ago the several educational institutions and the laity held these symbols above what they symbolized. The requirement by medical schools of two years of college training in certain definite studies has done much to restore the public mind to sanity in these particulars. The work done, and not the degree, is valued. This salutary change of attitude will facilitate the dental education system here to be advocated. This system will demand—(1) the total disregard of diplomas, etc., *in se,* and (2) the pursuit of certain subjects recommended solely by their value in dentistry.

The present intensity of competition and the urgent necessity of bringing forth men who can efficiently deal with contemporary problems and conditions demand a revision of the currently accepted ideas on professional education. In no field is this need more imperative than in dentistry.

The whole trend of the world-spirit is to show the necessity of asking, of any system or course of education, this question: Was utility the primary criterion in determining what subjects should be taken, and the relative attention given to each?

EFFICIENCY AND ECONOMY IN TIME AND ENERGY THE CHIEF CONSIDERATIONS IN PREPARATORY DENTAL EDUCATION.

There are two considerations, and only two, which are worthy to be mentioned in the preparation of a dental course. The first is of the greater importance —Efficiency; the second, included in a sense in the first, Economy of time and effort. To understand more clearly the relation these two touchstones bear to our subject let us recall their connotations. Efficiency and economy are but two aspects of utility. Efficiency is the power to do the most fitting, useful thing most expeditiously. And economy is included in the word "expeditiously."

The laity, the several dental faculties, and, above all, the general practitioners themselves, are realizing that logically dentistry is a specialty of the general art of healing, and must consequently, in the future, be considered as such. Efficiency demands for the dentist either a preliminary medical course, or a course in certain of the principles of medicine. A medical course occupies four years, and as a preliminary to medicine the better schools are demanding from two to the full four years of an academic course, consisting mainly of the basic sciences.

COMPARISON OF VARIOUS CURRICULA OF DENTAL EDUCATION.

The accompanying table, in the first eight columns (I–VI), gives the possible and more direct procedures, with the respective number of years required, under the present divisions of education, for the production of the most efficient dentist. The medical schools of Harvard, Michigan, Northwestern, Pennsylvania, and Columbia have been considered; and the dental schools connected with the first four institutions named. This selection was made solely because these schools have attracted wider national and international recognition than any others.

To describe the *status quo* of dental education most favorably, let us assume that the child enters school at the age of six, and each year accomplishes what he is supposed to accomplish, and loses no time through accident or carelessness. In column I of the table the dentist is graduated at the age of twenty-one. The consideration of economy of time and effort is surely fulfilled, but in efficiency the graduate is decidedly below what it is desired that the standard of dentistry should be.

In the second column (II*a*) the age of graduation is twenty-four; in the fourth column (III) it is twenty-five. The best that can be claimed for either of these courses is that the student's mind ought to be enabled to grasp more easily and understandingly the principles of dentistry. The keynote of modern ethics is social service. Perfecting of the individual is a beautiful and worthy ideal; but the individual must be sacrificed if the pursuit of perfection would sacrifice or compromise society's welfare.

Educational Years—Primary School to Professional Degree.

Course.	I	IIa	IIb	III	IVa	IVb	V	VI	VII	VIII
Schools:										
Primary and grammar school	8	8	8	8	8	8	8	8	8	8
Secondary school . .	4	4	4	4	4	4	4	4	4	4
College	. . .	3	. . .	4	2	No deg. 2	3	4	2	2
Medical school . . .	. . .	. .	4	. . .	4	4	4	4	2	[2] 4
Dental school	3	3	2	3	2	2	2	2	3	[2]
Total years spent at school	15	18	18	19	20	20	21	22	19	18
Graduation age (with 6 as age of entrance) . .	21	24	24	25	26	26	27	28	25	24
Degrees	D.D.S.	A.B. D.D.S. *	M.D. D.D.S.	A.B. or B.S. or Ph.B. D.D.S.	B.S. M.D. D.D.S. †	M.D. D.D.S.	A.B. M.D. D.D.S. ‡	A.B. or [—] M.D. D.D.S. §	D.D.S.	D.D.S.

* Offered at Michigan.
† At Michigan.
‡ At Michigan.
§ At Harvard, Johns Hopkins, etc.

In the all-important question of efficiency, the main desideratum, viz, an acquaintance with the general principles of medical science, is lacking in both. In economy of time the second column is preferable. There is but little choice between these two, but II*a* approaches a trifle nearer our goal. Neither, however, is what the future demands of dentistry.

In the third column (II*b*) we have a decided advance beyond any of the previous courses. We cannot complain that this course occupies too much time. It gives a general medical foundation for the superstructure of dentistry; but the premedical education does not, in this case, supply those general sciences which are essential to a thorough understanding and best application of medical practice.

In the fifth and sixth columns (IV*a* and *b*) we are reaching the age limit imposed by economy of time. The dental education is well prefaced. We have the training in general medicine and that has been preceded by two years which have been occupied with a serious and intensive study of the fundamental sciences. These two columns represent the best and most desirable curriculum possible under recognized existing educational systems for the preparation of the dental practitioner. If one were to make a choice between them, preference might be given to IV*a*, but solely on account of the slight and meaningless prestige which might arise from the bachelor's degree.

The arrangements represented in the seventh and eighth columns (V and VI) fulfil the demand for highest efficiency, but must be excluded from consideration if we consciencously consult the demand of economy of time and effort. The efficiency of the graduate as a dentist would be just as high after following courses IV*a* or *b*. In the one or two additional years added in V or VI to the academic course, whatever might be studied in the sciences or the arts would be superfluous to the grasping of the essential, fundamental principles on which medicine and dentistry rest.

In the above, all the possible combinations of the now existing educational systems—with deference to the popular prejudice for "regularity"—have been considered from the standpoint of efficiency and economy in time and energy. All have proved more or less unsatisfactory in one or the other particular, or in both. It is not useless to point out a fault, even if no improved substitute can be offered. In this case, however, a constructive arrangement may be advanced which would atone for the iconoclasm. These suggestions will be radical, but they will stand the acid-test of the questions of efficiency and economy. No other criteria will the eternal verities admit in judging what may be most desirable in a plan of dental education.

ADAPTATION TO ENVIRONMENT AS GOVERNING THE MOST EFFICIENT AND ECONOMIC CURRICULUM.

No one appreciates more fully than the writer that teaching of the descent theory that demands of every individual an adaptation to its environment, to the conditions of the world about it—whether these conditions be physical forces or the institutions of society. But in organic nature there exists an analogy to the physical law that to every action there is an equal and opposite reaction. There are two factors in this consideration. As the environment acts on the organism, so the organism reacts on its environment, and *vice versa*. The sole limiting feature is that the environment acts on material already existent, viz, the flora and fauna of any given geographical region at any given geological era; that the organism acts on material already existent, viz, the climatic, meteorological, and other components of the environment.

One example from geological history will illustrate this. In carboniferous times the percentage of carbon dioxid free in the atmosphere permitted and encouraged the growth of a luxuriant, magnificent flora. The very growth of this flora reacted on the environment (among other ways) in diminishing enormously the carbon dioxid percentage in the atmosphere. This diminution first permitted the appearance of the higher forms of vegetable and animal life, the descendants of which populate the earth today.

Man in his coal consumption is liberating this carbon dioxid, which within the present scientific era has appreciably increased in amount. This increase in atmospheric carbon dioxid will have its reaction on man in forcing him to adapt himself to it or perish. Thus the chain of action and reaction goes on forever. This interaction, we must notice, is always and only between material already at hand. Parallelisms with the laws of the indestructibility of matter and the conservation of energy point to the rational procedure which may hope for success in correcting what seems to us wrong—viz, to make use of and to modify the materials we have at hand. This is also the teaching of economy.

If we wish to train a dentist, those subjects (and those alone) must be chosen from those already offered in our schools and colleges which best accord with the demands of efficiency and economy.

THE WRITER'S PROPOSED COMPROMISE CURRICULUM.

With these facts in mind, let us follow our Emile from the time he trudges off to school—smudgy face, sticky hands, and school-bag—till he ascends the commencement platform, clean-cut, in cap and gown and hood, the idol of fluttering hearts. For our Emile we will take just an ordinary, average lad, who accomplishes his work in an ordinary, average fashion.

Primary and grammar schools. He avoids the kindergarten as he would soap-and-water—though he is right in the one and wrong in the other. He enters the primary school at the age of four. This is decidedly unusual, and will meet with objection; but conversations with mothers, supplemented by personal observation, are convincing that the child at four is just as fit, physically and mentally, to learn the elements of reading, writing, spelling, and arithmetic, as at any subsequent age. He pursues in an even, uneventful course the program usually followed in our public primary and grammar schools. He carefully avoids the fads of carpentry, plumbing, and bent iron-work at this period. If, during the latter years of the grammar school, an introduction to one or the other of the modern languages be made, so much the better. At the age of twelve he is graduated—young, care-free, and happy.

High school. The high-school terms are occupied with mathematics through trigonometry; American and general world history; American and English literature; if possible a course of general literature based on Moulton's "World Literature;" Latin for four years. The pupil begins or continues at least two modern languages, preferably German and French. These are so taught that, on graduation, he has a working knowledge of them, so that he may at first hand acquaint himself with the progress of his profession abroad. Manual training is intelligently and persistently applied, not to produce a carpenter, but a high degree of digital dexterity. All sciences should be assiduously avoided in his secondary school course. Science as taught in the secondary school leaves no impress either of detail or principle on the pupil's mind; and being a waste of time is positively harmful. This state has arisen possibly from the methods employed, but primarily because the pupil's mind is not yet fitted to grasp the scientific idea. Ontogeny recapitulates phylogeny; the high-school boy reflects the spirit and attitude of the man of the middle ages. And that period was not the heyday of the sciences. During this school period the studies of general cultural value should receive their greatest attention.

At sixteen the pupil is graduated. He is eager and ready for the unknown; his mind and temperament are plastic. From now on we must be especially careful to emphasize those mental habits which will be essential to the successful prosecution of dentistry.

Hitherto there has been little or no change from the customary educational procedure. Hereafter comes the new.

College. He enters a college—a college wide-awake and scholarly, where the sciences are taught in the spirit of pure science. Here he elects as a special student, with no regard for a diploma or "certificate of proficiency." His curriculum will be as follows:

FIRST YEAR. *First semester*—General physics, general chemistry, general biology, college algebra. *Second semester*—General physics, general chemistry, biology (anatomy of the cat), analytical geometry.

SECOND YEAR. *First semester*—Organic chemistry, qualitative analysis, comparative anatomy of vertebrates, calculus. *Second semester*—Organic chemistry, quantitative analysis, general physiology, calculus.

The general chemistry is taught in the spirit of Alexander Smith's book, emphasizing the philosophy of chemistry. The biology will include a statement of the theories of descent, of heredity; the general principles of embryology and the recognition of the elementary tissues. The anatomy of the cat serves as an introduction to mammalian anatomy. The vertebrate anatomy will afford much illumination when later he takes up the study of embryology in the medical school. Loeb's "Dynamics of Living Matter" is the basis of the course of general physiology. Whatever time this schedule leaves unemployed might be spent on detailed and advanced work in one of the subjects enumerated, or possibly better in studies of a general cultural nature. At the end of these two years and at the age of sixteen the pupil leaves the college.

Medical school. The following fall he

enters a medical school of the first rank: here again as a special student. He follows the courses enumerated below:

Anatomy (including osteology, histology, and embryology)—the regular medical course, with especial attention to the anatomy of the head and neck.

Physiology (including physiologic chemistry with laboratory work), urinary and salivary analysis.

Pathology—gross and histological—general and special.

Bacteriology—regular medical course, and in addition special attention to the oral flora; technique of blood count, opsonic index, and the preparation of autogenous vaccines.

Materia medica and therapeutics.

Lectures and clinical lectures on the principles and practice of medicine, with particular attention to the disorders of the digestive tract.

Neurology—clinical lectures.

Diseases of the nose and throat—clinical lectures.

The above medical courses could be completed in two years, or in two years and a half at most. If necessary, use could be made of summer courses, offered at all our large universities. At this point it is well to mention the system at the university of Chicago, where each year is divided into four terms of three months each, and the courses of any one term are as regular as those of any other term.

The subjects of surgery, obstetrics, etc., which occupy practically the last two years of the present medical curriculum—are in the majority subjects which have absolutely no bearing on dentistry. In the remaining few subjects the bearing upon dentistry is so questionable or indirect that the demand for economy eliminates them immediately from serious consideration here.

Dental school. Under the present law our embryo dentist must spend three years at a dental school, consequently he will have abundant leisure to complete any medical work of the above outline left undone at the end of two years. Thus at the age of twenty he enters the home stretch—the dental school. In these three years he will have time to acquaint himself further with studies of general cultural value, or to do some intensive work in one of the sciences, as his taste dictates. At twenty-three we have a D.D.S.

The system here briefly outlined meets the requirements of the utmost efficiency and economy in time and energy. Any reputable institution will always give a certificate for work done in it, which will be honored in another institution. If any technical difficulty should arise over the validity of a certificate, an examination is but a slight discomfort to determine one's standing. This system is to be looked upon as a compromise between the ideal and the present order of things—scholastic and statutory rulings; it is but a temporary arrangement in this transition period. Its most serious defect is that it lacks the regularity, prestige, and strength conferred by organization.

THE IDEAL CURRICULUM OF THE FUTURE.

Men most thoughtful for the best of dentistry see the need of a four years' dental course—the first two years to be devoted to general medicine, the last to those subjects which are the peculiar domain of dentistry. This four years' course (see column VIII of table) should —on the same grounds as the medical schools demand it today—entail a two years' preparatory course at a college in the fundamental sciences. One will recognize in this ideal system of the future a close similarity with German education —the "gymnasium," which is approximately equivalent to our high school plus two college years, followed by the university. This independent convergence bears witness to the validity of such an arrangement.

ADVANTAGES OF THE AUTHOR'S PROPOSED COMPROMISE CURRICULUM.

Until this hoped-for arrangement becomes definitely organized and offered by reputable institutions, and legalized by legislative enactment, its principles may be realized today, by those so desiring, by following the course advocated in this paper. The college work might well be taken at one institution; what follows, at another. The advice that all the post-high-school work be not taken at one university is given on the same ground that the German student finds it desirable to prepare for his degree at more than one university. On the other hand, the reason why it is suggested that the medical and dental courses be taken at one and the same institution is to obliterate the confusion and friction which one of necessity experiences in changing from one institution to another, in a country where education is not standardized by a central national bureau.

Our system is tabulated in column VII. If we assume that the boy starts school at six instead of at four—so that we may more fairly compare these suggestions with current practice—the graduation age will be twenty-five. An analysis of the table will show that the proposed system (VII) will graduate the student at an age intermediate between II*b* and IV*a*. The former was found unsatisfactory because it lacked instruction in the fundamental sciences. The latter was found to be the most desirable of any of the possible combinations of the official divisions of education; VII, because it saves one year, is, however, preferable even to IV*a*. Further, with the three dental school years of VII, much spare time is offered at the very period when the student is best equipped to judge in what field he wishes to specially engage.

We recall that in this paper we have expressed a belief in the need of a great, deep-reaching change. We realize that the likelihood of such a change in the near future is slight, if we regard man's life as long. To put these suggestions into practice it is not necessary, as we have begun here, to start back at the first year of the primary school. The high school pupil of today, the college freshman or sophomore, the first or second year medical student, in many individual cases throughout the country will not find it too late to follow the essential spirit of this plan.

If the reader is convinced of the supreme and predominant value of using efficiency and economy in time and energy as the standards for each and every course of thought and action, it will be but a step to agree that the course outlined as VII is the best possible under existing conditions.

CLINICAL PATHOLOGY IN ITS RELATIONS TO DENTAL AND ORAL CONDITIONS.

By ROBERT H. IVY, M.D., D.D.S., Philadelphia, Pa.,
ASSISTANT ORAL SURGEON, PHILADELPHIA GENERAL HOSPITAL; ASSISTANT INSTRUCTOR IN SURGERY, UNIVERSITY OF PENNSYLVANIA.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, January 28, 1913.)

UNDER clinical pathology are included laboratory examinations of various body fluids, tissues, and exudates, physically, chemically, and biologically, in aiding the diagnosis of given cases. In some conditions the diagnosis may be made by the laboratory examination alone, but in the majority of cases laboratory findings are only a part of the data which, when viewed together, bring us to a final conclusion.

The question may be asked whether a study of clinical pathology by the dentist would be of any practical value, and whether the time spent in obtaining such knowledge could be compensated for in the daily routine of dental practice. To one confining himself to the purely technical side of dentistry, the answer would be negative; but modern dentistry requires a broad understanding of all diseases pertaining to the mouth, with their relation to the system at large, and for a dental practitioner recognizing this fact, clinical laboratory methods should be of great value. It is not urged that great personal expertness should be possessed by the dentist in these procedures, but he should be able to carry out the ordinary ones himself, such as the simple urinary tests, and, what is more important, recognize which examinations will be of the greatest aid in given cases. I will not go into the technical details of the different tests, but will merely outline what they are, and indicate their special bearing on diseases of the mouth.

In the field of dentistry and stomatology, clinical pathology could often be made use of to aid the practitioner in his management of cases, by throwing light on the general health of his patient, and many times aiding in the diagnosis of the local condition present.

The routine measures carried out in the clinical laboratory include chemical and microscopic analysis of the urine, examination of the blood for percentage of hemoglobin or coloring matter and the number and varieties of red cells and leucocytes, examination of the stomach contents and feces, microscopic examination of pus and other discharges, and bacteriological examination by various culture methods. We may add to these the different serological tests, such as the Widal reaction for typhoid fever, and the Wassermann reaction for syphilis. In the clinical laboratory, also, bacterial vaccines are prepared, to be used so successfully in some cases of pyorrhea and other infections, the dosage being guided largely by determination of the opsonic index.

VALUE OF URINALYSIS.

At the present time, examination of the urine probably furnishes us with greater knowledge of the patient's general condition than any other single laboratory procedure. The quantity and composition of the urine is influenced by factors in remote regions of the body, as well as by disease of the kidney itself. Routine examination of the urine consists in: Determination of the quantity passed in twenty-four hours, normally about 40 ounces; color and reaction—acid or alkaline; specific gravity, normally 1016 to 1020; presence of albumin and sugar, both normally absent; microscopic examination for tube casts, epithelial cells, pus, blood, various forms of crystals, and bacteria. Tube casts are albuminous molds of the kidney tubules, and appear in the urine as cylindrical structures of many varieties.

In nephritis we find albumin and various forms of tube casts in the urine; in acute cases blood cells are also generally present.

In diabetes mellitus the patient voids a large quantity of urine with a high specific gravity, due to the presence of sugar.

Gouty diathesis. The gouty diathesis is frequently complicated with secondary disease of the kidney, with albumin and casts in the urine, but there is no direct evidence of gout to be elicited by urinalysis. There is a widespread impression that a deposit of urates in the voided urine is evidence of the gouty or uric acid diathesis. The deposition of normal urates, however, is usually due to concentration of the urine or to the fact that it is voided into a cold vessel. On the contrary, in the majority of cases of gout, the uric acid eliminated in the urine is distinctly less than normal, but may reach normal or exceed it a few days after the attack. In some cases of chronic gout, there is a tendency to a deposition of uric acid crystals in the urine in the form of "gravel," but these deposits occur usually in the intervals between the gouty paroxysms, and even in these cases the uric acid output is low.

In various general infections of the body, the bacteria are eliminated through the kidneys, and are consequently to be demonstrated in the urine. Thus, in typhoid fever, typhoid bacilli are commonly recovered from the urine by culture methods.

Pyorrhea alveolaris. Urinalysis in connection with mouth diseases is particularly important in regard to pyorrhea alveolaris. Patients suffering from diabetes are especially prone to pyorrhea, and a recognition of this constitutional factor as revealed by examination of the urine may be of great importance as a guide to treatment. Nephritis, in a patient under treatment for any mouth condition, is a complication that should always be considered, as the eliminating capacity of the kidneys is a vital factor in the overcoming of any disease by the system. In considering the general condition of a patient before performing an operation upon the mouth under general anesthesia, the condition of the kidneys, as ascertained by analysis of the urine, is of prime importance. The constant presence of sugar in the urine is generally a contra-indication to all but imperative operations, on account of the hypersusceptibility to infection in these cases.

VALUE OF EXAMINATION OF THE BLOOD.

By examination of the blood we are able to determine the existence of anemia, of leucocytosis—inflammatory increase in the normal number of white blood corpuscles, and of leukemia, in the several forms of which there is an enormous increase in certain varieties of the leucocytes. In anemia, we may have a diminution in the percentage of hemoglobin, or in the number of red cells, or both. One of the signs commonly looked for in anemia is paleness of the gums.

Pernicious anemia. In pernicious anemia the hemoglobin may be reduced to 20 per cent. or lower, and the red cells to less than one million per cubic millimeter, instead of five million, which is normal. In addition, in pernicious anemia, we note certain changes in the shape and size of the red corpuscles, and also the presence of nucleated red cells, as seen in stained smears of the blood. It is now known that a great many cases of pernicious anemia have their origin in chronic suppurations of the mouth, therefore it is important for the dentist to understand the blood picture of this disease. In lead poisoning, characterized by the "blue line" of lead sulfid in the gum margin, the diagnosis is confirmed on examination of the blood. Here we find anemia, and a peculiar condition of the stained red blood corpuscles known as "stippling" or basophilic granular degeneration. In this the red corpuscle takes the usual stain, but is dotted here and there with bluish or violet points, instead of being of a homogenous red or pink color. Lead may also be detected in the urine in severe cases of lead poisoning.

Leucocytosis. This is a condition of the blood characterized by an increase in the number of leucocytes, and is a response on the part of the body to infection. Leucocytosis usually occurs in acute infection of any part of the body by pyogenic bacteria in which there is any absorption of the toxic products of these bacteria into the circulation. Thus we would be apt to find leucocytosis in a case of alveolar abscess in which fever is present. The number of leucocytes per cubic millimeter, instead of being about 8000, may rise to 15,000, 20,000, or even 30,000. A stained smear of the blood in such a case would show also that the increase involves chiefly but one variety of leucocyte, viz, the polymorphonuclear. Normally, the polymorphonuclears comprise from 65 to 70 per cent. of all the leucocytes, but in leucocytosis the proportion may rise to 80 or 90 per cent. The procedure of determining the percentages of the different forms of leucocytes in a given specimen of blood is termed a differential count. The relation of the total number of leucocytes to the percentage of polymorphonuclear cells is often a good index of the resisting power of the patient in combating an infection. With an increase of total leucocytes—in other words, a leucocytosis—to about 18,000, and an increase in the percentage of polymorphonuclears, the patient's powers of resistance are regarded as good. If, however, the percentage of polymorphonuclears is increased without a corresponding leucocytosis, the resisting power of the patient is probably low, and the prognosis bad.

Leukemia. This is regarded as a primary disease of the blood-forming organs, of which the distinguishing feature is an enormous increase in the number of leucocytes—far greater than is ever observed in an inflammatory leucocytosis. Moreover, the increase is not so much in the polymorphonuclear leucocytes as in other forms of white cells. In the lymphatic type of leukemia there is an increase in the lymphocytes of the blood—*i.e.* the large and small mononuclear cells. The total leucocyte count may be from 100,000 to 200,000 per cubic mm., and the lymphocytes may rise from a normal of 25 per cent. to 80 or 90 per cent. of all leucocytes present. The splenomyelogenous form of leukemia may present a still greater number of leucocytes, viz, 400,000 or 500,000 per cubic mm., or even more. In this type of the disease, the preponderating leucocyte is the myelocyte, which is not present in normal blood, but is thrown into the circulation in leukemia from the bone marrow. The myelocyte is a large cell with a single, oval, deep blue nucleus, and pale blue protoplasm containing violet granules. Other myelocytes, known as eosinophilic myelocytes, have red granules instead of violet ones. The myelocytes make up from about 30 to 40 per cent. of the total leucocytes in a case of splenomyelogenous leukemia. A knowledge of leukemia is of considerable importance to the dentist, because in the acute varieties, particularly, the mouth is one of the first parts of the body to show the disease. The mouth lesions begin as sponginess of the gums, with hemorrhages, thought to be due to swelling of the tissues from deposits of leucocytes. Infection soon occurs in these points of lowered vital resistance, and is followed by ulceration, gangrene, and even by necrosis of bone. A blood examination in a case of this kind clears up the diagnosis at once, and the dentist, if he has the ability to recognize the association, will often be the first to suspect such a disease in the patient because of the early occurrence of oral lesions in leukemia.

VALUE OF EXAMINATION OF GASTRIC CONTENTS AND FECES.

Examination of the gastric contents and feces does not afford much direct information in diseases of the mouth, except that it often shows the deleterious effects of lesions of the oral cavity on the digestion. Patients with gastro-intestinal symptoms will often be saved much unnecessary laboratory work on the gastric contents and feces, if mouth conditions be investigated and corrected first. In examination of the stomach contents and feces, the detection of small quantities of blood by chemical tests is regarded as an important sign of organic disease of the stomach or intestine. It must not be forgotten that such blood may be swallowed from the mouth.

VALUE OF SALIVARY ANALYSIS.

Examination of the saliva as a means of clinical diagnosis has not yet been fully worked out, but shows great promise for the future. Extensive investigations have been carried out to determine the relation of the saliva to caries of the teeth and to caries-immune mouths. Pickerill, in particular, has discovered important facts bearing on the relation of the reaction of the saliva to this question. The composition of saliva in its relation to dental caries has also been investigated by this worker, as well as by many others.

The examination of saliva as an index of general bodily conditions sometimes furnishes important information when taken along with urinalysis and other tests. This has not yet been included among the routine procedures of the clinical laboratory, but there is no doubt that its importance will come to be fully recognized as the result of further investigation.

DIRECT MICROSCOPIC EXAMINATION OF STAINED SMEARS.

By direct microscopic examination of stained smears made from various discharges and tissues of the body, we are often able to find the micro-organism causing a particular lesion. Thus, in the mouth there is an infection of the gums called Vincent's angina, in which stained smears always show a delicate spiral organism known as the spirillum of Vincent, associated with a bacillus with pointed ends—bacillus fusiformis. We are often able by the aid of the microscope quickly to differentiate this disease from diphtheria, which it sometimes closely resembles. With special staining methods we can also demonstrate the spirochæta pallida in syphilitic lesions of the mouth.

I will not dwell on the immense field in the mouth for the application of culture methods in the search for the causative micro-organisms in pyorrhea alveolaris and other infections.

WASSERMANN REACTION AS AN ALMOST CERTAIN METHOD OF DIAGNOSING SYPHILIS.

In the diagnosis of syphilis, the lesions of which are so commonly found in the mouth, we have an almost certain method in the Wassermann reaction, the principles of which at least should be understood by every dentist. There is no time here to explain the reaction, which depends on the presence in the blood serum of a syphilitic person of certain substances capable of uniting with extracts made from syphilitic tissues and fixing complement. A positive reaction is found in practically 100 per cent. of cases of secondary syphilis. In tertiary syphilis the percentage of positive reactions is somewhat less, but is still high. No other diseases in this country liable to be confused clinically with syphilis give a positive reaction. In view of the common occurrence of mouth lesions in syphilis, and of their extreme contagiousness, the diagnosis of such lesions by the dentist is important, and the Wassermann test should be of use to him in this connection.

CONCLUSION.

There are many other procedures carried out in the clinical laboratory, but those mentioned should suffice to show how a familiarity with clinical pathology may be of assistance to the stomatologist in diagnosis. The general growth of knowledge along these lines is such as to render it imperative for the dentist to get into close touch with them, if progress in his profession is to keep pace with that made in other branches of medical science.

[See also *Discussion,* as reported under "Proceedings of Societies," this issue.]

Correspondence.

"THE MORE HASTE—"

To the Editor of the Dental Cosmos:

Sir,—At the last meeting of the New York State Dental Society, the writer discussed the negative side of the dental nurse question, endeavoring to answer in a fair and impartial manner the arguments that had been brought forward up to that time by those in favor of legalizing young women to do minor dental operations. Since then I have read with great interest the editorial in the November 1912 issue of the Cosmos, on the bill to amend the law regulating the practice of dentistry in Massachusetts. It was probably the recognition of the force of the arguments contained in that editorial (which pointed out the dangerous deficiency of the proposed law) that induced the framers thereof to modify Sec. 2 so that, as it now stands, it is so emasculated as to be even more inadequate and dangerous, if possible, than in the form in which it was quoted on pp. 1281 and 1282 of Cosmos. The new draft of the bill now before the legislature of Massachusetts, together with an editorial indorsing it, appear in the current issue (February) of *Items of Interest.* After a careful perusal of the latter, it seems well that your warning, "Festina Lente!" should again be sounded.

In order to make clear what follows, I will quote Sec. 2 of the original draft, and also Sec. 2 of the bill now before the legislature, according to the *Items.* In the former it is apparent that the framers were met at the very beginning with the difficulty of defining satisfactorily what should be the proposed dental nurse's duties and what should limit his or her sphere of activities. An attempt was made to do this by the legitimate but always unsatisfactory use of negative definition, as follows:

Sec. 2. No dental nurse shall be licensed to perform any service other than the examination, wedging, and cleansing of teeth, inserting and changing dressings in teeth for the relief of pain, and assisting a registered dentist during the performance of his dental operations. The above service shall not include the treatment of the disease known as Riggs' disease, nor the removal of deposits from teeth occurring in the tooth socket, nor the preparation of cavities for filling, nor the treatment of pulpless teeth. The removal of tartar under the gums is included in the cleansing of teeth.

It might be noted in passing that in one part of the above, "removing deposits from the socket" is prohibited, whereas in the latter part "the removal of tartar under the gums" is to be allowed!

The bill which is printed in the current *Items* and is now before the Massachusetts legislature for action, has this section entirely altered, so that it reads as follows:

Sec. 2. A registered dental nurse shall be licensed to perform only such duties as shall be specified in his license, and solely under the direction and in the office of a registered dentist. Nurses may be employed by schools and institutions, and directions for all their work shall be given by a registered dentist. The dental nurse shall be licensed to perform the service of cleansing the teeth.

The present writer was for a number of years engaged on two commissions authorized by Congress to revise and codify the laws and to prepare an organic act for the government of one of our island territories. He recognizes clearly the extreme difficulty involved in the drafting of a piece of legislation which is to become part of the law of a great commonwealth. But while the first draft of the proposed Massachusetts act at least defined negatively the limits of the dental nurse's duties, the present bill entirely sidesteps the question by saying that such duties shall be specified in a *license*—without giving the form or wording of that license; and then, apparently to satisfy those who might object to such a method of lawmaking, the dental nurse is also to be permitted to perform the service of cleansing the teeth. Surely such an ambiguous wording will not pass muster with the lawgivers of Massachusetts, since, if ever bill contained a "joker," it is apparent in this Sec. 2. The vital thing in legislation of this sort is that *the powers and privileges of any new creation of law should be carefully and exactly defined.* In this case they are not so defined.

It is further stated in the *Items* editorial that the duties of the proposed dental nurse are described in the single sentence at the end of Sec. 2, *i.e.* relative to the cleansing of the teeth. Surely the writer of that editorial could not have overlooked the first part of that section, which says that "he [the nurse] shall be licensed to perform only such duties as shall be specified in his license." This is the vital point, and it behooves the dental profession of Massachusetts, in order to safeguard their interests, to inquire closely how the license, which it is proposed to issue yearly, shall read. If the duties of the dental nurse are so clearly defined by saying that "he shall be licensed to perform the service of cleansing the teeth," why not do away entirely with the first sentence of that section, thus avoiding all ambiguity in the wording of the act, and insert the little word "only" in its proper place, making it read: "The dental nurse shall be licensed to perform only the service of cleansing the teeth." If this were done, and if it expressed the object of those who are fathering the bill, there could be no doubt in the mind of anyone regarding the limitations of the so-called dental nurse's activities, and it would furthermore conclusively prove the sincerity of their purpose.

Of course there would then arise the necessity, so well provided for in all well-thought-out enactments, of defining and limiting exactly what "cleansing the teeth" shall mean from a legal standpoint for the purpose of the act. This defining of terms is well illustrated under Sec. 4, 3d subdivision, of the excellent new dental law proposed for the State of Michigan, where "unprofessional conduct" is clearly defined, leaving no doubt in the mind of the reader or of the judge who might be called upon to administer the law. Such careful preparation of any proposed legislation can only result in benefit to the profession, and would not be likely to be called "pernicious legislation," as might happen with a bill in which the meaning was not clear.

The service called by dentists "cleansing the teeth" is susceptible of a wide range of possible interpretations, and requires first of all a correct definition of what constitutes a tooth—at least from the legal standpoint, as in this case. The same with the conception of "cleansing." Some dentists do not consider a tooth properly cleansed if a particle of calculus be present on it, from root-apex to incisal edge or morsal surface; if a cavity exists anywhere upon it; if bacterial plaques be present on its crown, or an abscess sac adherent to its root; or, finally, if it be bathed in vitiated salivary secretions. Other dentists are satisfied to consider that cleansing the teeth is menial work—scavenging, as I have heard men call it—and that it consists in rubbing the buccal and especially the labial surfaces of the teeth with a little brush revolving in the engine, thereby satisfying the esthetic sense of a patient while ignoring the actual cause or causes of septic mouths.

If the figures given in the editorial in the *Items* be correct, we might find it impossible to control the Colossus which might be created if a similar law became operative in New York City. We are told that as a "starter" it would take only about $200,000 a year and 320 dental nurses at $10 per week to care for 64,000 public school children in 32 clinics in that city. On the same basis of computation, allowing an actual combined public school, parochial school, and institutional school population of 750,000 from four to fourteen years of age, all legally entitled to free cleansing of their teeth if such an act became law, it would take 375 clinics, a yearly appropriation of $2,460,000, and a staff of 3750 dental nurses for the city of New York alone! There were only 3980 dentists in the whole State of New York in 1910.

While admitting the need of some such solution of the problem, I doubt if it would be possible to induce many young women of the required ability to enter this new field, if after the lapse of we will say two years' training in a training school for nurses we could only offer them $10 a week remuneration. School nurses in New York now receive $75 a month, which is none too much to support them at the present high cost of living. It cannot be done on $40 a month. It is also proposed that these clinics be in charge of competent dentists (who must of necessity have had much experience in real prophylaxis), at a salary of $1000 a year. The spirit of altruism is not yet sufficiently disseminated among the young men of the profession to induce them to take up this work at such a salary. Private clinics, under corporate or individual names, offer better inducements.

We are further told that cleansing the teeth less often than five or six times a year is not real prophylaxis. Of course it is not. Many who claim to practice it as a so-called specialty say that cleansing the teeth less often than once a month is not prophylaxis. And thus we arrive at another interesting question in connection with the discussion of this subject. Does cleansing the teeth, in the commonly accepted interpretation of the term—*i.e.* rubbing them with a brush or a stick loaded with pumice, from one to twelve times a year, combined with the more or less faithful use of a toothbrush—does that constitute prophylaxis? Or is it but the small part of prophylaxis, of preventive medicine in dentistry, which many dentists believe it is? If the use of detergents, whether with brush or stick, with or without the use of the engine, is all that is to be taught to the proposed assistants to whom it is desired to give legal status, then the title "trained nurse" is far too dignified, and would probably meet with great opposition from the medical nurses who have worked so hard to earn that title. Such tooth-cleaners would be better classified under the title given them by Dr. Wright, namely, "denticure."

On page 147, *Items* also says that it is an indubitable fact that real prophylaxis is not done in one-half of one per cent. of the dental offices of this country, and that where it is practiced it is done by trained dental nurses. *Ergo,* if a dentist does not employ a trained dental nurse he does not belong to the one-half of one per cent. of the elect, and is not qualified to practice real prophylaxis! This is the only logical conclusion that can be drawn from that statement. There are, according to Polk's Directory, some 40,000 dentists in the United States; hence, only 200, the fortunate one-half of one per cent. who are the proud employers of trained dental nurses, are practicing real prophylaxis—or rather, those nurses are doing it. If this be true, it would be interesting to know what the ninety-nine and one-half per cent. of the unchosen are practicing, handicapped as we are.

It is fair to assume that, in the schools for dental nurses which it is desired shall be founded, this small body of 200 men scattered all over the United States, the real masters of prophylaxis, will be the first to be called upon to train and put in the field within a very short time—if the Massachusetts law goes into effect—a sufficiently large number of trained dental nurses to supply the demand. Surely such an important matter would not be left in the hands of any less qualified!

Although I have attempted to point out what I consider a weak point in the proposed dental nurse act, I am heartily in sympathy—as I said in my discussion at Albany, printed at page 919 *et seq.* of the August 1912 COSMOS—with the proposition of properly and carefully training a body of young men and women to do rescue work of the mouth in our public schools and institutions; and I am therefore also in sympathy with the avowed objects of those who advocate that bill, which I understand to be—

First. To extend to the community at large the same service which at present only one in one thousand receives (if the figures quoted in *Items* be correct).

Second. To do this by means of properly trained dental nurses, worthy of that dignified title, and thoroughly acquainted with all the requirements of prophylaxis—which would take a number of years and require as a working basis a composite definition of the meaning of "real prophylaxis" to be formulated by the 200 men in whose offices alone its mysteries are now practiced, in order that no single detail might be overlooked.

Third. To found training-schools for such dental nurses, in order that only those best qualified to teach real prophylaxis may be the trainers of the dental nurse and may bring her to an ideal state of efficiency, a worthy handmaiden of the dental profession. Once this has been done, and a sufficiently large body of such nurses has been trained to supply a reasonable demand, it will be time to look to the legislatures to give them legal status. To them could be safely entrusted the work of prevention—of real prophylaxis, if you please—which the conditions in our public schools and institutions demand.

It is by no means certain that the dental profession as a whole is ready for or desires the dental nurse for private office work; nor are the dental nurses now existent clamoring for recognition. In general medicine the trained nurse was an evolution, from the Sairy Gamp depicted by Dickens, through the sisters of mercy and others who did such noble work in the wars in Europe that preceded the Crimean war, down to the highly-trained licensed and registered nurse of the present day, who has received legal status through the untiring efforts of Florence Nightingale and other pioneer nurses. General nursing was an established institution, a generally recognized and highly developed part of medical practice, before it received the sanction of lawgivers. With dental nursing it is not so. There is as yet no trained and united body of dental nurses who could meet the requirements of even such a law as that proposed for Massachusetts. So we should "make haste slowly," and first train such a body.

While writing the above, I chanced to read the article by Miss D. B. Johnson, a trained dental nurse of fifteen years' experience, in the current *Items.* Her contention is that if women wish to clean the teeth and do the other work of dentistry, they should take the same training as men and ask for no consideration on account of sex; and she makes the significant statement that "There can be no compromise possible on the legal question." It would be interesting to hear from other trained dental nurses, as thus far we have heard only from dentists employing them. Miss Johnson, in her article, does not demand that the assistants who are to be trained for a period of two years in a properly equipped school shall be licensed to practice any part of dentistry.

When the dental profession shall have trained, in the manner suggested by Miss Johnson, a sufficiently large number of women qualified to meet the requirements of the practice of true prophylaxis in our public schools and able to perform the minor operations contemplated in the first draft of the Massachusetts bill as given above, I shall gladly welcome them and accord them equal honor with the trained medical nurses, provided the limits of their activities be as carefully defined as are those of the latter.

Yours very sincerely,

CHAS. C. VOELKER.

BROOKLYN, N. Y., Feb. 17, 1913.

PROCEEDINGS OF SOCIETIES.

NATIONAL DENTAL ASSOCIATION.

Sixteenth Annual Meeting, held at Washington, D. C., September 10 to 13, 1912.

SECTION III: Oral Surgery, Anatomy, Physiology, Histology, Pathology, Etiology, Hygiene, Prophylaxis, Materia Medica, and Allied Subjects.

Chairman—W. H. G. LOGAN, Chicago, Ill.
Vice-chairman—E. E. HALL, Columbus, Ohio.
Secretary—T. P. HINMAN, Atlanta, Ga.

(Continued from page 324.)

WEDNESDAY—*Morning Session.*

The first meeting of Section III was called to order by the chairman, Dr. W. H. G. Logan, Chicago, Ill., on Wednesday morning, September 11, 1912.

The first order of business as announced by the chairman was the reading of a paper by Dr. J. F. BIDDLE, Pittsburgh, Pa., entitled "Diagnosis and Treatment of Important Diseases of the Dental Pulp."

[This paper is printed in full at page 353 of the present issue of the DENTAL COSMOS.]

Discussion.

Dr. ARTHUR D. BLACK, Chicago, Ill. It has been a delight to listen to the essayist, who has dealt with a comparatively limited subject and has gone thoroughly into the details of operative procedure. I am very much pleased indeed to have the opportunity of discussing a paper of this type, even though it is so thorough in itself.

The history of pulp treatment in this country is interesting, and I want to refer very briefly to the general waves that have gone over the dental profession. Previous to about 1860, it was common practice to extract teeth the pulps of which were inflamed. There were, of course, exceptions among the leaders of the profession. To Dr. Hullihen of Wheeling, W. Va., should be given the credit for bringing out a method in the early fifties by which the effort was made to save teeth which had exposed pulps by drilling a hole through the side of the root, close to the gingival line, into the pulp chamber, and then placing a filling in the cavity made by caries without removing the pulp.*

Following this came a treatment in which the pulps were removed, and permanent dressings of cotton with creasote were inserted as root-canal fillings.†

Occasionally we come across root-fillings of that kind, but that method has long since passed out of general practice. It marked, however, a step forward in the progress of pulp treat-

* See *Dental News Letter*, vol. vi, 1852–53, p. 34.

† See *American Journal of Dental Science*, vol. v, N. S., 1855, p. 458.

ment. Following it came various methods of root-canal filling. The first mention I have been able to find of the use of gutta-percha as a root-filling was made by Dr. B. Oscar Doyle of Louisville, Ky., in 1872.*

We have been a little too reckless in the removal of pulps. We have not been sufficiently careful in making diagnoses between pulps which should have been removed and those which might have been saved. Several men, whose judgment we have no reason to doubt, are on record as saying that they believe that 25 per cent. of the people of the country have alveolar abscesses today, due either to dead pulps or as a sequence to pulp treatment and root-canal filling. Many of these abscesses have no sinuses, but would be revealed by the use of the X ray. To this statement recent reports have been added of cases in which the general systemic condition has been shown to be seriously involved as the result of chronic abscesses. We are therefore facing a serious problem. We should be more careful in our diagnosis, as well as in our technique in treating these cases, and every time we operate on a pulp or make a root-filling we should have these facts in mind. The reports of cases of endocarditis, nephritis, arthritis, and other affections which have been traced to these conditions in the jaws, should always be considered. We are really treating the patient, not simply a single tooth, every time we treat a pulp. We have, indeed, the patient's life in our hands to a more considerable extent than most of us appreciate.

I wish to refer briefly to a paper read by Dr. Frank Billings before the Chicago Medical Society last winter in which he reported thirty cases of arthritis, eighteen of which were either cured or very much improved by the removal of the tonsils, and in most of these cases culture taken from the tonsils and inoculated into guinea-pigs produced a similar general lesion in the pigs, several of which died. There is no difference whatever in the possibilities and probabilities of such remote infections from chronic alveolar abscess; the person who has an infection about the root of a tooth is in the same danger as the one with an infected tonsil. I mention this in order to emphasize more strongly the importance of greater care both in diagnosis and in treatment, as suggested by the essayist in his excellent paper.

In the matter of diagnosis I have little to add to what Dr. Biddle has said, except that I wish he had dwelled at greater length upon those conditions of the pulp in which he considers pulp preservation to be indicated and those in which he would advise the removal of the pulp. He said that an inflamed pulp should be removed in all cases, but not in cases of hypermia. If a diagnosis is made of hypermia of the pulp, every effort should be made to restore that pulp to normal, and to save it rather than remove it.

I am very glad that Dr. Biddle showed an X ray of a lower second molar to which arsenic was applied before the roots were fully formed. This illustration calls attention to the fact that we become careless in examination and diagnosis. Ordinarily one should not mistake a second molar for a first molar, even though it be in the position of the first. We should be on our guard for that, especially when the other teeth are not in position. We should of course keep in mind the forms of all of the teeth and the time at which the roots are completely formed, and be careful in the application of our drugs.

I should like to emphasize especially the importance of antisepsis and asepsis in the treatment of these cases. There is no reason why the dentist, in the treatment of the pulp, should not carry out very nearly as strict measures of asepsis and antisepsis as would the general surgeon in an operation; no reason why the dentist should take a chance of carrying an infection into the pulp chamber, because the method of sterilization of the instruments employed is simple and easy, and there is no excuse for the use of non-sterile instruments within a root-canal.

Dr. Biddle did not mention the use

* See DENTAL COSMOS, vol. xiv, 1872, p. 371.

of the rubber dam in connection with the treatment of these cases, although it may be inferred from his remarks on asepsis that it should be used; yet I never like to hear a paper on this subject without emphasis being laid on the use of the rubber dam. I feel certain that a large percentage of blind abscesses are due to the failure of the dentist to place the rubber dam—and I do not except the upper central incisors in making that statement; the rubber dam should be applied in the treatment of every pulp, if it is at all possible to put it on.

One word should be said regarding the possibility of being deceived in the interpretation of radiographs. Dr. Biddle showed in his lantern slides that a great error may be made as to the closeness of a filling to the pulp chamber, depending on the angle at which the ray passed through the tooth. In connection with root-canal fillings, I wish to call attention to the fact that most roots appear larger in X-ray films than they are in reality, by reason of the fact that the film cannot be held in line with the long axis of the tooth, but is usually inclined corresponding to the curvature of the overlying tissues, whereby the length of the root is exaggerated. Especially in X-ray pictures of the upper anterior teeth are we apt to have this distortion.

No reference was made to the amputation of roots, Dr. Biddle contending that this is not properly a part of his paper. Yet I think he might have properly shown us these films as emphasizing what often happens as a sequel to imperfect technique.

The principal reason, probably, why we make so many failures in the treatment of pulps and the filling of root-canals is because we fail to charge a proper fee for the service. We render to our patients no other service which is quite as important as pulp treatment, which means the life or the loss of the tooth. The general custom of "throwing in" the pulp treatment with the filling, in the manner of the merchant who "throws in" a pair of suspenders with each pair of trousers, is wrong. We ought to so impress our patients with the time and care required for pulp treatment that they will be very glad to pay us the fee which we should receive for that service. I do not speak of this for the purpose of suggesting primarily that we increase our fees; I speak of it because I know that if an operator receives a proper fee, he will be more inclined to institute good pulp treatment.

Dr. J. P. BUCKLEY, Chicago, Ill. Dr. Black, in discussing the essayist's excellent paper, has referred to the history of pulp treatment. I am interested in this subject chiefly from the therapeutic or pathological viewpoint, and I wish to emphasize certain phases thereof that have long been in my mind.

Successful therapy, dental as well as general, depends largely on the proper interpretation of the disease that we are endeavoring to cure. The trouble with dentists in the past, and even today, in the treatment of diseases, especially the destructive diseases of the dental pulp—and I need not particularly specify the destructive diseases—has been that they do not take up and delve into the subject of pathology, do not school themselves so that they can read the clinical symptoms of the diseases that we are endeavoring to treat by the application of therapeutic remedies. Unless we study pathology and pharmacology, and know the symptoms of the various diseases and the drugs indicated in their treatment, we shall be groping in the dark. The dentist, unfortunately, is too busy, and has to attend to too many patients, to give to the individual who is suffering from these diseases the proper time, even if he knows the real cause of the trouble. In the average case of toothache, the dentist simply endeavors to find out one of two things, viz, whether the pulp is vital or dead. That, however, is not enough to know. If the pulp is vital, we should endeavor to find out its condition, whether it is in a state of active or one of passive hyperemia, or whether there is true pulpitis or true inflammation.

I agree with Dr. Black that too many pulps have been removed. Dentists remove pulps because they are afraid that a tooth will ache after a beautiful inlay or filling has been inserted. On the other hand, when they find that the pulp is dead, they generally proceed to take the first remedy that comes to hand, place it in the cavity of the tooth after opening into the pulp chamber, and seal it in with a pledget of cotton dipped in sandarac varnish or chloro-percha, being afraid to seal the cavity with cement. If the dentist, no matter what the pathological condition of the pulp be, would always hermetically seal the tooth in the first place, he would be compelled to delve more deeply into the subject and find out just what the condition of that pulp is, so that he may seal the proper remedy into the tooth. The dentist today who fails to hermetically seal his remedy in a tooth at the first sitting, or who advises the patient to remove his filling, if the tooth should ache, either does not understand the pathological condition which he is endeavoring to treat or else has absolutely no confidence in his remedy.

I want to make the appeal here today that we delve deeply into the science of pathology and pharmacology, that we learn to read the clinical symptoms of these diseases—because then, and then only, can we apply our therapeutics along rational lines. When it comes to the question of removing the pulp, the average dentist will do so, regardless of actual conditions, because of his fear that the pulp may subsequently give trouble. When we think of the pictures that have been thrown on the screen, of the small, tortuous root-canals from which pulps have been removed that could have been saved under proper treatment, it is a question whether we are conserving the patient's interests by so readily and indiscriminately, not to say ruthlessly, extirpating pulps as has been the practice in the past. I wish to be understood correctly. I am making no plea for the preservation of a pulp that is diseased to such an extent that it should be removed, but I am pleading for the conservation of pulps which are not sufficiently diseased to warrant removal.

I do not know whether or not it is true—and I hope it is not—that 25 per cent. of the people of this country are suffering with alveolar abscesses, but I do know that dentists have been blinking at abscesses in the mouths of their patients that they were unable to cure. They have been advising their patients that as long as a tooth, though abscessed and discharging pus, was giving no manifest trouble, that tooth should be retained. If anyone had an abscess on his toe, or thumb, or finger-nail, would he tolerate it? He would work continuously until it was healed, fearing that neglect would mean the amputation of the toe or finger, and yet it is infinitely worse for a patient to have his general systemic condition neglected by lack of attention to an alveolar abscess.

Dr. Moorehead, a student of pathology, in the *Journal of the American Medical Association,* reported recently five cases of tubercular infection of the glands in close proximity to abscessed teeth, inferring that these glands became infected through the canals of abscessed teeth, and every dental and medical man knows that from such infected tubercular glands tubercle bacilli can be carried throughout the system, these bacilli attacking any part of the body that is below par. During the year 1911 $14,500,000 was spent by the National Association for the Prevention and Cure of Tuberculosis. Dr. E. C. Rosenow, Dr. Billings' assistant in Chicago, to whom Dr. Black referred, reported recently before the Chicago Dental Society six cases in which the patients had died from endocarditis, the post-mortem examinations showing that the endocarditis was the direct result of poisons absorbed by the blood-stream from pyorrheal pockets containing pus or abscesses associated with teeth. It is time, then, that we stop blinking at these chronic abscesses in the mouths of patients, and if by therapeutics and surgery we cannot cure such conditions, let us extract such teeth, in order to avoid damage to the patients' systems.

If I have said anything in the discussion of the essayist's most excellent paper that will make dentists think more deeply along the lines of pathology and pharmacology, I shall feel that my effort to attend this meeting has not been in vain.

Dr. JAMES TRUMAN, Philadelphia. I do not wish to discuss this paper, valuable as it is, but I desire to correct a statement made by Dr. Black that prior to 1870 there was no treatment of root-canals. This may be true of the environs of Chicago, but not of Philadelphia and neighborhood. I have been a teacher since long prior to 1870, and I can state positively that some of us knew how to treat root-canals, perhaps not as successfully as my friend Dr. Buckley, but we did the best we knew. The trouble at the present time with many young practitioners is that they do not go back far enough; they do not understand, as a rule, the treatment and the work of the older men—the fathers of this profession—as some of us who worked at that period were able to comprehend it.

Dr. OTTO E. INGLIS, Philadelphia. Dr. Biddle has chosen a subject which has always been of interest to me, inasmuch as it involves clinical phenomena, scientific facts, and some degree of imagination. The proper utilization of these three factors will enable one to make a fairly just and practical diagnosis in pulp diseases, and to apply a rational treatment suitable in a given case. All cases of arterial hyperemia are due to causes which act directly on the exposed dentin of an exposed pulp, or to causes which produce an inflammation or hyperemia of the apical tissue so that the excess of blood flows into the pulp vessels, thus establishing that aseptic overfulness of bloodvessels and the consequent over-excitability of the nervous mechanism of the pulp which are characteristic of arterial hyperemia of the pulp. A profound arterial hyperemia of the pulp produced by direct causes can, in its turn, produce an overflow of blood from the pulp into the apical tissue, and thus induce an apical hyperemia with its characteristic phenomenon of tenderness upon tapping. Venous or passive hyperemia in its uncomplicated form is almost invariably secondary to arterial hyperemia, and is due to the compression of the veins at the apical foramen by the enlarging artery. Thus, as the arterial hyperemia increases in severity, the venous variety becomes also more severe, until stasis, either total or partial, supervenes. While there are conditions producing non-septic pulpitis, the vast majority of cases are due to pulp exposure and its mechanical, chemical, thermal, and infective irritation. When an abscess upon another tooth or a pyorrhea pocket upon the same tooth approaches the apical tissue of the tooth in question, the pulp of that tooth may be infected from the apex down, and thus its infective inflammation be produced.

There are clinical phenomena which require some imagination to understand as applied to a given case in a mouth.

I will explain. Recently I vainly treated a lower right first molar for a chronic abscess on the distal root, the abscess discharging over the middle third of the mesial root of the second molar. I could feel this root with a probe. The acute symptoms having abated, I let the patient go on her vacation. A violent pulpitis ensued in the pulp of the second molar, doubtless due to infection from the abscess tract. The dentist whom she consulted diagnosed inflamed pulp, and devitalized it. I do not know whether he saw the cause in his mind's eye or not.

Now, suppose that a tooth equally loose, and equally responsive to cold, should present, and the cause be a pyorrheal pocket not reaching the apical tissue; then the treatment which to the empiricist would be correct is not a correct one, as the diagnosis changes from apical inflammation to apical pulp hyperemia, a disease entirely curable in most cases upon simple removal of the cause.

Dr. Biddle has cited an interesting case of pulp hyperemia due to the alveolitis following the removal of an impacted tooth. This is analogous to a series of causes any one of which may produce inflammation or hyperemia of the apical tissue—by mere extension—and the surplus of blood in the part goes into the pulp, hence its hyperemia and supersensitivity, and hence its response to cold.

In the consideration of all conditions of inflammation, it has been of great value to me to imagine the central area of pus—or, in non-septic inflammation, of stasis—surrounded by an area of stasis in which phagocytosis is active, this being surrounded by a zone of active but less active inflammation, this by a zone of arterial hyperemia which may fairly be regarded as the first stage of an inflammation, and this by a zone of normal tissue. It requires some imagination correctly to distinguish these various zones in their anatomical positions as disease progresses.

Dr. Biddle's views on symptomatology coincide in the main with my own; I shall therefore not repeat them, but content myself with this brief amplification of the pathology involved.

Dr. Biddle (closing the discussion). I am greatly pleased with the discussion which my paper has brought forth. Dr. Black spoke of the use of the rubber dam. I use it always in an operation in the lower jaw, and in the posterior portion of the upper jaw, but seldom in the anterior, where I have everything necessary for the operation prepared in advance, and by using cotton rolls, and not permitting the patient to close his mouth till the operation be completed, obtain very satisfactory results.

Someone in the audience has requested me to speak of mummification, the kind of paste I use, etc. In reply I would say that mummification has no place whatever in my office.

The stereopticon operator failed to show a slide which I shall mention. The case is that of a man thirty-five years of age, with the upper right canine missing. The first bicuspid was crowned, with a canine facing attached, and there was a sinus opening above the place where the canine should have been. A radiograph was taken and revealed the natural canine above the central and lateral incisors. Two years previous to the taking of the radiograph, there had been hyperemic conditions of the lateral and central incisors, but the patient's dentist, upon making an examination, had failed to determine the true nature of the trouble, and had told him that he had better let the teeth alone. He did so, and the results are apparent. It was now necessary to remove the central, lateral, and canine, and to curet the bone, leaving an opening of one and one-half inches along the side of the nose and one inch in width. Had the trouble been correctly diagnosed at the time of the hyperemic condition, doubtless the central and lateral incisors could have been saved. I cite this instance simply to exemplify the need of more accurate diagnosis.

As Section III is pressed for time and there are a number of excellent papers to follow, I shall conclude my remarks, thanking the discussers for their kindly consideration of my paper.

The next order of business for Section III was the reading of a paper by Dr. T. B. Hartzell, Minneapolis, Minn., entitled "The Post-operative Treatment of Pyorrhea."

[This paper is printed in full at page 370 of the present issue of the Cosmos.]

Discussion.

Dr. J. V. Conzett, Dubuque, Iowa. The paper to which we have listened is, in my opinion, one of the most important on the treatment of pyorrhea that has ever been presented to the profession, because of the emphasis which the essayist has laid on the after-treatment of this disease. We know that we can cure pyorrhea, but those who are specializing in this field know that very frequently patients come into their offices with the assertion that some practitioner has said that pyorrhea is incurable, and that their teeth must be extracted. Others have been discharged as cured, but they come to us in as bad condition as before, because of the fact that they have received no after-treatment. I regard this paper as important because it emphasizes the feature that, if pyorrhea is a curable disease, it is curable just to the extent that the condition is followed up and after-treatment is instituted. Dr. Hartzell has indicated very valuable methods as to this after-treatment.

Despite the lateness of the hour, I

want to emphasize a few points in regard to this subject. Cleanliness is the whole secret of cure in this disease; if that condition can be maintained after proper surgical procedure, the patient will be cured and remain cured, but if not, there will be a recurrence of the pyorrheal condition. Dr. Hartzell tells us in a measure how a cure can be accomplished, which must be done largely by the patient himself. Recently I have had two cases that had been treated by two of the best practitioners in this country, and these patients said, "Dr. So-and-so treated me and discharged me as cured, and now you see what the condition is." If the treatment had been followed up by systematic prophylaxis, there would not have been any recurrence. It would be ideal if the patient would properly maintain cleanliness himself, but we all know that patients will not or cannot do this in a majority of cases. They must be impressed with the importance of keeping their teeth free of any salivary calculus, and if they are allowed to judge of this for themselves, considerable damage is apt to be done before the patient realizes that his mouth needs closer attention than he can give to it. Therefore I believe that it is best to follow up the treatment and have the patient present himself to you or to some other practitioner in whom you have confidence, at stated intervals, that the condition may be observed and suitable prophylactic care be instituted, so as to maintain the proper degree of cleanliness and the condition established by the original treatment.

If I were to criticize any suggestion made in the paper it would be the placing of removable bridges on loose roots, because I do not believe that a removable bridge placed on loose roots would allow the deposition of the cells of granulation tissue to take place and become permanent. It would seem to me that, if granulation tissue is deposited, and the bridge is then removed, the granulations would be broken up, and no permanent attachment of the teeth would be established. I should like to ask Dr. Hartzell to tell us in closing what his experience has been in the placing of these removable bridges in loose teeth.

Dr. N. S. Hoff, Ann Arbor, Mich. The essayist has presented two most important phases of the treatment of peridental diseases, both of which are essential to successful results in the more aggravated stages of these conditions. The post-operative treatment in some cases is so complicated that no specific can be safely advocated. In all cases the surgical treatment is preliminary, although some are advocating therapeutic measures for the entire treatment. The essayist has very wisely left these unmentioned, and we shall do likewise because of our time limit.

The suggestion for a proper toilet procedure for the patient is a good one, but we believe the one advocated is rather complicated for the average patient. We find that the simpler the toilet, the more likely is it to be practiced. The worst sufferers are usually busy people, who have no leisure for any but the most essential time-consuming procedures; and they resent innovations, even though they believe in them and realize their own need. They especially do not care to indulge in any habitual time-consumer. I find it difficult to induce these busy patients to remember their periodic visits to the office for treatment, but I have had some success in getting them to use floss silk and an abrasive that is convenient, such as hand sapolio, once a week. I ask them to sit down once a week before a mirror and spend a half-hour passing floss silk around each tooth. The waxed, broad floss, after being drawn over a cake of hand sapolio, is an effective appliance that patients can learn to use conveniently after a few trials, and they derive so much comfort from this process that they will keep it up after once getting the knack of it, and the habit is established. In some cases orange-wood points in the small holder made by Dr. Skinner will also be useful. This, with the use of a proper toilet outfit of brushes and powders, properly selected and advisedly used, constitutes about all the care the average patient will stand for.

The essayist's picture of the high-pressure injection of infectious material in the peridental pockets is rather overdrawn. In a case that has been properly treated surgically, there ought not to be any considerable quantity of pus or infectious material in the peridental pockets, and if so, the forces of occlusion would hardly force it into the healthy bone and soft tissue of the peridental region. I am of the opinion that the inflammatory condition of these parts is due in a large measure to local absorption, or to an auto-infection from the blood and lymph vessels. The movement of the root in the alveolar socket under the force of occlusion, especially when improperly directed, will cause a stretching of the peridental fibers, and a consequent fatigue, with nervous irritation, that results in the congestion and irritation frequently present in these cases. This condition, as the essayist observes, provides an ideal opportunity for external infection, but it is remarkable that we so rarely have serious infection from this source to contend with in these cases. The histologic pathology of these diseases has not been scientifically determined as yet, and its actual character can only be a matter of clinical conjecture, but it would seem as though the disease would spread more rapidly and would more often assume a semi-malignant form if it were of an external character or source.

Massaging the gums is certainly a useful treatment, if applied properly. It should, however, not be excessive, especially in irritable and easily congested tissues. The use of the cotton rolls with an astringent lotion is useful, but not without its limitations. The bulk of the application hinders its use on the buccal and lingual surfaces of the distal molars, and then, too frequently a severe application of an astringent lotion will dry up the mucous membrane so as to hinder the normal secretion and to cause, after a time, an inflammatory condition that is difficult to subdue. The astringent is not indicated when the gums are normal. A simple antiseptic solution that readily mixes with the salivary and mucous secretions is better. The trouble with placing in the hands of the patients a potent drug is that they never know when not to use it. I have had good results from having the patient wet the finger and dip it in tooth-powder, particularly one containing a little myrrh or quinin, and massaging the gum, after having brushed the teeth with powder. If much friction is needed, a little powdered sulfur applied on the finger will increase the friction. As a rule, the use of detergent drugs in massage is dangerous, and should be carefully watched.

In regard to the comparative merits of fixed and removable bridges serving as splints in pyorrhea cases, it is difficult to dogmatize, especially since the innumerable variations of the cases presented have to be treated as individual cases, scarcely two ever being alike. As a rule, I find that teeth that are left free in their own sockets recover sooner than those that are held rigid by a splint. This, of course, is largely dependent upon the extent of absorption of the supporting structure, and the liability to continued irritation from malocclusion. For this reason, and also the reasons given by the essayist, I prefer temporary retention to the fixed splint or any such radical operation as that advocated in the paper. The advantage of a temporary fixture is the possibility of avoiding a fixed retainer, or such a formidable operation as is suggested. In the large majority of cases the teeth can be temporarily retained by the use of ordinary brass ligature wire, such as is used by orthodontists. The orthodontic arch is another valuable means for temporary retention. By these means the teeth can be held in approximate position, with just enough freedom of movement to afford the stimulation to the root environment during occlusion required to cause healthy nutrition, and sufficient recovery in time to justify the removal of all retention. These appliances can be so adjusted as to allow perfect cleanliness, and they can be changed or modified so easily that in suitable cases they are much to be preferred to any fixed bridge work. There are, of course, cases where many of the teeth have been lost, and some form of bridge work and splint in combination becomes necessary. In such cases, I have first used the temporary splints to secure recovery of the peridental tissues to a normal condition, and then have had satisfactory results from fixed bridges.

The operation suggested by the essayist is similar to that suggestd by Dr. W. V-B. Ames,* and I should object to it on the principle that it involves the destruction of the pulps in teeth that are practically sound, also because it involves banding or capping of the roots at a point where extreme skill is required to produce a condition that is even tolerable by the tissues. Banding or capping undoubtedly renders prophylaxis difficult and uncertain. I do not wish to put my judgment against that of Dr. Hartzell, who has had so much more experience in dealing with this condition, and who I am sure would not advocate a procedure had he not thoroughly tested it out. I have never been able to satisfy myself that the destruction of pulps in teeth affected by peridental inflammation is necessary in any considerable number of cases. Pulps must be extirpated in cases of encroachment of dental caries and uncontrollable sensitiveness, but in my judgment pulp extirpation should not be resorted to as a means of curing peridental troubles, because I know that these conditions can be cured without resorting to this procedure, and also because I am convinced that in a pulpless tooth the peridental attachment will certainly degenerate more rapidly than in one in which the pulp is vital. It is my opinion that permanent cures of pericementitis are more practicable in teeth with vital than in those with dead pulps. It is practically impossible to keep a root surface smooth in a pulpless tooth. Besides, the additional hazard of bad root-canal filling and the resulting apical trouble must be taken into account, this being no unimportant consideration in our decisions as to methods of procedure. I have no doubt that the essayist's method will be of great service in some cases, and that operators possessing the skill and judgment of Dr. Hartzell can use it advantageously in many cases, thus adding materially to their resources; but at the same time I fear that in the hands of practitioners of average skill and immature experience, the virtues of the procedure will be endangered, and more harm come from its use than benefit.

The essayist's other suggestion of attaching plates and saddles to isolated teeth is also liable to result in disaster in teeth having a tendency to peridental trouble. In the majority of cases, the retention teeth will become affected, and be lost in a few years. We should like very much to see our way clear to adopting the removable splint in the treatment of these conditions, as it certainly possesses more sanitary features, but our experience has led us to have more confidence in the fixed bridge for the sake of permanence.

Dr. J. D. Patterson, Kansas City, Mo. It surely must be said that when disease of the gums has progressed so far as to involve considerable gum recession and loss of underlying alveolar attachment, a recurrence of the trouble after the initial treatment is more rapid than at its first appearance. It therefore is of vital interest to know how best to avoid its recurrence, and our essayist deserves high praise for bringing the subject to our consideration.

In advanced cases of pyorrhea we do not anticipate more than satisfactory relief and comfort in the affected tissue. A "cure" under these circumstances is a misnomer for that term, to the patient's mind, involves the restoration of the lost tissue and a return to original conditions, which can only be expected in the first stages of the disease. The question therefore is, how we can prolong or render permanent the relief which we have obtained after instrumentation. To attain this end, several methods have been suggested, which may be divided, however, into two, viz (1) local sanitary measures, and (2) systemic treatment.

In the first class we confine ourselves

* See Transactions of the National Dental Association, 1901, page 119.

to all means of preventing irritation and infection by various mechanical means and by the local use of antiseptics, germicides, absorbents, stimulants, or cauterants. In the second class we seek additional aid from drugs or serums acting systemically, and the question before us therefore is, Which method is the most potent in restoring the health of the involved tissues? Does the employment of drugs or vaccines retard or prevent the recurrence of the disease after operative skill and scrupulous hygiene have been exhausted?

Let it be understood that the question of drugs should not be considered until after all mechanical skill and after-care have been exhausted; and those who proclaim that vaccines render unnecessary much of the surgical removal of irritants —and they are not a few—do not, I think, merit the least consideration. We are prone to be slaves to drugs. In these days dental and medical literature are full of cure-alls, as from time immemorial, yet it can be noticed by the careful observer of the trend of current thought that more and more reliance is being placed upon good food and diet, fresh air, sunlight, reasonable exercise, plenty of sleep, and freedom from care, and many great minds have thrown off the shackles and have declared that drugs are rarely, if ever, actually curative in their effects in systemic conditions.

When some twenty years ago the systemic treatment for pyorrhea was first advocated, I hailed it as the crowning relief, and made diligent use of this therapeutic method, said to be effective. Careful observation, however, has entirely failed to show the benefits of this or any other remedies more recently brought to notice. Now we are strongly advised to adopt the vaccine treatment, and the pages of our journals are filled with reports in which relief or cure is supposed to have been effected. This reminds us that if one is prone to believe a certain thing, he can find any amount of evidence in support of his contention. Our knowledge of pathology is so limited that we would gladly call to our aid some therapeutic measures, but the actual benefits derived from drugs are difficult to determine. We have all heard of cures or improvement in pathological conditions in which absolutely no drugs have been administered. They "take up their beds and walk," even though no "laying-on of hands" has been practiced. So we must go very warily when we say that drugs have produced this or that cure, and remember that the *vis medicatrix naturæ* may have had a hand.

A very remarkable paper has recently been published from the pen of Dr. Beverly H. Robinson of New York, who has spent a lifetime in hospitals and private practice. Among other statements he says:

> All medical men today who are thoughtful and informed recognize fully how much more important it is to prevent disease than to cure it. Indeed, what is termed a cure is not in any strict sense a cure at all, nine times in ten, in acute disease, medical or surgical. Nature with intelligent guidance, which usually means little or no active interference, works out the ultimate well-being of the patient so far as may be. Of course, I do not wish to say for an instant that there should not be help rendered in a proper and judicious way. This may be given by a good and reliable nurse, sometimes without much, if any, medical supervision on the part of the physician or surgeon; again, with oversight and instruction from time to time by the latter. But as to very frequent counsel or advice, acting from either source, it is often more than questionable whether or not benefit results. . . . Do we really cure chronic diseases? I fail to have seen it in the large majority of instances. We simply render them more bearable, and by modifying or lessening symptoms for a shorter or longer period, we give comparative ease and comfort, and no doubt also prevent at times the development of certain untoward sequelæ. If the foregoing be admitted as true, doesn't it seem far better to interfere medically or surgically as little as possible? Doesn't it seem wrong to give medicines to correct what at best is doubtful as to origin and consequences, or to use the knife except where the evident condition and natural results amply justify it? . . . Perhaps there are a few exceptions, because up to date we still acknowledge a few specific drugs. But apart from these, I challenge my affirmations to be gainsaid successfully.

In the light of these extracts, what becomes of the claims that a diabetic patient must first be treated for that complaint ere local surgical treatment of concomitant pyorrhea shall be instituted? What of the claims that faulty metabolism must be corrected before local surgical treatment avails? What of the claim that vaccines will be the coming antagonist to pyorrhea alveolaris, and that local treatment is unsatisfactory? The advocates of these measures with one accord claim that pyorrhea is caused by "faulty metabolism and its irritating end-products," and that first of all faulty metabolism must be eradicated or the "opsonic index raised." How soon do these men expect to correct and cure faulty metabolism, if it has become well enough established to cause pyorrhea? Beverly Robinson says *this cannot be done;* that nothing more can be done than to alleviate. In the very last work on pathology by Adami we find that the evidences of faulty metabolism do not come at once, but after a long time of high living, alcoholic indulgences, or other bad habits, if it is not caused by hereditarily predisposed tissue.

The whole weight of the most recent and best authority proves that serious faulty metabolism becomes manifest after long abuse of proper nutrition, and that its cure is well-nigh hopeless. Dr. Beverly Robinson would certainly place this disease in the class that drugs would never cure.

Those who preach the virtues of systemic treatment for pyorrhea must necessarily find systemic conditions to combat, and so they have made the strange pronunciamento that all, or nearly all, who suffer with pyorrhea are on the brink of the grave. One extremist says that those of his patients who have pyorrhea are syphilitic; another that they are usually tuberculous; another hints at degeneracy, while a large coterie sing the song of waste end-products and the uric acid diathesis.

In my opinion, rational "post-operative treatment" consists in the maintenance of perfect sanitation secured by proper brushing with a proper brush and plenty of powder. The interproximal spaces must be cleansed of food remains and glutinous deposits inviting fermentation, by the careful use of Cutter ribbon floss and of a high-power blunt-pointed syringe charged with a salt solution, in order to reach and remove all matter which would soon become irritative. This latter work should be accomplished by the patient under the operator's careful guidance, or, if that is not possible—and often, it seems, it is not—the operator himself should do this cleansing at frequent sittings, all with the express and positive idea *absolutely to divorce the dental organs from any form of irritant whatever.* Instead of drugs and vaccines, if any prejudicial systemic conditions exist, open air, golf, tennis, walking, the drinking of plenty of pure water, sleeping in the open air or with wide-open windows should be prescribed, thus stimulating phagocytosis and the bactericidal action of the blood serum until the "opsonic index" is raised to normal.

In hundreds of cases positive relief has been thus assured, and "so far as the mind of man runneth," or science has proved, there is little necessity for deluging the internal economy with lithia compounds—breeders of appendicitis—or by injecting dead bacteria which may relieve one condition and yet cause a graver one.

The essayist is a careful and successful specialist in pyorrhea, and his paper is a distinct addition to the literature upon after-treatment in cases of gum disease, such treatment being entirely of a local character, the writer ignoring, apparently, the benefits supposed to be derived from systemic treatment. I cannot criticize his position, as it coincides with my view of the matter, but considering the prominence which is being given to systemic remedies, especially to vaccines, in dental literature and at dental conventions, it would seem that the essayist should have noticed these as belonging in the speculative field, at least, of post-operative treatment.

The essayist's observations upon conditions following surgical treatment, and his description of the methods by which a cure or relief can be rendered permanent, are to be commended, though the use of a stain—composed of zinc iodid

15 gr., potassium iodid 15 gr., iodin crystals 15 gr., glycerin and aqua 4 drams each—by the patient as a "revealing" stain for the purpose of detecting fermentative plaques should perhaps be criticized. This preparation is suitable enough for the dentist's use before and after instrumentation, but it is too potent, we think, for frequent domestic use, nor is it necessary, for if brush and powder are employed correctly, no fermentative patches will remain to be revealed, save in concealed interproximal spaces not easily viewed.

Considerable space has been devoted in the paper to the important consideration of retainers, but it seems hardly appropriate to consider these under post-operative treatment, for I think that in nearly all cases retainers should be applied before instrumentation. Teeth that are so loose that their movement annoys the patient, precludes cleaning with the brush and prevents healing, can scarcely be scaled until they are firmly held in position, and the most suitable time for splinting them is prior to the surgical procedure. A fixed splint of one form or another is placed in such a way that the scaling is not rendered difficult, and the cleansing with brush and points can be perfectly accomplished.

The remarkable splint bridge described in the paper, made by cutting the teeth off at the gum margin, placing a pin and cope on the root permanently, soldering the copes together, and placing a removable bridge upon that foundation, would seem an unjustifiable appliance unless the crowns of the teeth were in an advanced stage of caries. Every practitioner, moreover, who has given attention to this subject knows that such dental arches as have been attacked in their entirety by this disease usually exhibit good teeth, free from caries. The expense, also, of such a complicated procedure would, it seems, render it prohibitive to the large majority of patients. Each operator, however, has his own peculiar way of accomplishing satisfactory results, and each case may demand a different method for reaching the desired end.

Dr. Wm. Crenshaw, Atlanta, Ga. I have been very greatly interested in the discussion of Dr. Hartzell's paper, as I am with everything pertaining to pyorrhea, because I am doing that kind of work exclusively. I think Dr. Patterson's ideas as to post-operative treatment are most sound and correct. Dependence on drugs of one kind or another is hardly to be countenanced in this day and time; there was a time when drugs were depended on to do everything. Fifteen years ago I asked Dr. James Truman what antiseptics he would use in pyorrheal pockets after instrumentation to effect, or assist in, a cure of pyorrhea. He opened my eyes for the first time, by asking me what need there was for an antiseptic in a pocket from which all necrotic tissues that had established and maintained the irritation had been removed by proper curetment. "Well," I replied, "would it not be well and safe to introduce a positive antiseptic carried into the pocket for the purpose of killing any form of bacteria there?" His answer was that if any bacteria or irritating material were left in a pocket, it would not be disposed of by antiseptics. He said, "If you can do it that way, what is the use of doing anything else? Why not place the antiseptics in the pockets and have the cure at once?" I have proved to my satisfaction that if the pockets are properly cleansed by removing all incrustations from the roots, and any patches or vestiges of necrotic membrane sticking to the surfaces of the teeth—then they may be filled with any one of three dozen antiseptics, and a cure will be effected. From experience I have found that the pockets will be cured without the injection of any antiseptics whatever. I have proved this convincingly by treating the teeth on one side of the mouth by injecting antiseptics in the pockets, and limiting myself on the other side to as perfect instrumentation as possible, and the pockets not injected with antiseptics became quite as healthy as the others. Any operator can prove this to his satisfaction by a trial.

Dr. E. A. Lundy, Los Angeles, Cal. I am in hearty accord with the remarks of Dr. Patterson and Dr. Crenshaw.

Dr. Patterson's suggestion of retention before cleansing seems to be very advantageous. I have resorted to relieving all malocclusion, but have never inserted permanent retentive appliances before instrumentation, and I fully appreciate Dr. Patterson's useful suggestion.

Pyorrhea is not caused simply by malocclusion or improper care in cleansing the teeth, although these are both important etiologic factors. In my opinion, however, seventy-five per cent. of cases of pyorrhea are caused by malnutrition. I have myself suffered very much from pyorrhea for a number of years. I was able for a time to be under the care of Dr. Younger, formerly of San Francisco, but afterward was limited to what treatment I could apply personally. Those who treat pyorrhea know that one cannot properly care for his own teeth, so my teeth became very badly incrusted.

Neither Dr. Patterson nor the essayist, if I remember correctly, spoke of this disease with a view to dietetics. I have had great success in dietetic treatment when I have been able to obtain the patient's co-operation. The patient is put on a non-uric acid diet as strictly as possible. We have to learn, of course, from the patient's report from time to time as to a desirable or necessary change of diet. I usually ask my patients at the first consultation whether they indulge in stimulants such as tea or coffee, particularly coffee. Generally I find that when the patients refrain from tea or coffee, I am able to cure them more quickly.

Dr. M. L. Rhein, New York. Having been asked to say a few words, I would like to protest against the tenor of the discussion. The essayist's purpose is not being adequately served when a discussion is raised on etiological factors, which Dr. Hartzell did not intend to consider in his admirable paper. Realizing that the treatment of these conditions does not vary, no matter how much different practitioners might quibble over their genesis, he confined himself solely to treatment. Consequently, it seems bad taste to bring up some phases which the essayist has carefully avoided, because he desired to confine the discussion to methods of treatment.

Nevertheless, I must protest against the peculiar views on pathology that Dr. Patterson has given utterance to. It requires a peculiar imagination to see a practical phagocytosis ensue from exercise. The raising of the standard or quality of certain substances in the blood not entirely known even yet, which is spoken of as raising the opsonic index, is something entirely apart from phagocytosis.

It is a great pleasure to approve of the essayist's methods, and I would especially approve of the teaching opposed by Dr. Patterson, the essayist contending that the retention apparatus should not be applied to teeth before treatment. If Dr. Patterson had said that, when the teeth are very loose, some temporary splint should be applied during treatment, he would have met with approval. The treatment of these conditions almost invariably is complicated with a correction of malocclusion, and only when treatment has been concluded can there be any positive knowledge of the position which the teeth should maintain. It is not uncommon to see a splint fail to secure the benefit intended because the teeth have not been placed in the most desirable position. Twenty-five years ago I first called the attention of the dental profession to the great value obtained by splinting loose teeth together permanently. At that time I carefully illustrated the steps taken in bringing them into proper position, and demonstrated the splint as the locking device, after the parts were healthy and the malocclusion had been corrected. This doctrine has stood the test of all this time, and consequently I strongly protest against a form of treatment that is generally followed by disaster.

Dr. Hartzell (closing the discussion). I have no wish to refute the statements of the men who have been kind enough to give my paper attention, with the exception of possibly two remarks that have been made. I did not bring out that phase of post-operative treatment which deals with the raising of the opsonic index or the increasing in the blood-stream of those substances which have the power to inhibit bacterial progress in the system. I had expected to take some little part in the discussion of another paper that dealt with that particular subject, but I did not undertake it, for the reason that in ninety-nine per cent. of cases treated surgically such post-operative treatment is unnecessary. Perhaps I am putting the percentage a little high, but I wish to leave the idea in the minds of my hearers that the main points brought out by Dr. Patterson and those who followed, and in my paper itself, would tend to show that such systemic treatment is not necessary. There are a few cases in which we can build up resistance by the use of vaccines, and in these few cases it is well enough to resort to vaccines; but these instances are so few, comparatively, that it is not necessary to consider them under the heading of post-operative treatment.

I want to make another statement. Of the splints described, three out of five were attached to teeth the roots of which were not much more than an eighth of an inch long, and have been in the mouth from three to five years. No matter whether or not I was justified in putting splints on these teeth, I will say that none of them would have been preserved until today if I had not inserted that appliance, and I leave it to your judgment whether we should insert a splint and fix the teeth, or leave them loose in the mouth.

Section III then adjourned until a later session.

WEDNESDAY—*Evening Session*

Section III was called to order on Wednesday, September 11th, at 8.30 o'clock, by Dr. A. R. Melendy, president of the association, who introduced Dr. W. H. G. Logan, chairman of Section III, as the presiding officer of the evening.

Dr. LOGAN announced that the music of the evening would be furnished by local talent, through the courtesy and kindness of Mr. Bristow, superintendent of the Sunday-school of the Calvary Baptist Church of Washington.

Dr. Logan then introduced Dr. H. W. WILEY, the first speaker of the evening, who delivered an address entitled "A Consideration of the Effects that Impure Foods and Adulterated Drugs Have upon the Human System," as follows:

A Consideration of the Effects That Impure Foods and Adulterated Drugs Have upon the Human System.

Mr. Chairman, ladies and gentlemen,—When I came into this room, realizing that I had not long been a member of the party, and seeing the severe simplicity of the garb of the male members (on account of the heat many were *en manches de chemise*), I wondered if I had struck a democratic ratification meeting, but when I heard the shouting and tumult, I knew I was mistaken, and that I was in a convention of "bull-mooses." My principle is to catch them coming and going, and so I talk for both.

FOOD AS OF PRIME IMPORTANCE TO HUMANITY.

Eating is the greatest industry of humanity; we know that it is widely pursued by all civilized nations, and those of the missionaries who come back tell us that it is practiced also by the savage cannibal. I need not substantiate this, although I have been put down in the Ananias club, but if I were called upon to substantiate it, I should undertake to determine what percentage of human endeavor is devoted to supplying the food of the people. It would certainly be a great proportion of all human effort, if we had any method of getting at the truth of the matter. The principal outlet, I believe, for the salaries of most laboring men and of all wage-earners of every description is to supply the wants of their bodies and their families' bodies; therefore I say it is the principal industry of humanity, and it is that industry which requires of man the greatest amount of his effort.

NECESSITY FOR CONSERVATION OF THE TEETH, AND SUPERIORITY OF AMERICAN DENTISTRY.

Granting for the moment that this is a true statement, it follows that everything connected with that industry is of prime importance, and I take it that all agree with me that, after the cook, the teeth serve the most important function in the nutrition of man—even more so than the cook, for if we have good teeth we can eat raw foods and do not need a cook. It is a pleasure to me to see assembled and be able to speak to such a body of men, whose duty it is to care for the teeth of humanity. I speak with the greater pleasure on this occasion, because it is recognized the world over that American dentistry leads the world in its profession. There may be nations whose physicians are greater—I doubt it, but there may be; there may be nations whose surgeons are more eminent—I doubt that too, but there may be; but I think there is no question of the fact that American dentistry stands first among all the nations of the world. No better proof of this could be given than to point to the success which many American dentists have attained in foreign countries, simply because they have brought into those countries improved methods in their science as taught and practiced in the United States. Therefore I am addressing tonight a body of men who are leaders in their profession, and who have come from all states of this country to take part in the deliberations of this national body.

I am not a believer in that theory according to which one can chew a very little bit of food long enough to make up for a square meal. [Laughter.] I believe in good chewing, and a lot of it. At dinner a very good friend of mine—a man who is somewhat of a valetudinarian and who devotes a great deal of time to thinking what he shall eat for his best welfare—and myself were discussing the subject of nutrition, and he said that the least lapse from the regular course of living might be followed by serious incapacity. I said that I was sorry he had to be so careful; that I for one gave no thought to what I was to eat; that I had followed the scriptural advice about the morrow, as to "what ye shall eat and wherewithal ye shall be clothed"—I let other people worry about that. "Sufficient unto the day," it is further said, "is the evil thereof"—and sufficient unto the day is the food thereof; the thing is, to get enough of it.

Another thought that struck me as I looked at this audience and first thought it was a democratic meeting, was that the democrats had not had a chance at the public crib for more than sixteen years, and when I saw the fulness and roundness of your forms and faces, I was convinced that I was not addressing hungry democrats. You believe, evidently, in supporting in practice the efforts of your profession, and you show in your physical appearance only good nutrition and the good mastication which goes with it. Evidently you either practice on yourselves, or go to your brother to do it. Dog does not eat dog in the professions. So the physician who gets ill can have all the others left to get him well; as one professional brother, you can invite all your professional friends around to attend you, as far as compatible with your own safety; but you do not want to get too many! You know the testimonial Dr. Quack received: "Dear doctor,—My mother-in-law was at death's door. She took two bottles of your remedy, and it pulled her through." [Laughter.]

DUTIES OF THE STATE IN REGARD TO HEALTH PRESERVATION.

We hear a great deal at the present time about medical inspection in public schools, and no one believes in this more than I do. Whatever we may think ourselves about the matter, the fact remains that we are becoming every year more and more socialistic, becoming confirmed more and more in the belief that the state owes us something as citizens; everybody is becoming more sensitive to the idea that the state must care more than it has been doing heretofore for its citizens. We realize it today in the public schools. What right has the state to establish public schools under the doctrine of human rights? None whatever. The citizen must care for himself, and the state has no right to interfere with his education; and yet what would we think of the person who would preach today the doctrine that public education was wrong? No, it is right, and public education is but a step toward socialism—the state does for the citizen what the citizen may do for himself, according to the theory of human rights. We are adopting that idea in education, as well as in the matter of public roads, so that we can all drive automobiles—at least those who have been in practice a few years can do it; our poor farmers of the East cannot do it yet, but they do out West—even if they have to put a mortgage on the farm. Thus we are more and more adopting the doctrine that the state must care for our opportunities. We are also coming to realize that the state must care for the health of the public, and we are coming to it rapidly. [Applause.]

IMPORTANCE OF PRESERVATION OF DECIDUOUS TEETH.

When are we going to begin to care for the health? I should say that in the first years of toothhood—this is a new name!—we should begin to care for the health. The baby's mouth should be as carefully cleansed as the adult's every time it takes a square meal. The little tooth that just puts forth its appearance—and I have seen two in the last month that are the sweetest little teeth you ever saw—must be cared for. [Applause.] I can assure you that I never have taken so deep an interest in dentistry as in the last few months. I have not only made one examination, but about a hundred, to try to see if these young teeth were all right. So I say, in the first days of toothhood the care of the public health should begin. The state should see to it that its citizens are taught these principles of oral hygiene, which they can apply to their own infants in the beginning of their toothhood years. You may say that these teeth are only deciduous. That is true, but there is no reason why they should be lost by decay, because decay is contagious, and if it attacks the deciduous teeth there may be an infection left for the permanent ones, and then those permanent ones may be only as "temporary" as the first. And yet how careless we are, every one, of these first teeth!

Last year, while visiting my farmer, who has three little girls ranging from three to eleven years of age, I noticed that they paid no attention to their teeth at all, and so, in the goodness of my heart, I gave them tooth-brushes and told them how to use them. Some time after that I was back at the farm again, and I asked one of the little girls if she used her tooth-brush three times a day as suggested. "Oh, no," was her reply, "we are saving them until we become grown girls" [laughter]—then, of course, there would not be anything to brush. That was her idea of the way to use the gift; she would not use it in her childhood days, but would wait until she was grown and had no teeth. That is the way people regard the ordinary fundamentals of public health. The important thought to impress on them is that we cannot have good health without good teeth, and yet how often we leave the teeth to rust and be thrown on the scrap-heap early in life! I have seen in the year past girls of fifteen and sixteen years with teeth so badly decayed that they were almost as good as gone, simply owing to negligence on the part of their parents. When I was a child nothing was heard in the public schools of the idea of taking care of the teeth. It was not mentioned in the public schools of that locality. We were taught hygiene of the body in a way, some primitive ideas of living, but never a word of that most important part of personal hygiene, viz, starting infant as well as adult life with a good set of teeth.

Not everyone is born, like Richard Cœur de Lion, with a full set of teeth. That only happens to geniuses, but of course the brighter they are, the sooner they have teeth. My son has two teeth at four months of age. [Laughter.] But whether they erupt soon or late, that is the time to begin to brush them. The teeth are like other blessings. We all know how "blessings brighten as they take flight," and I never appreciate a tooth so much as when I see it coming out of my mouth in the hands of a dentist, because I realize that it is through my negligence that I have lost it. There is no physiological reason why a man should ever lose his teeth; there is no reason why he should not keep them until old age, and I can assure you that, to my mind, there is no better way of reaching old age than by the preservation of the teeth. [Applause.]

DENTAL INSPECTION OF SCHOOL CHILDREN ADVOCATED.

For this reason, while I approve of medical inspection in schools, I approve also of dental inspection. Although this is no new idea, I insist that we should care for the deciduous teeth, and preserve them before the child goes to school. The state can hardly go into the homes and command that we shall preserve our children's teeth, but we can preach at least to the rising generation, so that when they become parents they will realize the importance of tooth conservation. We cannot perhaps save the teeth that are erupting now, but we can do so twenty or forty years from now, just as I preach the doctrine of saving infants' lives. We cannot save the infants dying at the rate of a thousand a day now, but we can save those that will be born forty years from now by beginning to preach infant hygiene today, so that the new generation will grow up with a new idea and a new purpose, namely, to preserve intact as long as possible that precious endowment that has come to us, which we call life—that mystery which we cannot fathom, that heavenly gift which we should appreciate so much as to care for it so that we may get the most possible out of it. Therefore what I say tonight is not for the children of today—it is too late for them, but for the next ten, twenty, and thirty years, when the child will be taught at the family fireside the principles of personal hygiene before he goes to school. As I have been preaching for the last third of a century the health of the public and the importance of preserving human life chiefly by means of proper nutrition, so I have more and more become convinced of the extreme necessity of saving the teeth for the purpose for which nature intended them.

PREDIGESTED FOODS DISCOUNTENANCED.

That brings me to the fact that our country is being flooded with preparations which are prechewed and predigested, with all kinds of infant, invalid, and breakfast foods, the manufacturers of which have taken the trouble to perform the functions not only of mastication but also of digestion. By this feeding of mankind with partially digested food, what happens? Just what happens to everything that is not in use. The next time you take a trip on a railroad, look out at the silver-like appearance of the rail that is in use, and then at the one at the siding which is rusting away. Both tracks are made of the same steel, probably put down at the same time and in the same way, but one is bright and shining, and the other is rusting away because it is not in use. So it is with every organ of the human body; there is a legitimate physiological function for it to perform, and the law of all nature is, that if an organ fails to perform the function that nature intended it to perform, its function diminishes in efficiency, and every time we take prechewed and predigested food we injure the teeth and the stomach. After I have lost my teeth I will thank the manufacturer for chewing for me—until I can raise money enough to get an artificial set. After my stomach is gone and is no longer able to perform its functions, then I will thank him for digesting my food for me; but as long as I am in my present condition—I still have a few teeth left, and also a stomach which produces every day a certain amount of pepsin and other secretions necessary to dissolve my food—I do not want anybody to chew for me, and I want to do my own digesting; and I can assure you that I derive a great deal of comfort from both these performances. Even if this is not the best, I like to have the pleasure of doing it myself. In this respect I do not believe in socialism; that is one of the things that I do not want the state to do for me unless I become incapacitated. If you want to lose your teeth as soon as possible, eat prechewed foods, and if you want to ruin your stomach, eat predigested foods. The Lord knows that most of us can digest our own starch, and do not need the chemist to put sulfuric acid in it to dissolve it for us. All the efforts of the makers of the more modernized foods seem to rest on the assumption that we have no teeth and no gastric juices, and both of these assumptions are erroneous. True dental hygiene demands normal, natural foods on which the teeth and the stomach can exercise themselves, in order to perform their normal functions; and I think, in saying this, that I am preaching not only good physiology, but plain common sense, and am voicing the experience of everyone who has taken the trouble to look into this matter at all.

SOME DIETETIC HINTS.

My next theme is how to give the teeth proper food for mastication, which is as important as having the mill to masticate with. The miller may have a good upper and lower millstone, but if he tries to grind pebbles into flour, he will have hard work. So, after we bring into good condition the millstones which nature has furnished, let us bring good grist to the mill. That is the reason why I have made the keynote of my fight for public health, good, nutritious, unadulterated food, because, without this, health is impossible; and in the same way the dentists of this country should do their share in this great warfare for the welfare of the public. This follows as a natural corollary to that which I have already illustrated. After we have secured the nutritious food which is necessary to the happiness and health of man, we must have proper mastication. I am not so extreme on this question, however, as Mr. Fletcher is. I believe in his doctrine, but, like the rest of us cranks, perhaps he emphasizes it too much. Still, I believe in thorough, slow mastication, in careful selection and a proper and generous quantity of food. I am not an apostle of starvation; I do not believe that humanity will be helped by starving. I am a great admirer of Upton Sinclair, but when he says that fasting will cure every form of disease which attacks humanity, I say, "What are you going to do with the man who is dying of hunger? Thousands are dying from that, and do you propose to preach that doctrine to them?" Fasting is good for a man who habitually overeats, and a great many of us are too well and too often fed.

A few years ago I addressed a company of farmers, worth fifteen millions or more each, and as I looked at them at Sherry's, sitting around the table drinking champagne which cost as much as the milk they produced—when you visit one of these farmers they set before you milk and champagne, and suggest that you help yourself, one costing as much as the other—I felt that they were in danger. I am not speaking disrespectfully of these men, but every one of them was eating himself into an early grave. It is said that Napoleon ate himself into Waterloo; that had he not been such a gourmand and had he not dulled his faculties by overeating, the battle of Waterloo would not have been lost by him. And these men were Napoleons of finance, and were eating themselves into their Waterloo as fast as they could. For that kind of people, fasting is good. The man who really works, who puts forth exertion every day to the utmost, is not the man to preach starvation to, but the man who "sits still," as Mrs. Browning says, "in easy chairs and damns the general world for standing up"—he is the man to recommend starvation to. Physiologists all over the world advise us to eat pure food and masticate it well, and that is the doctrine I preach to you tonight.

PREVENTION AS THE AIM.

Let me ask for a moment what is to become of the medical and the dental professions in that day, which I hope is not far off, when disease will be banished from this world, and when all will be born, not with actually sound *teeth,* but with sound germs for perfect teeth, which are not found in all newly-born today. We inherit the tendency to caries, as all know. What is to become then of the physician and the dentist? I have said this summer in lectures before chautauquas that only two really learned professions are necessary to the happiness of mankind, the one the profession of agriculture, the other the teaching profession, to which we all belong—every good citizen is a teacher. When the propaganda for public health has had its full fruition there will be no disease, and as far as we are informed at the present, we would have no need of physicians; and when my propaganda for good teeth has reached its fruition we will have no need for the dentist as he works today; but, as we shall see immediately, physicians and dentists will still be needed in another way. Then I hope, when we are all perfectly well and need no doctors, and when we have good teeth and need no dentists, we will not need many preachers. We will be so good that we will not need anybody to tell us how to get to heaven—we will just get there naturally; and when we do not need any ministers of the gospel, we will not need any lawyers; we will not break the laws. In short, in the Wiley millennium there will be no physicians, no dentists, no ministers, no lawyers, just farmers and teachers—that is the Wilson platform, that's all. [Laughter.] My friends, I am not trying to put you out of business, since, as I have said, there will still be use for the physician and the dentist. We will be employed then for the prevention of disease of the body and the mouth, and then, in those future days of ideal socialism, the physician and the dentist will be employed as officials of the state to look after the health of the state, and their salaries will be in proportion to the good teeth and the health of the people, and as people become sick, and lose their teeth, the salaries of the physician and the dentist will diminish! That is the way in which we will employ the physician and the dentist of the future; but you need not be afraid that you will lose your jobs tomorrow. Somebody will have toothache tomorrow in spite of my talk, and that ideal time is still far off. It is not going to come through any battle of Armageddon, but it will come through the preaching of the gospel of health and the teaching of this generation and the next to care for their children's teeth and health, and not have them die by the thousands, as they are dying today in the United States. Nearly a thousand babies not yet one year of age have closed their eyes today in this country of ours, and this can be avoided when the mothers and fathers are educated to understand the principles of hygiene, and know how to bring healthy children into the world, as well as care for them after they are born; these will grow up to be healthy men and women, and gray hairs will be as common then as bald heads are today [laughter], and we shall not look with disfavor on age, as we do at the present time. Then we shall have four grandfathers and grandmothers, instead of none, and happiness and prosperity will come to this country; not wealth for the few and poverty for the many, but an even distribution of the wealth of the country, according to the individual's effort and usefulness, and everyone will have an opportunity to make an effort for the good of the world, and health and happiness and contentment will be the lot of humanity. [Applause.]

Dr. Logan, the chairman, then introduced the next speaker of the evening, Dr. George Edwin Hunt, Indianapolis, Ind., who spoke on "Teeth and Health," as follows:

Teeth and Health.

Mr. President, ladies and gentlemen,—Our distinguished guest of the evening, as you all know, has been engaged for some years in harassing those who desire to put impure or adulterated foods and impure or adulterated drugs before the American people, and has displayed such pernicious activity in this direction that naturally those who desire to profit by that sort of business did what they could to make it unpleasant for him—and I rather imagine from the action he took last March that they succeeded in their endeavor. Since he resigned his office in Washington, those manufacturers of impure foods and drugs have shown renewed activity, and this reminds me of the story of the little mouse that lived in a wine-cellar. One day a boy came down into the wine-cellar to draw some wine, and before departing did not turn off the spigot fully, so that a quantity of wine dripped on the floor. The little mouse soon afterward found a little pool of wine and tasted it. He liked it so well that he tasted it again, and after the wine was gone, the mouse, feeling pretty good, climbed up on the wine-keg, looked around, and said, "I wonder what has become of that blamed old cat that has been hanging around here for the last week." [Laughter.]

The Program Committee announced that I would speak on "Teeth and Health," and now that I have the floor, I want to say a few words on the status of the mouth hygiene movement before taking up the subject assigned to me by the committee.

PRODUCERS AND NON-PRODUCERS AS INFLUENCED BY HEALTH.

A socialistic writer recently observed that there are three ways of making a living—begging it, stealing it, or working for it; and furthermore, that since it was manifestly impossible to beg or steal something that does not exist, the workers of the world must first create the living which the beggar begs and the thief steals. I do not believe that I can divide humanity into beggars and thieves and workers, because there are some people whom we cannot classify under any of these divisions, and so I would prefer to classify everyone as either producers or non-producers. Producers are those who contribute to the mental, physical, or material welfare of themselves and others. Men may differ in their classification of their fellow men as producers or non-producers, but in my mind this classification is perfectly clear. I believe that tramps, hobos, criminals, bankers, brokers, "middle men" of all sorts, and the men of the army and navy, so far as they are men of war, are non-producers, and I believe the rest of us are producers.

There are two kinds of producers, the direct and indirect. Direct producers are those who actually create things necessary to life, who grow products on or in the ground, or dig raw material out of the ground which can be converted into useful things. These are the agriculturists, the stock-growers, the miners and the artizans who take the raw material and convert it into clothing, houses, etc., for our citizens' comfort and well-being. There are a number of other people who do not directly produce, who do not create the materials necessary to life, but who are nevertheless necessary to our life, and in this class of indirect producers I would place all people who look after the health and intellect of the citizen. The physician and the dentist are indirect producers, because they enable the direct producer to produce to his fullest capacity, or at least to a fuller capacity than he would otherwise possess.

There are other men who are rightfully called indirect producers, because without their aid direct producers would not produce their full capacity. For instance, it is necessary that the direct producer be intelligent, that he may know how best to produce his product, and it is necessary for someone to teach him how to achieve this; therefore the pedagog is an indirect producer. Furthermore, in order that the direct and the indirect producers both may cultivate their intellectual capacity to its limit, we must have writers, musicians, and poets, all of whom are indirect producers who contribute to the mental welfare of the world. The distinction, therefore, between those who serve mankind, the producers, and those who do not serve mankind, the non-producers, can be quite sharply drawn.

The mouth hygiene movement is but a part of the grand, world-wide movement toward the bettering of the physical, mental, and material condition of the people, the increasing of the efficiency of our producers, and the decreasing of the number of our non-producers. The mouth hygiene movement, as the phrase implies, is especially concerned in the betterment of physical conditions, and is therefore intimately allied with the tuberculosis campaign, as well as all other movements toward better health. Physical incapacity reduces production more than any other one cause. It makes non-producers of those who should be partial producers, and partial producers of those who should be full producers. Perfect physical condition is necessary for anyone who would produce to his full capacity.

ORAL HEALTH AS INFLUENCING MAN'S EFFICIENCY.

I believe that but few of you are producing to your fullest capacity, are doing all you are capable of doing. I know I am not, and I doubt if any of you are, but the more nearly we reach our full productive capacity, the more we add to the material welfare of the nation and of each individual in the nation. I have said that there is no one other factor which reduces the capacity for production more than ill health. It is true that a good many non-producers are not in ill health. Some non-producers are too lazy to work, others do not fit their groove in life—they went to dental colleges when they should have become streetcar conductors; but ill health is responsible for the largest number of our non-producers. Thirty per cent. of the unemployed are out of employment because of ill health, therefore the less ill health there is, the less will be the number of non-producers, and the greater will be the united product of the workers.

Among the many factors which produce ill health in individuals, limit and retard the output of their work, and are responsible for a large portion of these two classes of partial producers and non-producers, I believe the condition of the mouth to be a leading one. Let me give you my reasons.

METABOLIC DISEASES DUE TO ORAL CONDITIONS.

There are two classes or divisions of diseases which are largely influenced by the condition of the mouth. These are, first, diseases of faulty metabolism, or faulty nutrition, to use a more familiar term. Diseases of faulty nutrition are very largely due to oral conditions. Some of these diseases of faulty nutrition are due to the fact that the patient has not enough teeth to chew his or her food properly, while others are due to the fact that the condition of the patient's mouth is such that he is continually swallowing quantities of poisonous matter. Among the diseases due to faulty nutrition I might mention rheumatism, cancer, gout, gastritis, diphtheria, appendicitis, diarrhea, biliousness, constipation, arterio-sclerosis, diabetes, and various other manifestations of auto-intoxication. Three forms of food are necessary for the nurture of the body, viz, carbohydrates, proteids, and fats. The digestion of carbohydrates—viz, starchy foods, such as grain products of all sorts, potatoes, sugars, etc.—actually begins in the mouth by the action of the saliva upon the food. It is certain that if the digestion of these foods is not started properly, it will not be completed successfully.

For the digestion of proteids and fats, it is necessary that they be well divided and subdivided before passing into the alimentary canal and being acted upon by the digestive juices. The stomach has no teeth, as has been aptly said, and unless that comminution takes place in the mouth, it will be but imperfectly accomplished. So one can readily see how these diseases of faulty nutrition depend on the condition and use of the mouth. If a person has no teeth to chew food with, or if the teeth are in bad condition, digestion cannot be properly begun. If the mouth is in such a condition that the individual is taking into the stomach quantities of pus along with the food, digestion cannot properly be performed, and faulty metabolism results. Furthermore, even if the mouth is in good condition, and there are enough teeth to masticate the food, but the teeth are not used properly, diseases of faulty metabolism will occur. They frequently occur in patients who, although their masticatory apparatus is splendid and their mouth in fairly clean condition, bolt their food instead of chewing it.

INFECTIOUS DISEASES DUE TO ORAL CONDITIONS.

The second class of disease-producing factors especially under the control and influenced by the condition of the mouth—more so than the average person realizes—are the various infectious diseases. Five times as many micro-organisms pass into the lungs through the mouth as pass through the nose. The nose has a series of filters which sift the inhaled air and remove a great many micro-organisms even though they may be in the air when it enters the nares, but the mouth has no such protection; therefore many more micro-organisms reach the lungs through the mouth than through the nose. This, of course, is true to a greater degree of the stomach than of the lungs. Seventy-five per cent. of tubercular trouble is the result of infection through the mouth. Tubercular trouble occurring in the glands of the neck is claimed to be due either to infection from tubercular tonsils or from carious teeth and diseased gums. Pneumonia is another disease largely due to the condition of the mouth. It has been proved that the tubercle bacillus and the pneumococcus will exist in carious cavities in teeth for forty days; therefore if cavities are present in the teeth, it may readily be seen what the effect may be if the patient's health deteriorates at any time during these forty days. Dr. Evans has told about the epidemics of scarlatina which had to be combated in the schools of Chicago; of the children who had to be sent away and quarantined until they were well, and how, when they were allowed to return, the epidemic of scarlatina broke out again. For a long time the cause of this recurrence could not be determined, until the sterilization of every mouth and the filling of every cavity in the teeth was insisted upon before these children were permitted to return to school; and in that way the epidemic was stopped. The school authorities of Valparaiso, Ind., have had the same experience.

Typhoid fever is another disease in which the condition of the mouth plays a large part. In a neglected mouth with carious teeth, food débris collects around the teeth, and the opportunity for the cultivation of the typhoid bacillus in such a mouth is great. On the other hand, a person may harbor innumerable typhoid bacilli in the mouth without being harmed, if he has no carious teeth and if his physical condition is perfect. Some of these bacilli will probably pass into the stomach, but if the person's condition is perfect his physiological resistance will be sufficient to throw them off, as the field is not ripe for them. But inside of ten, twenty, or thirty days this same person's condition may change so that the typhoid bacillus finds the alimentary canal an easy field in which to propagate, and then typhoid fever may be the result. So a person may have typhoid fever two or three weeks after having been exposed to it, if the state of the mouth favors retention of the bacillus. The condition of the mouth, therefore, is of serious importance in stamping out the different contagious diseases. A neglected, septic mouth, with carious teeth in which food is constantly putrefying, will bring about an inflammation of the mucous membrane the effect of which will be felt by the mucous membrane of the throat. The membrane becomes inflamed, the physiological resistance is depreciated by the presence of these conditions, and the result is that the diphtheria bacillus finds a favorable field upon which to grow and propagate. In the same way a great many other of these infectious diseases may be produced through infection in the throat.

UNCLEAN MOUTHS A MENACE TO THE COMMUNITY.

I would impress upon you, then, that the condition of the mouth and of the teeth is not a matter of only local importance. It affects the individual's whole body, and not the mouth alone. Its influence goes even farther than that. I believe honestly and earnestly that the time will come when the condition of a person's mouth will be taken as much into account by the municipal authorities as the condition of his morals is taken into account to some extent today. The time will come when no one will be allowed by the municipality to carry around an immoral mouth, as it were. This is only a question of the *mores,* of the custom of the time. At present the opinion prevails that the condition of a person's mouth is his own private affair, and if you went up to a man on the street today and told him that his mouth was a menace to the community, and he must either clean it or go to jail, he would probably knock you down or consign you to a place which is even hotter than Washington—if any such place there be. The time is coming when a dirty, immoral mouth will be considered as much a menace to the community as an infectious disease, and the person with such a mouth will be quarantined the same as the person who has smallpox. And that is the thought I want to leave with you—that the condition of a person's mouth is not only of importance to that person, but is a matter of moment to the community at large; that a dirty, uncared-for mouth is not only a source of disease to the individual, but also a menace to the health of every person who comes within a reasonable distance of him. When viewed in that way, it can readily be seen that the condition of your mouth is not only your business, but is my business, and everybody's business; it is the business of the community.

Dr. J. P. Buckley. Mr. Chairman, I move that we extend a rising vote of thanks to Dr. Wiley, and also wish to include Dr. Hunt, the singers, and others who have taken part in the program.

The audience then rose as a vote of thanks to those who had taken part in the meeting.

Section III was then declared adjourned *sine die.*

(Report of clinics to follow.)

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held January 28, 1913.

The regular monthly meeting of the Academy of Stomatology of Philadelphia was called to order by the president, Dr. Joseph Huggins, in the lecture hall of the College of Physicians and Surgeons, Tuesday evening, January 28, 1913, at 8 o'clock.

Dr. Huggins announced that since the last meeting he had taken the liberty of appointing a committee to draft resolutions on the death of Dr. Wilbur F. Litch, such committee being Drs. Gaskill, Lee, and Jaquette, and called upon Dr. Gaskill for a report of the committee.

Dr. J. H. Gaskill then reported the following resolutions, which were adopted and were recommended to be published by the Academy:

Whereas, the Academy of Stomatology learns with deep regret of the death of Dr. Wilbur F. Litch, one of its most distinguished Fellows; and

Whereas, we feel that we should spread upon our records a testimonial of the esteem in which this society held him as an author, teacher, and editor; and

Whereas, while owing to failing health for several years Dr. Litch had not been active in society work, his death will be felt by the profession in general, and to those near him the loss will be a personal one; therefore be it

RESOLVED, That in the death of Dr. Litch the Academy feels that, in common with the dental profession as a whole, it has lost one of its most honored members; a man endowed with most scholarly attainments, kindest of dispositions, and noblest of characters; and be it further

RESOLVED, That a copy of these resolutions be sent to Dr. Litch's widow, with expressions of our sincere sympathy.

J. HOWARD GASKILL,
ALFRED P. LEE,
W. A. JAQUETTE,
Committee.

Dr. Huggins then announced as the first essayist of the evening Dr. E. J. GREENFIELD, Wichita, Kans., who read a paper entitled "Implantation of Artificial Crown and Bridge Abutments."

[This paper is printed in full at page 364 of the present issue of the COSMOS.]

Discussion.

Dr. M. H. CRYER. This is a very interesting subject indeed, but whether the operation is a success from a surgical standpoint depends on the length of time this root will remain in position. The implantation of roots in the manner described by the essayist will be a very valuable operation to the dental profession, if the implanted root will remain in the jaw for any appreciable length of time. I am, however, somewhat afraid that this desired result will not be as permanent as the essayist seems to think it will be. He is very sanguine in regard to this method of implantation of roots, as all men are who have something new to present, but it will require the test of time for us to determine whether or not operating in this manner will be worth while.

Judging from my studies of the anatomy and formation of the jaws, I am of opinion that there are very few places where I could insert such a root or crib in the jaws. A few minutes before I started for this meeting, I ran into my workshop and gathered together a few specimens of jaws to show tonight. In this case [demonstrating] we have a section of the full face; here we have the two orbits, and here the maxillary sinus on each side of the nasal chamber. In the center the alveolar process is absorbed until it is not more than two or three millimeters in thickness. Now, if we undertook to implant an artificial root such as has been described by the essayist in this process in any position, we should simply go into the maxillary sinus or into the nasal chamber, and in this case we should go into both; in this case, therefore, such an operation would be neither possible nor practical.

Here is another specimen in which there is a good alveolar process, but the roots bifurcate, and the antrum goes down between the roots. Looking into the maxillary sinus on either side, we see a thin layer of bone covering the apices of the roots, and we readily see that if we inserted an artificial root here, we should go into the sinus.

Here we have another bone, somewhat similar to the last. Looking into the maxillary sinuses on either side, we see a half-dozen conical processes covering the roots, and again in this specimen, in fact in almost any specimen I might select, excepting one of a negro skull, there would not be sufficient room to insert a post as deeply as we have here, figuring the depth of the root in proportion to the length of the crown. I am therefore at a loss to know how the essayist manages to implant these artificial roots in the majority of cases. It is possible that in the case of the anterior teeth, the canines, or the first and second bicuspids, there may be room for this operation, because the alveolar process is usually thick here, but in many cases, like this one, there would not be sufficient room in this region.

Take the lower jaw. In this specimen, if one attempted to go into the mandible to the depth of this artificial crib, one would strike cancellated tissue, and at this point, posterior to the canine, be liable to cut into the inferior dental canal. This would produce anesthesia of the lip, which would result in great discomfort to the patient.

Here we have another specimen in which about half of the upper portion of the alveolar process was cut away, leaving nearly half the sockets of the teeth. If one attempted to insert a crib in this jaw, one would drill into the cancellated tissue, which would not afford the support necessary. Right here I should like to emphasize the reason why the natural teeth stand so firmly. Here is a case, for instance, showing the bony walls of the socket with the bracing of the cancellated tissue through the bone in every direction, making a firm socket for the tooth. Now, if we penetrate into the cancellated tissue of the jaw where the tooth has been lost, we lose this bony socket, and have nothing for the cancellated tissue to brace against.

Here is another specimen which shows these bony sockets braced by the cancellated tissue, and making the teeth firm. If we drill into the bone at this point, down into this cancellated tissue, we have nothing to approximate the support that the natural bony socket affords.

I am very much interested in this method, and I like men who try innovations and keep dentistry from standing still or perhaps going backward. Therefore I am very much pleased to have had the opportunity of hearing the demonstration of the method, and will be glad to watch the results in the future.

I wish, in closing, to thank the essayist for coming before our society and offering to us this very interesting paper.

Dr. John B. Roberts. I do not know of anything that I, as a surgeon who operates on various parts of the body, have heard in a long time which has interested me so intensely as this method of implantation therapy brought forward by one of your colleagues of Kansas. This revolution in surgery must delight you who are interested in the mechanical side of oral surgery; and to those of us who are not so closely associated with this branch of surgery, and who take up these methods with some hesitation unless we have an oral surgeon to stand back of us, it must be equally interesting. Looking at this method as a surgical proposition, it seems to me absolutely feasible. So far as I know physiology as it applies to our surgical work in bone, such as fractures, the treatment of deformities, sections of the jaws, etc., the essayist's operation seems to me perfectly feasible. Hence, when Dr. Greenfield tells us that he has tried it successfully, I cannot but believe that his prognosis that it is going to stand the test of time is correct. It apparently is going to be a great advance, like the crowning of teeth, which has been so valuable to many dentists and to people in general. We medical men safely put gold or glass balls within the sclerotic coat of the eye, and in this way improve very much the cosmetic appearance of the face; we put paraffin and celluloid in noses of saddle shape and make Roman noses with perfect freedom; in fractures we insert screws that remain for years, and in many cases, like Dr. Greenfield, we do not know whether we shall live long enough to see these screws come out; we insert metal plates in bones to hold fractures together, and in many instances we put two Lane plates in broken bones of the forearm, and hold fragments together in this way, with no special inconvenience to the patient. We may take these plates out after the fracture has united, but if they cause no inconvenience to the patient we allow them to remain, because it is necessary to subject the patient to a second operation for the removal of the plates. We thought once that these screws and plates must be removed, else a softening of the bone might follow, such as the essayist mentioned in cases where there was a softening of the bone around the implanted root, followed by a detachment of the tooth. This does take place, if the operation is not done aseptically, but when inserted under aseptic conditions the screws and plates in the forearm, the leg, the clavicle, and other bones will remain in a quiescent state for I do not know how long. There are many people going around Philadelphia today with metal plates three or four inches long in their arms or legs who have never had any trouble therefrom. If surgeons can do these operations, if we can remove a portion of the lower jaw and insert a plate or fenestrated ramus of wire to hold the parts together, can use plates to hold together fractured tibias and fibulas, why cannot Dr. Greenfield, or anyone with sufficient skill, implant a fenestrated root in the alveolar process, put a crown upon it, and have it remain without irritation? The only wonder is that somebody has not successfully advanced this scheme earlier. These operations have perhaps been tried with more or less varying success before, but by the essayist's efforts this method has reached apparent perfection. When one takes into consideration the fact that the osteoblasts may develop bony tissue that will extend through these openings and cause attachments between the outer portion and the inside column of the alveolar process, it seems to me that this method is almost certain to be successful surgically and physiologically, if the operation is performed aseptically. When Dr. Greenfield, in describing this operation, says that he cleanses the gum with ether, sterilizes his instruments by boiling, and then fills the cavity with bismuth paste, he is not a mere dentist, he is a surgeon. That is the way surgeons perform such operations of implantation therapy, some of which I have rather carefully described in volumes v and vi of "Keen's Surgery."

We surgeons, however, cannot do well these operations that involve such fine mechanical work. If I want to have anything done of that nature, I have to send for help to one of my dental friends.

Surgeons, after resecting the jaw for a non-malignant tumor at times insert a firm wire substitute between the ramus of the jaw and the symphysis. It will stay there without causing trouble for months and probably years. The Greenfield operation seems to me a finer piece of work in the same region, the essential feature of success being the necessity of thorough asepsis. In the mouth we cannot maintain the same perfect asepsis as in other regions. Wounds, however, readily heal there, although there are so many bacteria present. Your colleague Miller of Berlin showed their abundance at the beginning of our study of bacteria of the mouth. I have found that somehow or other wounds of the lips and cheeks, which I had imagined would not do well in plastic surgery of of the mouth, heal with less irritation than would be expected. This is probably because of the good drainage obtained after oral operations.

I have been exceedingly interested in the essayist's paper, and I consider that you have heard tonight something of much value to you. and which after a while will become of great value to us medical men.

Dr. Edward C. Kirk. I want in the beginning to express my great pleasure and interest in the exhibit made by Dr. Greenfield. I have been interested in the subject of implantation for a great many years. I believe I did the first implantation operation done in Philadelphia, after Dr. Younger demonstrated the technique of that method in my office in 1886, and my experience with this operation, in so far as it has involved implantation of natural teeth or crowns mounted on natural roots, is on the whole about the same as the essayist's, viz, that implanted teeth are invariably lost by resorption of the roots and after varying periods of time. I have had cases where they were lost in six months by resorption; on the other hand, I have had cases in which the implanted teeth have given good service for sixteen years. The question of the conditions which modify the rate of resorption has never, to my mind, been clearly solved. I have repeated the operation in a mouth in which one implanted tooth was lost in a year, while the second implanted tooth lasted six years. There are some factors about the question of absorption of the natural roots which I am unable to understand, but all implanted roots ultimately undergo resorption, as stated by the essayist.

The question of the implantation of metallic roots has been under consideration for a number of years, and I took occasion today to look up some of the records of this operation, and would call to your attention some of the historical data that I picked up in the course of a very superficial search through the literature on this subject as published in the DENTAL COSMOS. I find the following records of operations of this character:

1887. Dr. S. M. Harris of Grass Valley, Cal., implanted in an artificial socket formed in the jaw of a Chinaman a porcelain crown fixed upon a platinum post around which lead was melted in a mold to resemble a tooth-root, and was slightly roughened to afford a retaining hold for the new tissues in the socket after the ligatures should be removed. The operation is said to be original with Dr. Harris, who reports the case at this date doing well.

1889. Dr. J. M. Edmunds of New York, on October 21, 1886, implanted a porcelain crown mounted on a platinum shell made in tooth-form coated with metallic lead, afterward roughened with a wheel bur, and performed the same operation at a clinic of the First District Dental Society of the State of New York on March 12, 1889. He again demonstrated his appliances and artificial root at the First District Society meeting on May 14, 1889.

1889. Dr. Edmunds inserted one of his crowns, an upper right incisor, in the mouth of Dr. Juan José Ross of Guatemala. Dr. V. H. Jackson examined the operation four days subsequently, and reported the tooth as being at that time remarkably firm, and the surrounding tissues free from any evidences of irritation.

1895. Dr. W. G. A. Bonwill reported at the First District Dental Society of New York in March 1895, his experiments with the implantation of metal tubes or pins of gold or iridium into the solid alveolar process, one or more to retain one tooth or a full upper or a full lower set.

1898. Dr. R. E. Payne gave a clinic before the National Dental Association on "The Implantation of a Silver Capsule." Again, in 1901, he demonstrated his method of implanting a silver capsule in a tooth socket to act as the support for a porcelain crown, which was to be mounted after a few weeks' time.

1905. Dr. C. R. Scholl of Reading reports the implantation of a porcelain tooth with a corrugated porcelain root. The operation was done in August 1903, and the operator reports the conditions satisfactory in November 1904. This tooth, however, was held in place by pins anchored in the crown and to fillings in adjoining teeth, which were sound otherwise.

I report these literary records merely as experiments or attempts made to overcome the tendency of resorption of the natural roots by using metallic substitutes therefor. In this connection I had a faint recollection of an attempt at implanting in a tooth socket an artificial root of gold, made by some French operator in the early part of the last century. I spent varying portions of several evenings rummaging for this record, and finally ran across it. I am reporting it with no desire or intention to detract from the credit which the essayist should have for originality in this method, but it is an excellent example of the way in which the human mind acts, and of how ideas are discovered and independently rediscovered from time to time. The following is a translation from a book by Maggiolo printed in 1809 that I picked up some years ago in the Latin quarter of Paris.*

* The title of this book, translated, reads—

MANUAL OF DENTAL ART. Containing the Description of New Mechanical Appliances, etc., invented by Monsieur Maggiolo, Doctor of Surgery of the Faculty of Genoa, Member of the Society of Medicine of Lyons, etc. New edition, embellished with engravings. Nancy, December 1, 1809: Printed by Claude Leseure, Rue de la Constitution, No. 392.

The authenticity of Maggiolo's invention is indorsed by William Rogers in his book "L'Encyclopédie du Dentiste." Paris: J. B. Baillère, 1845.

After speaking of the use of roots for the fixation of pivot teeth, Rogers says, in his chapter on "Pivot Teeth," p. 434: "The use-

Only one of the bibliographers seems to know anything about it.

The description of the artificial metallic tooth-root and its implantation is contained in the tenth chapter, and is as follows:

CHAPTER X.

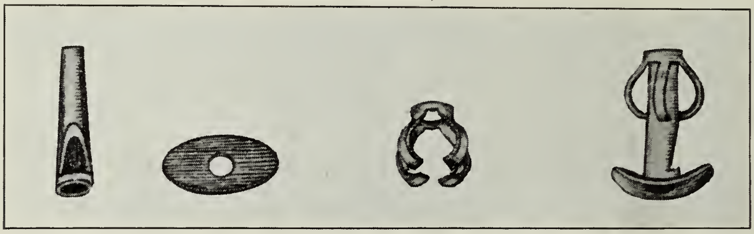
The Making of Artificial Roots Suitable for Carrying a Pivot Tooth.

It often happens that persons who wish to have artificial teeth inserted have nothing left but old roots too weak and dilapidated to carry firmly pivot or spring dowel crowns. In this case, before resorting to ligatures, one should investigate if it is not possible to replace them by an artificial root made of gold, which should be strong enough to receive and support a pivot tooth as solid as if it had been placed on a natural root.

This operation is practicable in all cases in which an old root is still entirely inclosed in its alveolus, that is to say, when it has not half protruded from its socket, and when the alveolus still possesses all its natural capacity. In any other case failure would be certain if one were imprudent enough to attempt this operation.

If circumstances are such that one may hope for certain success, one should start by making an artificial root proportionate to the thickness of the root which it is to replace.

Farsighted and ingenious dentists should have an assortment of all sizes, varying in all the natural dimensions to the incisors, canines, and bicuspids, which are the only teeth in which this operation is practicable. The following is the method of construction: The artificial root illustrated in No. 14 of the first plate, requires three different small pieces as represented in Nos. 11, 12, and 13 of the same plate. [See illustration.]



11 12 13 14

In order to make the first piece, No. 11, which we call the body of the root, a long and thick metal tube is selected answering to the thickness and height which the artificial root is to have. Its lower portion is distended by a triblet or slightly tapering mandrel, which is driven into the tube by hammer blows. It is then notched like a spring dowel, of which we have already spoken; then the surface of the root is made by shaping up an oval metal base, being about equal in size to the horizontal surface of the root which is to be replaced. In the center of this base a hole is made the size of which must be equal to the diameter of the tube which forms the body of the root. These two pieces, Nos. 11 and 12, must be soldered together as they are seen united in No. 14, in such a way that the hole in the base corresponds quite exactly to the open-

---

fulness of the roots for the fixation of artificial teeth seemed so great that the idea of making even roots was conceived. This procedure was indicated by Jourdan and Maggiolo. If an old root was too weak and dilapidated to maintain a pivot tooth, or entirely buried in its alveolus, and this alveolus still possessed all its natural capacity, a root of gold could be supplied. Mr. Maggiolo, author of a good work on the 'Art of the Dentist,' invented a means for fixing pivot teeth in natural or artificial roots by means of a spring. . . . This procedure was, without doubt, the most ingenious, because the person who had the artificial tooth inserted could maintain in his mouth the greatest cleanliness and protect himself from evil odors.

"The insertion of the pivot teeth was inevitably followed by more or less intense pains, divers accidents, gingival inflammation. To remedy this, gargles, emollients, footbaths, and narcotic lotions were employed. These medico-surgical precautions were mostly unavailing, and the patient demanded loudly to be delivered from the pivot teeth which caused his torture."

ing in the body of the root, and that one of the two apices of the elliptic base comes to lie over the notch made in the lower part of the body of this root. The soldered portion is then trimmed, in order to give to these pieces a smooth and polished surface. After the base has been solidly soldered its ends are slightly bent, this being an indispensable precaution in order to make the base adjust itself more perfectly to the contours of the gum upon which it is to rest.

After this is done in the way described, a piece of gold tubing of such thickness is selected that it will just fit the tapered extremity of the body of the root. It is split into four blades up to nearly its upper extremity, which then forms a sort of a ring uniting the blades. With a fine file these four blades are filed so that they are slightly separated from each other. All the four blades are then bent to form a sphere, as seen in No. 13 of the first plate. This little globe is then set on the pointed extremity of the body of the root in such a way that two of its blades correspond to the two extreme ends of the oval base, and the two others to the lateral portions of the base which are most closely together. They are then fixed in place by soldering the ring which unites them to the end of the body of the root, and three of the ends of the same blades to the body of the root itself, toward the middle of which they must taper. I shall explain still further why the fourth blade of this globe must not be soldered.

The three pieces, the union of which is necessary for the making of artificial roots, must be made of eighteen-karat gold—first, because this gold has sufficient solidity for this kind of work, and second, because no inconvenience can result before it rests for good within the gums.

After the artificial root is thus constructed everything must be prepared for putting it in place. First, the old root which is still in the mouth must be extracted. Since it is, however, absolutely necessary not to break the alveolus, it should first be split in three pieces with a cutting pliers having side-cutting edges, by introducing one of its beaks into the root and placing the other between the root and the gum in a perpendicular direction, then by closing the two beaks of the pliers the natural root will immediately split along its entire length up to its apex. These pieces are grasped and removed one after the other with a flat, watchmakers' pincers. By pulling them in a perpendicular direction and with gentle and gradual movements, they can be removed without injuring the gums or fracturing the alveolus. This operation requires a few minutes of patience, but this is nothing if success is the operator's aim. In fact, it is desirable that no dentist should ever be in a hurry in making an extraction of teeth or roots.

After the root has been entirely removed from the alveolus the patient is made to wash his mouth with tepid water and vinegar mixed in equal portions, then this artificial root is introduced into the alveolus. It should enter quite accurately, and the base of the root should be well supported by the gum, which will quickly tighten itself upon the artificial root. Care is to be taken that the notch in the body of this root is turned toward the cavity of the mouth. The root is then pushed forcibly into the alveolus so that it touches its bottom. By placing the thumb in front and the index finger on the back of the gum one seeks to compress the walls of the alveolus by a gradual and sufficient force. The patient is then given a rest until the following day. The same compress is renewed for two weeks, and the patient is advised not to touch this artificial root. Astringent and alcoholic lotions are used even after the root has solidified in the alveolus.

A very extended experience proves to us that after the extraction of a tooth the walls of the alveolus, being no longer supported in their natural place by the presence of the root, approach one another and fuse together, thus obliterating this alveolar cavity, which no longer exists in persons who have lost their teeth. We believe even that it is less the loss of the teeth than the approachment and obliteration of the alveoli which alters so visibly the lines of the physiognomy, and produces on the face those disagreeable wrinkles which announce premature old age.

If no disease has altered the substance of the alveoli and the gums, and if the alveolar walls have not been fractured by the extraction of the natural root, one can easily conceive how the walls of the alveoli, which continually tend to approach each other, contribute to rendering solid an artificial root which replaces the natural one, before this approachment has taken place. For this new root, made of an incorruptible material, filling by its globe the whole bottom of the alveolar cavity, prevents the walls within the alveolus from becoming obliterated. On the other hand, the inferior portion of this root, being narrow, permits the alveolar plates and the gingivæ to approach the neck of the artificial root and to close themselves in a circle around it, thereby insuring its solidity to such a degree that afterward it could not be removed without breaking portions of the alveolus. Although the four little blades, the contours of which form the globe of the artificial root, are arranged in the same manner, we have observed that one of these four should not be soldered to the body of the root, for the following reasons:

It is quite possible that if the globe is slightly larger than the cavity of the alveolus, the root cannot enter to the bottom, which would prevent its surface from resting well upon the gum. On the other hand, the pressure applied in order to make the root go to the very depth of the alveolar cavity forces the unsoldered blade to approach the body of the artificial root, and acting as a spring in the depth of the alveolus, the latter is entirely filled, a condition which is absolutely necessary for the success of this operation.

A few days generally suffice to insure success. One will find that the artificial root has assumed sufficient solidity if, upon touching its external surface very slightly, one notices that it no longer shakes in the alveolus, and that the root stays in place when slight pressure from below upward is exerted on the gum. This is evident proof that the alveolus has fastened itself against the artificial root with enough energy to insure its solidity in the alveolus.

No undue haste should ever be made to insert the tooth, the pivot of which must enter the artificial root, of whose solidity one must be perfectly assured; otherwise this valuable work will be destroyed. I therefore advise not to insert a simple pivot until one month after the root has been inserted, so that it may no longer be possible to impair its solidity.

This operation never involves any subsequent inconvenience, because the humor which can flow from the interior of the alveolus can circulate at full ease through the fenestrum made in the base of the body of the artificial root.

This operation may be considered as one of the most beautiful of the art of the dentist. It combines such important advantages that for some time I have never missed an opportunity to employ it. I have almost always obtained results that were as satisfactory to me as to the persons on whom I have operated.

There is, as Dr. Roberts said, ample surgical or physiological justification for this operation. The fact that foreign metallic bodies will be tolerated in the tissues has been demonstrated over and over again. Some of you probably attended the International Dental Congres held in Paris in 1900, and saw the patient exhibited by Michaels of Paris, who had restored the patient's entire shoulder joint. The shoulder joint had been affected by tuberculosis and had been removed by Pean, the great French surgeon, and was replaced by Michaels with an artificial joint consisting of an iridio-platinum and vulcanite mechanism attached to the bones. That patient, after recovery from the operation, could take a bucket of water and swing it over his head with ease. We saw a radiograph of the joint at the time, and some six or seven years later, when the man died, the piece was taken out, and embodied in Michaels' collection in the Stomatological School of Paris. That is an example of an extensive replacement which was tolerated by the tissues. We have also the recorded work of Delair and Sébileau with reference to the replacement of portions of the cranial wall by fenestrated metallic plates:

> In replacing pieces of bone of the skull after craniectomy, Delair and Sébileau, since 1903, employ anchored fenestrated metal plates. The fenestration reduces the weight, and the plate is quickly immobilized by fibrous tissue. In order to fasten the plate at first, they use metal hooks, which seem to invite condensing osteitis, while screws produce rarefying osteitis. The tissues seem to take more kindly to silver than to gold. Drainage must be maintained by a bundle of horsehair, as abundant hemato-serous discharge will take place.—*Gaz. des Hôpitaux.*

I offer these facts as proofs that there is abundant surgical justification for this operation in so far as that aspect of it is concerned.

Dr. Cryer has spoken about the mechanical relations of this metallic crib to the structures that may be immediately involved by the operation, but there is a further question of the difference between the alveolar process and the character of its structural tissue, and that of some of the other bones. Talbot has taken the ground—and not without justification, I think—that the alveolar process is a provisional or temporary tissue, and because of its transitory character he has regarded it as being particularly vulnerable to that class of infections which we group under the general term of pyorrhea alveolaris; it is useful so long as it is functionally active in supporting the teeth, but as soon as the teeth are lost, it disappears. This, then, seems to represent a different type of bone, and the question to my mind is how such a tissue, with its tendency to undergo degenerative changes, would be affected by an operation of the character we are now considering; whether under stimulation it would tend to promote functional activity in the alveolar border again, or whether it would have the effect of hastening the alveolar resorption.

I congratulate the essayist on his enthusiasm. I believe in the enthusiast, the optimist, the crank, because they have the courage of their convictions. But in listening to the paper, I divided the essayist's statements into two classes, viz, first into his personal opinion about this operation, his prognosis, and his prophecies, and second, into his actual knowledge regarding the success of this operation. I did not hear him say what was the date of his first operation, and what its status is today, nor did I hear him say that radiographic studies had been made of his work. It seems to me that we should have such records, so that we might see what these cribs and the surrounding tissue look like under the X rays. We should also have other data with reference to actual practical results, in order that we may form our own judgment as to the possible endurance and utility of the operation.

I want, in closing, to express my gratification at having had the opportunity of listening to this interesting paper.

Dr. Otto E. Inglis. I had the pleasure of seeing Dr. Greenfield perform this operation this afternoon, and I was surprised at its extreme simplicity. Like the rest of you, I know nothing particular about the operation, although I have made some implantations by the old methods. We must depend entirely upon the length of time which has elapsed since the first use of this cribriform root, for forming an opinion as to whether this operation is really a success.

In discussion with Dr. Greenfield this afternoon, I mentioned the fact that a few months ago I had published in the *Garretsonian* a description of his method by Dr. Guilford. Since that description was published, Dr. Greenfield has to some extent modified the process of this operation, and I should like very much to have him state his reasons for the change. Dr. Greenfield also told me of several peculiar accidents he has had during operations, as for example, cutting into the inferior dental canal, the operation still being successful, and I wish he would mention this in closing the discussion.

From a mechanical viewpoint, this operation looks very promising. The appliance used is so readily introduced after the circular opening is made in the bone that it really seems as simple as pushing a drawer into its proper receptacle.

Dr. Robert H. Ivy. I would like to say a word about the form of anesthesia Dr. Greenfield uses in this operation. I should think that in view of the danger of injuring the inferior dental nerve, particularly if the patient is rendered unconscious by a general anesthetic, the use of local anesthesia would avert that danger. The patient would feel when the drill or trephine went into this region, and the operator could then guide the depth of his incision into the bone.

Dr. Dudley Guilford. I had the pleasure of seeing Dr. Greenfield perform this beautiful operation this afternoon, but to my mind, the gist of the matter, if it is to prove a permanent operation, lies in the ability of the gingival tissue to resist infection.

Undoubtedly an appliance of this kind, inserted in the bone and entirely covered by normal tissue so that it cannot be exposed to infection later, would remain indefinitely; such appliances have been used by surgeons for years. Granting that this operation can be done aseptically, the whole question hinges on the manner in which the gingival tissue is going to act, and how it will heal. Of course there is a cicatrix formed around the cap, and this would afford some protection, as it would hug the cap very tightly, owing to the contraction which always takes place; however, we would not have a normal attachment, as we have between the natural root and the gingival tissue. To my mind, the crux of the matter lies in the question whether the gingival tissue will heal in such a way that it will prevent infection. If the tissues around the platinum root do not become infected, I see no reason why it should not last indefinitely, because it certainly cannot be resorbed.

Dr. W. A. Jaquette. There is one phase of this subject that has not been touched upon. The natural tooth is held in its socket not only by the bony wall but by the peridental membrane, which acts as a cushion, and the blow of the force of mastication on the tooth is taken up somewhat by this cushion. The natural tooth is very much more able, therefore, to stand this force than I would suppose this mechanical appliance would be, as the latter has no cushion to receive the blow. We would naturally suppose that force or pressure or a blow exerted on a rigidly supported crib such as this would much more readily produce absorption.

Dr. Greenfield (closing the discussion). Dr. Cryer has shown you a few selected cases of maxillæ that do not seem to me to be fair examples at all. They are jaws in which absorption has fully taken place, and which are dried out and narrow. Here is a bone [demonstrating] which, while it is not the bone of a human jaw, will demonstrate the point I wish to make. This is the bone of a cow, which shows that the socket I make is so small that, when I place the crib in the bone, it is as solid practically as before. The crib becomes more firm in time, as the bone condenses over it. This shows very clearly that owing to the smallness of the opening that I make, we have a solid foundation, if any ridge is left at all. I do not advise this operation in every case, because there are some cases in which the ridge is so narrow that it is not practicable. When a person comes to me with a thin, narrow jaw and an absorbed ridge, I refuse to perform this operation.

I wish to mention one case of a man whom I treated six or eight months ago, one-half of whose jaw had been replaced by Dr. Brophy by an operation that had been performed some fifteen years previously. The bone had grown over the plates, and was almost united again. I cite this case to show that bone does grow in these places and under the conditions mentioned. This operation for which I claim success is being done at the gum line, and while the mouth, as has been said, is one of the most unclean portions of the body, it seems that nature has come to our aid by making provision for the care of these portions. It appears as though the bacteria are carried away more quickly from these than from any other parts, and it is a well-established fact that wounds of the mouth and in the region of the rectum heal more quickly than in any other part of the body.

Dr. Roberts mentioned different operations where surgeons use metals in bones. I have read a great deal about the use of different metals in bones, and I find that it makes little difference what kind of metal is used, so long as it is aseptic. Surgeons are using steel screws, steel plates, etc., in different kinds of fractures and operations with perfect freedom.

Dr. Kirk has asked how long ago these operations have been performed, and while I know, of course, that he did not mean to intimate that I had intentionally failed to mention how long these teeth had been in place, I will say that I have been doing this work about seven years. Most of the cases that I treated at first were lost very early, but I had the right idea, although I did not know just what I wanted to do. I had no suitable instruments for the work, but this difficulty was overcome later. My attention was first directed to this work by an operation on a fractured leg that I saw. A lady of my acquaintance fell and broke her leg, and in the attempt to set the bones properly it seemed that as a portion of the bone was gone entirely, the ends of the bone would have to be drawn together and attached, which would necessitate the lady's going through life with one leg shorter than the other. She was a fine-looking woman, and it worried me a great deal to think that she would become crippled. While investigating as to how the surgeon used metal in the operation, which in this case resulted in preventing the condition so much dreaded, the thought came to me that, if we could twist wire into the shape of a root, it could be implanted. My thought was that the bone would grow into the crib, and there would be no infection, because these wires were so small that the infection would be carried off by the blood before it could do any damage. In my office the next morning I made a root of this kind, and implanted it. I had nothing but an old rubber bur to make the opening in the alveolus with, and when the opening was completed, nothing but two walls of the alveolus were left. I put the root in position, and it was not long before I found it in fairly good condition. It never became very solid, because there were no means of fastening it, and as a consequence there was motion, and no very firm growth of tissue occurred. But that was my start, and after continual experimentation, I finally made an appliance of the shape which you see here [illustrating], and implanted one of these. The first case in which I tried it was that of a second molar. I drilled out all the bone and made a hole of the size of the root and inserted the root. In about six weeks I attached to this root a four-teeth bridge, which extended to the first permanent bicuspid. This was done six years ago. Dr. Herrick in this case asked me how long I thought it would last, and I replied that I did not know whether I would live long enough to answer that question. That case today is in as good condition as it has ever been, and the patient has never had a particle of trouble with the bridge.

I believe I have answered all the questions that have been asked, and in closing, I wish to thank the members of this society for the kind treatment and reception accorded me.

The President then announced as the next paper for the evening one by Dr. Robert H. Ivy, Philadelphia, entitled "Clinical Pathology in Its Relations to Dental and Oral Conditions."

[This paper is printed in full at page 398 of the present isue of the Cosmos.]

Discussion.

Dr. Edward C. Kirk. I do not think that this very interesting topic should go by without some comment. I am very glad indeed that Dr. Ivy has brought the subject before us this evening, for it is one of those that we should know about and should take advantage of in a practical way. The tendency in the past has been too much, I think, to regard dentistry as purely a mechanical handicraft, and to concern ourselves too largely with that aspect. Dentistry is making progress inevitably along lines of larger development of our knowledge with reference to what may be called the biological side. No one would question, for example, in considering the first paper of this evening, the mechanical perfection of the device which Dr. Greenfield uses for restoring the lost tooth-root, that it is sufficiently strong, sufficiently resistant, of correct form, etc., but the problem that concerns us most in that connection is not these mechanical factors, but rather, What will nature, the tissues, do with this mechanical device? Its utility is determined not by the question of whether the crib or the attachment between the crown and the bridge is strong enough, but by what the tissues will do with it. That is the vital question. The mechanical, the restorative side has been worked out almost to the point where there is little opportunity left for larger improvement along these lines, so for that reason, among others, we must give our attention to the other aspect of the question. Therefore I am glad our attention has been drawn to it.

I wish to make a few practical applications of what Dr. Ivy has called attention to. I read a paper on arthritism—the exact title of which I have forgotten—before the National Dental Association at its Birmingham meeting some years ago,* and in that paper I reported a case of infection of the lower jaw that originated about the central lower incisor. The dentist who treated the case had diagnosed it as one of ordinary dento-alveolar abscess. A little abscess broke out just over the apical region of the lower incisor, and the dentist drilled into the pulp chamber of that tooth upon the assumption that it was an abscess due to putrescent pulp, but to his surprise he found a vital pulp; then thinking that he was mistaken as to the particular tooth affected, he drilled into the other lower incisor, and found that this also contained a vital pulp. He then began to make some inquiry, and found that what he was dealing with was one of those peculiar cases called by Dr. D. D. Smith pericemental abscess—abscess upon a tooth with a living pulp, and that the adjoining teeth were becoming loose very rapidly. I asked this man if he was in good health, and he said, "Yes, generally speaking," but that he had had a little sugar and a little albumin in his urine, off and on for several years. I felt that the diabetic condition gave the case a grave aspect, and told the patient and his wife that I considered the case serious so far as this particular infection was concerned, because we know very well that resistance to infection by pyogenic bacteria is greatly reduced in diabetes mellitus. I advised him to go to the hospital and avail himself of the services of two competent men, one to look after his nutritional condition and the other the oral condition. After considerable persuasion he agreed to do so. Dr. Cryer took charge of the surgical aspect of the case, Dr. Edsall of the nutritional side, and a careful record was kept of what was taking place, which included making examinations of the blood and testing the opsonic index regularly. This patient, however, went from bad to worse, and in less than two weeks he died. Dr. Cryer will remember the case and how rapid was the spread of that infection to the periosteum of the mandible up to and including the temporo-mandibular articulation, and down the neck to the arm. But what Dr. Cryer in particular and all of us were interested in was the absolute synchronism between the rise and fall of the sugar contents, the opsonic index, and the flow of pus; the resistance to infection of pus germs was synchronous with the elimination of sugar by the urine. I believe that this patient died from pyorrhea alveolaris, because, on account of the internal resistance to infection being lowered, the pus spread from that single point of local pericemental infection and involved the whole alveolar border, resulting in the loss of teeth in the lower jaw, and involving the periosteum of the mandible, etc. So if this was not pyorrhea, what was it?

Now, this is the practical application of this case history: Had it not been known that the diabetic individual is particularly liable to pus, and this particular patient had not been therefore warned of the seriousness of his infection, or supposing he had gotten no farther than the dentist, or the family physician, and the case had not been successfully diagnosed because we had not this knowledge of the fact of the lowered resistance involved, it is entirely possible that his wife might have felt that the dentist, by drilling into these pulp chambers, or by the use of instruments not properly sterilized, had infected the tooth with some particularly virulent germ, and would have blamed the dentist for the fatal result that followed. This is not an overdrawn picture, because this particular case has happened in my own knowledge. Insurance against that kind of calamity, which results from ignorance of the situation, is to be furnished by the help which the laboratory of clinical pathology offers to the practitioner. So often,

* [See "The Dental Relationships of Arthritism," DENTAL COSMOS for July 1909, vol. li, p. 793.]

when papers of this kind are read, the attitude of the audience is—"Oh well, what is all that to us? We do not have the time to do that sort of thing." That is doubtless true, but granting that, we cannot afford to neglect the time and study necessary to find out the possibilities of such help. That is to say, we must recognize the possibility of helpfulness from the expert along these lines, and we should utilize his abilities, if only as a means of protection in practice as well as of benefit to the patient. I have had a number of instances which have convinced me that it is quite possible, through a careful study of the mouth secretions, the urine, and the blood with reference to certain pathological conditions, to get at the inception of the nutritional fault, and be able to detect the particular pathological difficulty back of the local lesion, long before the patient is so ill that he feels it necessary to engage the services of the physician. I believe the dentists who awaken to the possibilities before them along that line will be the ones who will be the advance guard in the diagnosis of important bodily diseases, and be able to refer their cases to physicians for treatment in time to prevent illnesses and to save life in many instances.

Dr. Ivy (closing the discussion). I have nothing further to add in closing, except to thank the society for their kind invitation, and for listening so courteously to a paper which is a little out of our general line of work.

The meeting then adjourned.

EDITORIAL DEPARTMENT.

THE NEXT STEP.

IN closing his paper read before the Chicago Dental Society, in Chicago, January 31st, Dr. Charles H. Mayo, the eminent surgeon of Rochester, Minnesota, said: "It is evident that the next great step in medical progress in the line of preventive medicine should be made by the dentists. The question is, Will they do it?" On a former occasion—to wit, in December 1905—we called attention to another important pronunciamento emanating from an authoritative medical source, namely, the address delivered by Sir William Osler at the Royal Dental Hospital, London, October 13, 1905, upon which occasion he called attention to the important position which dentistry as a scientific profession was called upon to exercise in relation to public health matters by the relief of suffering, the improvement of the digestive capacity of the public, and the beautification of the race. The address made certain practical suggestions for the promotion of the propaganda of dental service as a public health measure.

Attention was editorially directed to Professor Osler's address at the time, for the reason that it had received much attention by the lay press as well as the medical, both in Europe and in this country, the interesting feature of the whole matter being that while the substance of the address and its contentions were matters quite familiar to the dental profession in all countries, and while much had been written thereon for dental professional consumption, but little advance had been made in the way of attracting the attention of medical men and the lay public to the importance of the care of the teeth and of mouth hygiene until the facts were re-stated by the eminent medical authority just mentioned. While many influences and activities since that time have helped to bring about the more general recognition of the importance of the care of the mouth and its contained organs, it may be safely stated that no single influence up to that time accomplished so much in the way of directing public attention to dental affairs as did the address of Dr. Osler above referred to. The reasons for the widely aroused interest that was expressed in his statements at the time need not be here rehearsed, as they were gone over in the editorial pages of this magazine in December 1905.

An analogous situation is apparently created by the statement made by Dr. Mayo, quoted at the beginning of this article. When an authority of such eminence makes, as the result of his deliberate judgment, the statement that "The next great step in medical progress in the line of preventive medicine should be made by the dentists," we have as clear a recognition as could be desired, from as high medical authority as exists anywhere, of the opportunity presented to those whose life-work is the study and care of the mouth; and in his appended inquiry, "Will they do it?" we have the implied recognition of the equivalent responsibility which this great opportunity involves. The main difference between the situation which is created by the statement of Dr. Mayo as compared with that created by the statement of Sir William Osler is that in the latter instance the response has materialized in a practical recognition by the public and the medical profession of the possibilities of dentistry, and growing out of this recognition has now come the demand that the dentists shall do something commensurate with their opportunity.

For centuries, much—indeed, practically all—of dental service in a prophylactic direction has been to preach and to put into practice the axiom that "Clean teeth will not decay." We have at last come to realize that the ancient axiom is subject to certain qualifications—that it is only relatively and not absolutely true, and that the prophylactic idea in its broader conception must deal not only with local diseased conditions, but must deal with the problems of general bodily health; that mouth sanitation, the integrity of the dental and oral tissues, is intimately related with the more complex problems of bodily nutrition, and that prophylaxis, in order to be broadly used as a principle in safeguarding the bodily health through the integrity of the mouth and its contained organs, must be so expanded in its conception and application as to embrace a scientific understanding and adjustment of the whole nutritional process. Each progressive step that has been thus far taken toward the scientific protection of the dental apparatus from the destructive effects of disease has been attained only through the larger conception of the underlying principles of nutrition and the scientific study of those factors which tend to disturb normal nutrition both locally and generally. It is through just such lines of investigation and only by means of such studies that we can hope to affirmatively answer the as yet unanswered question of Dr. Mayo—"Will the dentists do it?"

Much valuable preliminary work has already been done, but much more remains to be accomplished. The realization of the necessity for additional research into the various causes of tooth destruction is manifested not only by the frequent reports of scientific studies of the caries problem in its various aspects, but most encouraging of all is the demand which comes from the dental profession at large for more light of an original character upon these questions. The creation of a National Dental Scientific Foundation Fund for the prosecution of original dental research under the auspices of our National Dental Association, with the activities of the committee in charge in arranging the preliminary phases of the work, and above all the activity of the committee in securing benefactions to meet the expense incident to the research work involved, presents a condition of the utmost hopefulness that the forward step indicated by Dr. Mayo will undoubtedly be taken by the dental profession. We shall in a succeeding issue present the purpose and plan of the National Dental Scientific

Fund for the information of our readers, in the belief that the importance of this great work will arouse a sympathetic and liberal response to the appeal which the National committee makes for support by the dental profession at large.

BIBLIOGRAPHICAL.

DISEASES OF THE MOUTH. For Physicians, Dentists, and Medical and Dental Students. By Prof. Dr. F. ZINSSER, Director Dep't Dermatology, City Hospital, Lindenburg; Dozent, Academy for Practical Medicine, Cologne. Translated and Edited by JOHN BETHUNE STEIN, M.D., Prof. of Physiology, New York College of Dentistry; Late Instructor in Genito-Urinary Diseases, College of Physicians and Surgeons, New York City. Pp. 269, with 52 colored and 21 black-and-white illustrations. New York: Rebman Co., 1912.

While this book is entitled "Diseases of the Mouth," it deals exclusively with syphilis in its oral manifestations and their differential diagnosis from other conditions liable to be confused with them. There is a short account of syphilis in general, but by far the greater portion of the work is taken up by colored plates showing practically all the lesions of the different stages of the disease as it may occur in the mouth, together with a few illustrating follicular tonsillitis, Vincent's angina, herpes labialis, aphthæ, carcinoma, and other conditions. There are also several black-and-white illustrations of casts showing Hutchinson teeth and other dental hypoplastic defects attributed to hereditary syphilis. Finally, the various forms of spirochætæ found in the mouth, as well as the treponema pallidum, are shown.

The chronological chart at the end of the book would indicate that calcification of the teeth begins earlier and occupies a shorter time than has been generally accepted in the past. Whether this applies both to dentin and to enamel or to dentin only is not clearly stated in the book. If the view be true that calcification of the crowns of the permanent incisors, canines, and first molars is complete before the end of the first year of extra-uterine life, then it follows of necessity that hereditary syphilis is practically the only cause of developmental defects in these teeth, since it is the only disease commonly causing severe nutritional disturbance thus early in life. While it is very likely that the dentin is fully calcified by this age, yet there is good authority for holding that the hardening of the enamel goes on up to the time of the eruption of the teeth—viz, six years of age and upward. Therefore the teeth mentioned may all show hypoplasia of the enamel due to exanthemata and other diseases causing nutritional disturbances within the first six or seven years of life.

The translator and editor has performed his task in an able manner, but shows here and there a leaning toward foreign words where English would be better understood by the average reader. The word *moulage,* for example, if not recognized as French, might puzzle many not familiar with the language as to what dictionary to consult in order to translate the term into the equivalent English designation—"cast."

The colored plates form probably the finest collection illustrating these particular lesions ever assembled under one cover, for which reason, if for no other, the work is most valuable; and it should be as useful to the student or practitioner as a study of the living subject—at least so far as visual examination is concerned.

THE USE OF ROOT-CAPS WITH CAST PLUGS. By Professor Chr. Bruhn, Duesseldorf.

In order to avoid the perforation of root-canals, which frequently occurs in an effort to enlarge them for the reception of a pivot, the writer prepares the root in the same way as for a cap and pivot; then the pulp chamber is widened, imparting to the chamber a round shape in single-rooted teeth, oval in bicuspids, square in molars. The diameter of this chamber is about the same throughout its extent. The roof of the cap, which has been made in the usual way, is then perforated so as to correspond exactly to the enlarged chamber. While the cap is in place on the root, softened modeling compound is pressed through the aperture in the roof of the cap, the compound is cooled with cold water from a syringe, and the cap and the plug formed by the compound are removed together. A plaster model of the chamber can then be made, the modeling compound is removed, the plaster chamber is oiled, and the plug is modeled in wax that is pressed through the apertures in the cap on the plaster model. The cap and plug are then invested, and the plug is cast in gold. (In our opinion, this operation can be greatly simplified by modeling the plug while the cap is on the root in the mouth, as there is little danger of distortion of the wax in removing the plug and cap from the tooth.) The cap is held by such a plug more firmly than by a pivot, and is of special advantage in teeth with small diameter, as in lower incisors, and in those with strongly curved roots. The retention of the plug can be enhanced by a groove cut in it.

INDUSTRIAL MERCURIAL POISONING AS SEEN IN FELT-HAT MAKERS. By F. E. Tylecote, M.D.

The association of chronic mercurial poisoning with the carroting process carried out by hatters' furriers has long been known, and as a result many methods of dressing the skins have been suggested as alternatives to the process of carroting, or brushing the fur with a solution of acid nitrate of mercury, but all the suggestions have so far proved useless in practice, or have not had a fair trial, and carroting is still the favorite method of preparation. It is, however, not so much the writer's intention to deal with mercurial poisoning as it occurs in furriers, but as it is met with in felt-hat makers themselves. In America the work of Dr. Lloyd and in Austria that of Dr. Teleky have brought this vocational disease into prominence, while in England it has been only scantily referred to in the literature.

In Tylecote's exhaustive treatise, the chapter relating to the mouth and alimentary canal is of special interest to the dentist.

In all cases of mercurial poisoning, whether acute or chronic, special attention has to be paid to the mouth, for it is here that some of the most distinctive and diagnostic signs are seen. To those accustomed to cases of chronic mercurialism some of these signs are quite diagnostic, but others may entirely miss their significance. The profuse salivation of acute mercurialism is hardly ever seen, neither does ulcerative stomatitis occur, but slight increase of saliva is the rule. The tongue is large, flabby, silvery or dove-colored, with indented edges. The teeth are blackened, especially near the crowns, and the front teeth more markedly so than those farther back. Caries is not often seen, and the process is rather one of erosion. The black, eroded teeth are seen in their most typical form in the furriers, and next in the plankers, so it is a reasonable assumption that the acid fumes play an important part in the causation of this condition. The teeth often show a considerable amount of tartar. Some degree of pyorrhea alveolaris is common, and pus and blood may often be squeezed out of the sockets. The gums then become retracted, and soon the teeth become loose and may fall out. Dr. Legge has shown that they often fall in a definite order, the upper molars first. The mouth-changes as a whole are more marked in inveterate smokers, and most of all in tobacco-chewers. Vomiting was complained of in three cases, as a rule at night after work was over, but in two cases occasionally in the morning also. Diarrhea was not a usual symptom.

The appearance of the gum margin recalls the blue line in lead poisoning, though the gum, apart from the margin, may be quite pale. There is not a blue line in the proper sense of the term, *i.e.* there is no line of granules; but there is often a cyanosed edge to the gum, which at a casual glance can be taken for a blue line. It is an almost uniform line, a purplish blue, not a "lead" blue. Tylecote makes a plea for greater care in the diagnosing of a lead blue line, as, in his opinion, it is far too lightly diagnosed. Any line, or even any blue line, is not a typical lead blue line any more than any spot is a typhoid spot; but to listen to evidence in a county court on occasion one feels that some, at any rate, give to it a much broader definition than others. In some cases there was slight edema of the fauces and palate. The margin of the gum may be swollen.

The question of an odor must be mentioned. In acute mercurialism one has only to have smelled it once to be able to diagnose a case from it again at some distance. This is not so in chronic mercurialism, but there is a curious odor, definite, though not easy to describe, and not very pungent, but fairly lasting, so that it can be detected after the patient has left the room. Some would call it a metallic odor; it emanates from the body as a whole, and is not localized, as is the case in acute mercurialism. Some of the patients complained of a bad taste in their mouths, but none of them described it as metallic. Anorexia was mentioned as a symptom by two.

One case was quite different from the rest. Here a blower of twenty-five years' service suddenly had an acute attack, which from the after-history was apparently mercurialism; he had profuse salivation, diarrhea, and bloody stools; when his condition improved, he went back to work, but in a week tremors began. Yet he had worked all those years with no signs at all. This is the only case observed by Tylecote.

UNTOWARD SECONDARY EFFECTS FOLLOWING THE APPLICATION OF ARSENOUS OXID, AND THEIR PREVENTION. By Dr. M. Lipschitz, Berlin.

The dangers which inhere in the careless application of arsenous oxid for the devitalization of the dental pulp are the following: Pericementitis, necrosis of the interdental papilla, necrosis of the alveolar septum, osteitis and necrosis of larger bony portions, and general intoxication, and Lipschitz cites very interesting cases from practice as examples of each one of these possible accidents. All of these can be prevented by the use of a minimal quantity of the drug, by hermetically sealing it in the cavity with a dense reliable cement, and by avoiding the mixing of the drug with the obturating material. In regard to the therapeutic treatment, the writer advises, in cases of mild pericementitis, to wait for from two to three days after extirpation of the pulp, when the pain usually disappears. In severe pericementitis, an antiseptic cotton dressing is inserted under temporary stopping, and the permanent filling is inserted about a week afterward. If the interdental papilla is necrosed, all necrotic portions are carefully removed with a bistoury or sharp spoon, when healing generally occurs after a few days. Witzel recommends touching the necrotic portions with iron chlorid. If the alveolar septum is affected, the part is removed with the bur, or, if pus and a sequestrum have already been formed, the sequestrum is removed, and the wound treated like any other. In cases of general intoxication, a medical man is to be called. In the meantime, unless the antidote, an emetic, or the stomach pump are at hand, albumin or milk are to be administered. As antidote, the ferric hydroxid with magnesium oxid of the U. S. Pharmacopeia is recommended, which is to be made freshly, and is given in doses of from one to two tablespoonfuls every few minutes, later on every hour.

[*Lancet*, London, November 16, 1912.]

NITROUS OXID AND OXYGEN AS AN ANESTHETIC FOR DENTAL AND SURGICAL PURPOSES. BY MR. W. GUY AND DR. J. S. ROSS.

The advantages claimed by the authors for the mixture of nitrous oxid and oxygen are: (1) That it produces an anesthesia most closely resembling physiological sleep; (2) that it produces the least disturbance of respiration, circulation, and alimentation, and (3) that it involves of itself the least risk of life. Heretofore, they claim, the disadvantages which attached to the apparatus and the methods of administration had discouraged the ordinary practitioner from employing the mixture. The general and extended use of this valuable anesthetic depended on the adoption of a simple and inexpensive method which enabled the anesthetist to control with some degree of accuracy the percentage of oxygen in the mixture, and by allowing re-breathing of the bagful of gas and oxygen for definite periods gave economy of consumption with the advantages attendant upon conservation of CO_2 and a moderate rise in the CO_2 content in the blood. Henderson might or might not be right in stating that a deficiency of CO_2 in the blood was a common cause of syncope and shock under ether and chloroform. It would, however, be admitted that this gas was the stimulant of the respiratory center, and that the alternate cessation of respiration attendant on the administration of nitrous oxid through valves was as much acapnic as anoxyemic. While conservation of carbonic acid was to be desired, oxygen starvation must be avoided. According to Starling and his co-workers, Kaya and Jerusalem, excess of CO_2 acted, so far as the nervous system was concerned, upon the medullary centers only, and mainly upon the respiratory center, of which it was the natural stimulant. It was also a cardiac stimulant until the percentage of CO_2 in the air respired rose to 12 per cent. when it began to have a depressant action. Lack of oxygen was a much more serious matter, and affected the whole nervous system, especially the spinal and vaso-motor centers, causing a rapid rise in blood-pressure, and eventually convulsion. The heart, depressed from the first, was rapidly overcome by the rising peripheral resistance. It was thus apparent that, with a method providing for a sufficient supply of oxygen under due control, the pressure of a slight excess of CO_2 in the air respired might be regarded with equanimity. They felt themselves, therefore, on firm ground in adopting the re-breathing principle. In America much important work and research bearing on the administration of gas and oxygen had been carried on, and the mixture had been extensively and successfully employed. The importance of re-breathing had been generally recognized by American anesthetists. The apparatus employed might be described as a lineal descendant of the Guy "gas and ethyl chlorid" inhaler. The facepiece, Barth 3-way tap, and bag mount with the side tube for ethyl chlorid were the same, but instead of the one-gallon bag, a two-gallon bag was used, the distal end of which carried a Y-union. One limb of the Y was connected directly by rubber tubing to the nitrous oxid cylinder. To the other limb was attached a ball syringe, the bulb of which was of two-ounce capacity. At each end of the bulb was a rubber valve, so that squeezing the bulb propelled its contents into the two-gallon gas bag. The distal end of the ball syringe was connected to a one-gallon bag fixed in front of the oxygen cylinder, with which it was connected by a metal tube. A portable fan was also shown. For use, the one-gallon bag was filled with oxygen, and the two-gallon bag moderately distended with nitrous oxid. The facepiece having been adapted to the face, re-breathing was commenced with the two-gallon bag. At the end of fifteen to twenty seconds the patient required some oxygen, and four ounces were supplied to him by two squeezes of the bulb. Further known quantities of oxygen were supplied at such intervals as were indicated by the complexion, care being taken to steer between the two extremes of rosiness and cyanosis. Usually, about four ounces were required every fifteen or twenty seconds, until from six to ten ounces had been given in all; this sufficed for the 110 to 120 seconds required to induce anesthesia for a dental case—*i.e.* extraction of two or three easy teeth. If a more lasting anesthesia were required, from 1 to 3 cc. of ethyl chlorid were run in at the end of from 25 to 40 seconds, and the mixture was re-breathed for another thirty seconds, when anesthesia lasting for from 70 to 100 seconds resulted. If longer anesthesia were required, after the mask was removed the Clover inhaler was inserted, and a little ether given with the gas and oxygen. This system had been in daily use at the dental hospital for five months, and 800 cases had been so anesthetized. The results were very much better than with gas, or with gas and ethyl chlorid unmixed with oxygen. There was a striking absence of crowing respiration, and of cyanosis or excitement. The addition of measured quantities of oxygen may make the difference between slight risk and perfect safety. The average quantity of gas used is from 2 to 3 gallons, and of oxygen from 6 to 12 ounces.

Dr. Ross said that the method was applicable for minor surgery, but at the end of each two minutes or so, the bag must be emptied out to get rid of CO_2 by placing the valve at the intermediate position. When the bag was nearly empty, a fresh supply of gases was run in. The amount of oxygen required to keep a good color rose steadily with the first few bagfuls, until a point was finally reached when about forty ounces of oxygen were being given on each new bagful, and another 10 to 20 ounces were gradually introduced during the following two minutes. This gave a percentage of about 12, and corresponded with the figures arrived at by Hewitt in his experiments with a gasometer. For major surgery, nitrous oxid had many valid claims to be ranked above ether. It did not irritate the mucous membrane or excretory glands, produced no anemia and no reduction in the phagocytic power of the blood, did not damage the central nerve cells, while ether did all of these in varying degrees. Above all other questions was that of the prevention of shock, and here Crile's results showed that nitrous oxid was from three to four times more powerful than its rival. Nitrous oxid and oxygen of themselves might give too light an anesthesia for abdominal work; it could be helped by the preliminary administration of quite a small dose of morphin and atropin, and by giving a little ether by the drop method to help the induction stage, after which it was possible to maintain anesthesia for an almost indefinite time by the gases alone. Proceeding by this plan, abdominal section became quite a feasible operation in a large group of cases. A number of cases could be quoted where the patients had recovered from grave conditions with a rapidity and a certainty that could not have been expected had ether been given throughout the operation. The list of surgical cases included gastro-enterostomies, hernias, extensive breast operations, amputations, goiters, etc. His youngest patient was 2¼, and the oldest 69 years. The longest period during which the gases were given was 75 minutes on two occasions. Both of these patients awoke in a few minutes perfectly fresh.

[*Boston Medical and Surgical Journal*, Boston, February 13, 1913.]

PERSISTENT MOUTH-BREATHING FOLLOWING ADENOIDECTOMIES. By Dr. I. Sobotky.

In his inquiry why there are so many failures after adenoidectomies, and what can be done to facilitate nasal breathing, the writer comes to the following conclusions:

For the cure of persistent mouth-breathing, the nasal breathing exercises have not proved efficient. An operative treatment of the nasal condition is indicated, which treatment must be appropriate for the age of the patient. Patients should have the adenoid removed before the typical high palatal arch is formed. If this high arch is formed, the treatment should be dental, such as spreading the arch and regulating the teeth. Cutting a slice of mucous membrane from the enlarged lower turbinates, as an aid to nasal respiration, has given good results. A submucous resection should not be made in children under sixteen. Electrolysis, using the bipolar method, is effective in reducing the enlarged turbinates, but is not suited for children.

[*Dental Surgeon*, London, November 16, 1912.]

A METHOD OF GIVING NITROUS OXID WITH THE ADDITION OF ETHER IN MINOR SURGERY. By J. K. Pedley.

Having witnessed the very painful recovery from nitrous oxid administered for the opening up of a whitlow, and having once had a similar experience himself, the author recommends the following method of administering nitrous oxid and ether. The mention of ether is sufficient to call up a vision of violent emesis; administered, however, as an addition to nitrous oxid in the following manner, it will be found exceptional that the patient becomes sick. The nitrous-oxid anesthesia is conducted in the usual way, but after the inhalation of the first bag of gas, which is, of course, refilled, the ether is turned on fairly quickly until the indicator stands at full ether. On the commencement of stertor, the anesthetic is withheld. This will produce an anesthesia of about twice the length of anesthesia by nitrous oxid alone. If a longer anesthesia than this is required, air is given from time to time. No to-and-fro breathing takes place at any time during the administration. The difference in the feelings of the patient on recovery from a short though painful operation under this anesthetic mixture as compared with anesthesia by nitrous oxid alone has to be experienced to be fully appreciated.

[*Beitraege zur Klinischen Chirurgie*, Berlin, 1912, vol. 76, No. 3.]

A CASE OF DEATH UNDER NITROUS OXID AND OXYGEN. By Dr. John Olow.

The patient, a very stout man of fifty-three, exhibiting unmistakable symptoms of emphysema and coronary sclerosis, was given 0.01 cc. of morphin hypodermically half an hour before the operation. As usual, a high percentage of nitrous oxid was administered at the beginning of the anesthesia, followed by a gradually increasing percentage of oxygen. The patient became suddenly cyanosed, and, although pure oxygen was at once turned on, ceased to breathe; a slight twitching of his legs was observed. After another thirty seconds, pronounced pallor ensued, despite artificial respiration and ether hypodermically, and the heart-beat could no longer be perceived. The air could not be made to pass properly through the nose and mouth, although the tongue was held well forward, and no obstacle to respiration could be detected. The post-mortem showed luetic aortitis, secondary hypertrophy of the heart, sclerosis of the coronary arteries, and degeneration of the heart muscle.

The author attributes the asphyxia to the narrowing of the oro-pharyngeal aperture ensuing upon the light cyanosis occurring during nitrous oxid anesthesia, and giving rise to impeded respiration, especially through the mouth, which, as Threwby has pointed out, occurs mostly in cases of large and flabby tongue.

In the case described, the short asphyxia sufficed to produce symptoms of heart collapse. In similar cases, a quickly instituted tracheotomy might save the patient's life.

Periscope.

High-pressure Hypodermic Needle Packing.—Waxed floss silk wrapped around a shortened hypodermic needle used for a high-pressure anesthesia makes an absolutely tight joint.—W. H. Craft, *Dental Brief.*

Preventing Nausea in Taking the Impression for a Denture.—In sensitive patients an impression can be taken without causing nausea, if the palate is first touched with spirit of camphor.—*Archiv fuer Zahnheilkunde.*

High-frequency Currents in Trigeminal Neuralgia.—W. F. Sommerville reports the successful result of the use of these currents in a case of very resistant trigeminal neuralgia which had not been improved by any other form of treatment.—*New York Med. Journal.*

Etching Gold Inlays to Obtain Better Cement Adhesion.—The part of the inlay to which the cement is to adhere is dipped in mercury, the surface being evenly coated by using a moist piece of cotton and spreading the mercury around. When this has been accomplished, the inlay is inverted over an alcohol flame and the mercury is slowly driven off, leaving a rough surface for the cement to adhere to.—R. I. Lewis, *Dental Review.*

Wax Inlays.—It appears to be a very common practice to suck out wax inlays, by the mouth, before investing to cast. Such a procedure is certainly inviting infection, particularly tubercular infection. To obviate any possible danger, a motor horn, the bulb of an enema syringe, or suchlike, can be conveniently attached to the wax absorber, and will produce the same result without any risk of infection.—H. C. Moxham, *Commonwealth Dental Review.*

Use of Paraldehyd as an Intravenous Anesthetic.—Starting at first with extremely small doses, 4 cc. of the pure drug were injected by the writer into the median basilic vein. Almost before the syringe was empty, the patient was unconscious; he slept naturally for about two hours. Subsequently 8 cc. were injected, with satisfactory results. It was found, however, that the pure drug caused a certain amount of local discomfort and coughing, and it was therefore diluted with saline to form a 10 per cent. solution. 100 cc. of this solution produced in about forty seconds an anesthesia lasting about twenty minutes, and suitable for minor surgical procedures. Paraldehyd, while acting temporarily as an anesthetic, has a prolonged hypnotic effect, considerably reducing the amount of ether subsequently required. Being volatile, it is rapidly excreted by the lungs, an important element in the safety of the drug, an advantage which cannot be claimed for hedonal.—H. L. C. Noel, *Lancet.*

Repair of Vulcanite Dentures.—Time may be saved by fixing two pieces in proper relation, and then making a modeling compound model; the latter having hardened, the pieces of the denture are removed and the undercuts are prepared for repair, the pieces replaced on the model, and wax is flowed in to take the place of the rubber which has been cut away. The wax having been smoothed, it is only necessary to flask and proceed as usual.—*Dental Record.*

Vaccine or Ionization in Pyorrhea.—An autogenous vaccine will undoubtedly produce good results in all forms of pyorrhea, and will temporarily raise the resistance of tissues to reinfection. But the vaccine often takes some time to prepare, especially when the trouble is due to a mixed infection. Ionization with chlorid of zinc is available for every case without any delay. The zinc ions take the place of an autogenous vaccine, and destroy all bacteria, thereby permitting nature to restore the normal resistance of the tissues.—R. F. Reading, *Commonwealth Dental Review.*

Removing Gum Tissue with Trichloracetic Acid.—To remove gum tissue projecting into a carious cavity, trichloracetic acid is applied on a small pellet of cotton, and in a few minutes the gum can easily be removed with a spoon excavator. This acid can also be used for gum tissue overlying a third molar when badly inflamed, instead of lancing the gums or trying to remove this tissue with the scissors. It is applied on cotton wound around a root-canal plugger, protecting the tongue and cheeks from the action of the acid with absorbent cotton rolls.—M. M. Brown, *Dental Summary.*

Removing Deposits from German Silver Appliances.—Regulating appliances of German silver can be freed of deposits and discoloration by ordinary pure hydrochloric acid applied cold. The cleaned appliances are immersed in a solution of sodium bicarbonate.—*Archiv fuer Zahnheilkunde.*

Drying Root-canals.—The important process of drying a root-canal following the extirpation of a pulp can be accomplished—as well as it can be done at all—by applying alcohol of three successive strengths, viz, fifty, seventy, and one hundred per cent., and drying with hot air after each application. —*Archiv fuer Zahnheilkunde.*

Removing Platinum Matrices for Porcelain Inlays.—It is often difficult to remove the platinum foil matrix from the cavity without distortion. To prevent this, the platinum foil is allowed slightly to overlap the cavity margins. Over it, a piece of heavy lead foil is burnished to fit approximately. The platinum foil will stick to the lead foil during removal from the cavity, and can subsequently be easily separated.—*Les Annales Dentaires.*

Allocain in Local Anesthesia.—Although we have in novocain an almost ideal local anesthetic, it is a matter of fairness to mention the more prominent of the innumerable local anesthetics which have recently flooded the market. Allocain is composed of novocain, alypin, synthetic suprarenin, and traces of thymol. By the mixture of novocain and alypin a more rapid anesthetic action is intended. Clinical experience has shown that in extractions, for instance, complete anesthesia was established in three minutes in the maxilla, and in five minutes in the mandible.—*Zeitschrift fuer Zahnheilkunde.*

Amalgam Dies for Gold or Porcelain Inlays.—An impression of the prepared cavity is taken with a stick of impression material, cut off in a small piece. A small amount of plaster of Paris is mixed and built up in a little heap. Into this, the impression is pushed with the mold uppermost, making a little wall around it. When the plaster is hard and trimmed, it forms a small cup. Into this a sufficient amount of softly mixed amalgam is then carefully packed. When the amalgam is hard, the plaster and impression are removed, leaving a very clear die, from which the inlay can be formed either by making a wax model for a gold inlay or by burnishing a platinum matrix for a porcelain inlay.—G. D. Sitherwood, *Dental Review.*

Vaselin as a Separator in Plaster Casting.—When a model from a plaster impression is needed in a hurry, the impression is coated with vaselin by rubbing it on the impression with a lock of cotton and carefully wiping off the surplus. This fills the pores of the plaster, and is absolutely impervious to moisture, therefore there is no adhesion. It is not advisable for general use, as to some extent it is liable to fill the fine lines of the impression. It is excellent for use on a model when casting on it an articulating model, and also when flasking for a vulcanite denture.—W. H. Craft, *Dental Brief.*

Disinfection of the Oral Cavity.—The authors recommend a one per cent. solution of oleate of soda, viz, soap, heated to 45° C. To counteract the disagreeable taste, the mouth is subsequently rinsed with a five per cent. solution of potassium chlorate. Investigation has shown that by this disinfection the microbic contents are reduced to one per cent., returning to the original only after twenty-four hours. By repeated rinsing the bacterial flora are reduced and modified. Leptothrix and spirilla are diminished in number, and pneumococcus disappear. The mucosa resumes its normal state, and the breath becomes clean; at the same time, dental caries is arrested.—Pane and d'Agata, *Les Annales Dentaires.*

Rheumatic Fever, and the Relation of Oral Sepsis to Its Cause and Cure.—(1) Rheumatic fever is an acute or attenuated general infection accompanied by toxemia, auto-intoxication, chorea, high blood pressure (51), anemia, carditis, and arthritis. (2) The micro-organism and its toxin most concerned in the stimulation of the particular symptoms evidenced in rheumatic fever is the *diplococcus rheumaticus*, of the streptococcus family. (3) The portal of entry for the infection is the oral cavity. (4) Oral sepsis plays a direct part in the causation of rheumatic fever by supplying the necessary conditions and ingredients for the absorption, via the gastro-intestinal tract, of the factors concerned in the excitation of the symptoms exhibited. (5) Oral sepsis plays a direct part by supplying the necessary conditions also for the absorption from the mouth of the agents that induce the train of symptoms manifested in rheumatic fever. (6) The correction of the conditions contributing to oral sepsis will exert a positive and favorable influence in preventing and curing rheumatic fever.—A. M. Nodine, *Items of Interest.*

Simple Means for Polishing Fillings and Cleaning Teeth.—Around an old inverted-cone bur, while it is revolving in the engine, cotton is wound in sufficient thickness so that the bur will not cut through the cotton. This polisher is dipped in a solution of pumice and water for polishing amalgam fillings and cleaning the teeth. For polishing gold inlays and fillings, it can be dipped in prepared chalk and water.—F. SCHWARTZ, *Dental Review.*

Repair of Broken Facings on a Bridge or Crown.—A piece of regulating tubing is mounted on the shank of a bur. This tubing should just fit over the individual pins of the new facing. With carbo-powder the porcelain is cut away from around each of the pins until they fall out. The holes remaining are undercut, and the facing is ground to fit at the gingival margin and cemented over the headed pins which were left standing on the bridge or crown backing. This gives as good a fit as a Steele or any similar facing. With a headed pin thus cemented into an undercut cavity, the facing is securely held. The effect is neat; the work can be quickly done, and the backing remains unchanged in contour.—G. B. MITCHELL, *Dental Brief.*

Purifying Gold for the Casting of Gold Inlays.—Sometimes a small pit, fissure, or imperfection in the gold of a well-fitting inlay will make it necessary to repeat the operation. At times the gold will not run smoothly; this is many times caused by impurities in the gold at the time of casting.

A useful method for warding off this difficulty is to purify the gold before each casting operation. A prepared charcoal block is used, after scraping a hollow in the center and placing the gold in it. Over the gold a little powdered borax is sprinkled, and the gold melted. Then, still applying the blowpipe, a little potassium nitrate or common saltpeter is sprinkled on the molten gold. This is repeated several times, still keeping the gold boiling with the blowpipe. The ingot is allowed to cool slightly on the block, and then put in a pickle of sulfuric acid and washed, and the gold is ready for the casting operation.—R. W. CALKINS, *Dental Brief.*

Oral Sepsis and Heart Disease.—Oral sepsis has sometimes a definite association with infective disorders of the heart, and although the mere existence of the unclean mouth does not, of course, indicate any cardiac condition, yet, given the suspicion of endocarditis, the presence of a focus of infection is in a measure a confirmation. A case which recently came under notice illustrates this. The patient, a man, had been for some weeks in bed with a persistent but intermittent temperature showing an excursion of three or four degrees. No Widal test had been tried, and the diagnosis hung between enteric fever and infective endocarditis. There were no cardiac signs other than those common to all febrile conditions. The existence of a septic sinus in the mouth pointed to the greater probability of infective valvular mischief. The agglutination test subsequently proved negative, and still later an autopsy revealed a recent and destructive lesion of the aortic and mitral valves.—*Dental Surgeon.*

Tuberculosis and Dental Practice.—(1) Tubercular lesions in the oral cavity are very rare, while the pharynx and larynx are not uncommon locations. (2) The dentist should make an effort to discover the presence of such conditions and recommend his patients to the proper source for treatment, although they come to him for mechanical work only. (3) He should possess such knowledge on these subjects as to enable him to use the utmost care to prevent contagion, and to protect himself. (4) He should be able to use his mouth-mirror in the pharynx and larynx of all suspicious cases, and get a history of such cases, to be kept on record. (5) He should add his mite to the host of enthusiastic workers in the endeavor to stamp out the ravages of disease. (6) He should improve every opportunity to give the patient and the public the best there is in him, and at the same time protect himself from any unnecessary exposure to or contact with diseases liable to shorten his years of usefulness.—J. W. SHANKLAND, *Dental Summary.*

Filling Deciduous Teeth.—In deciduous teeth it is well to make an application of silver nitrate when the enamel is decalcified or caries is just beginning. This will retard the carious process, or may even stop it. But when caries has progressed far enough to permit food particles to lodge in the cavity, the application of silver nitrate will be insufficient. Time and later trouble will be prevented by filling such cavities. If, however, there are several cavities to be filled, it is wise to make an application of silver nitrate to all the cavities at each sitting as the work proceeds. These applications should be made several days before any attempt is made to prepare the cavities for the filling. The soft dentin may then be removed from one or two of the cavities, and an application of

Cocain hydrochlorate,	grs.	v
Menthol,	"	xx
Thymol,	"	xl
Phenol,	"	xl
	Ad	℥iij

or of eugenol and aristol may be made. A small pellet of cotton may be dipped into the eugenol and squeezed with a napkin, and then dipped into the aristol. Either of these applications may be left in the tooth several days before the final preparation of the cavity for the filling.—G. H. WESTHOFF, *Dental Summary.*

A Substitute for Window Crowns in Bridge Work.—Window crowns have lost some of their popularity since we have discovered that the support they lend in bridge work is very unreliable. They can be trusted to hold for a considerable time only when they are fixed upon long and nearly cylindrical teeth, such as, for instance, the lower incisors and canines, when they are standing well up out of the alveolus, as is the case in older patients. Even thus they are not always successful, especially if the band on the labial side be at all too narrow. What is to be done in those cases, occurring almost every day, in which two or more molars are absent, and one canine and a molar are required for abutments? A full crown on a canine is undesirable from the esthetic point of view; a sufficiently large inlay is hardly possible, and many patients object to the drilling and cutting away of sound tooth substance demanded by the Carmichael method. Only a root-pivot remains. If there is a cavity, the pulp should be opened from that side, the pulp removed, and then the cavity extended until sufficient space is obtained to allow of the easy introduction of a pivot in the direction the bridge will follow when it is pressed down. The whole of the posterior and, if necessary, also the approximal surfaces of the tooth should be covered with a backing soldered to the pivot.

In the case of a sound tooth, I find the backing unnecessary, and use a free-lying root pivot, thus avoiding the risk of the collection of alimentary detritus. Fractures need not be feared if the pivots are made of strong materials, such as clasp-gold or iridio-platinum.—*Deutsche Zahnärztliche Zeitung* per *Dental Record.*

Nursing versus Bottle-Feeding and Dental Irregularities.—As to the relation between nursing babies and bottle babies there is a great difference of opinion. Some claim that the nursing baby has to work harder to obtain his food than the bottle baby, and as a result of this more powerful suction, a similar condition is present to that found in cases of thumb-sucking.

In answer to this argument it may be said that there is a wide variety in the supply of milk among nursing mothers, and many babies find it very easy to obtain their meal. A similar variation is found among the bottle babies, depending on the kind of nipple used and the size of the opening. A very common nipple is one with a large, rounded extremity and rather stiff rubber to prevent collapsing. Such a nipple gives as much or more chance for extra exertion on the part of the baby than a mother's breast with a limited milk supply. In addition, the nipples are usually long and press against the roof of the mouth, similarly to the pressure obtained by sucking the thumb. The proper nipple should be straight, with an opening just large enough to allow the milk to drop steadily when the bottle is inverted. On the whole it seems that, considering the large variety of nipples for bottle-feeding and the great chance for carelessness in feeding a bottle baby, there is no more opportunity for damage to be done to the mouth than in the case of nursing babies. It is simply a question whether either method of feeding has very much to do with the formation of irregular arches and teeth.—A. C. EASTMAN, *American Orthodontist.*

Technique of Making an Accurate Matrix for Porcelain Inlays.—The following is a description of the technique of using medium weight China silk, instead of gold-beaters' skin, as suggested by Dr. Emil Schreier of Vienna, as a cradle support for gold or platinum in obtaining matrices for inlays. The silk may be regarded as an improvement over the velum, as it has greater bulk and better sustains the foil.

The foil being cut sufficiently large to cover the prepared cavity amply, is placed between a fold of silk, dipped in water, and with a wet pellet of cotton or spunk is quickly carried to the floor of the cavity. With a suitable instrument in one hand it is held firmly in position; in the other hand, with ball-pointed pliers, the metal is grasped, together with the silk, pulling and smoothing out all folds or wrinkles. Then it is packed full with wet cotton or spunk, using heavy pressure, turning all margins with a large pellet of wet spunk held in the ball-pointed pliers. It is then taken from the cavity, the silk is carefully removed, and the matrix returned for completion by again swaging with pellets of cotton or spunk, this time used dry. The operation is completed by filling with wax or gum camphor for safe removal. At the same time all margins are made perfect with a roller burnisher. The matrix is then removed and invested. When the wax has been melted or boiled out, the porcelain is introduced and baked in the usual manner. Much time can be saved, however, with a smaller number of bakings, by packing the wet porcelain into the matrix with a short, stiff camel's-hair brush, absorbing the moisture after the introduction of each layer of porcelain.—E. S. GAYLORD, *Dental Brief.*

Mixed Tumors of Salivary Glands.—Fifty-six cases of mixed tumors of the salivary glands, which were removed, are analyzed by Wilson and Willis. The sexes are almost equally divided, but with a slight preponderance of males. The age at onset in more than two-thirds of the cases is under forty years, while in one-half the cases it falls between twenty and forty years. These figures agree, on the whole, with those of other observers. The length of the period between the onset of the tumor and the time of surgical operation varies from one month to forty-four years, with a large preponderance of the cases running from one to ten years, and an average of six years and four months. The obvious lesson from this is that these tumors do not cause sufficient inconvenience to the patients to make them seek operation early. In only fourteen cases was there a history of pain. Of the twenty-one patients with tumors of the parotid who could give a definite history concerning mumps, fourteen (66 per cent.) were sure they had never had the disease. In other words, there seems to be no etiologic relationship established by the statistics of mumps and "mixed" tumors of the parotid. Of the fifty-six tumors, fifty were in the parotid and six in the submaxillary glands; thirty were on the right side and twenty-six were on the left. Grossly, the tumors may be divided into four groups: (1) Hard, fibrous masses with little cartilage and with little parenchyma—in this group were fifteen cases; (2) very hard tumors containing large cartilage masses—in this group were seventeen cases; (3) soft, more or less sarcoma-like tumors, with a relatively small amount of fibrous connective tissue and a relatively large amount of parenchyma cells—in this group were four tumors.

There is little evidence that these tumors arise from proliferating adult epithelium, or endothelium; on the other hand, there is considerable evidence to support the theory that they are mesotheliomas of embryonic origin. After fairly complete operative removal, few of the tumors recur.—*Amer. Journ. of Med. Science.*

Electroplating on Plaster.—At different periods attempts have been made to produce dental plates by an electroplating process. So far it has not proved a practical success. The deposited metal lacked the tenacity of metal cast into an ingot and rolled into plate. If it could be satisfactorily accomplished, with certainty and economy, depositing the plate directly upon the plaster model would be ideal. Processes at present in use for depositing gold upon plaster are not promising; substituting a less desirable metal for the body of the plate, and covering this with a substantial coating of gold, while theoretically promising and readily accomplished, leaves a great deal to be desired. The more accurate adaptation secured does not compensate for the loss of durability, the time consumed, and the inability of such a plate to stand laboratory manipulations. The first difficulty encountered in electroplating upon a plaster model is the porosity of the plaster. Not only does this cause a loss of plating solution, but the solution penetrating the plaster may cause its disintegration, and would make the metal surface in contact with the model quite rough. It is essential to not only thoroughly fill the pores in the mass of the model, but to give the model a smooth surface. Varnishes are not effective. Paraffin is effective but too smooth to hold the graphite or other conducting medium; beeswax, and rosin also, has too high a melting-point. About equal parts of beeswax and rosin gives satisfactory results. The plaster must be perfectly dry; a long-continued heat of about 220° F. gives a better result than a shorter time at a higher heat. The high heat is apt to distort or crack the model. After the moisture has been nearly all driven off, the heat may be increased to 300° F., so as to make it perfectly dry. Then the model is immersed in the wax and rosin heated to just its melting-point, not higher, and allowed to remain until no bubbles appear, and a little longer to make sure that it is thoroughly saturated. The model is removed, the surplus wax wiped off, and the surface is coated with a cheap furniture varnish, giving it a thin, even coat. This is allowed to dry until it is just sticky, then graphite or copper powder is applied over all the surface which it is desired to coat, and the model is allowed to dry. The surplus is dusted off with a soft brush, and the model is then ready for plating.—*Brass World*, per *Western Dental Journal.*

Investigations Concerning Surgical Methods of Treatment for Trigeminal Neuralgia.—Otto considers that the justification of the operative treatment for trigeminal neuralgia is generally recognized, but that just which operation should be done in a given case is not an easy question to decide. Neither the peripheral operations nor the resections at the base of the skull will always give permanent relief. Even the extirpation of the ganglion in many cases gives only temporary relief, probably because of incomplete operations. Only rarely do we find the seat of changes in the nerve, and the mode of origin of the neuralgia is rarely determined; nor do we know whether the neuralgia is due to functional or organic disease. As the result of his studies, Otto believes that the peripheral operations are frequently followed by recurrence. Thiersch's nerve exeresis in most cases leads to recurrence, very frequently after a few months. The condition recurs more rarely after resections at the base of the skull. Extirpation of the Gasserian ganglion gives the best results, provided the ganglion is wholly removed. The operation is, however, technically difficult, and should be reserved for otherwise hopeless cases, and especially for those in which the three branches of the ganglion are involved. Under these circumstances, one is fully justified in trying out the injection method of combating the affection. Alcohol—from 70 to 80 per cent.—is the most suitable fluid with which to inhibit the conductivity of the nerves without damaging the other tissues. The deep injection at the base of the skull suffices even in severe cases to anesthetize the regions supplied by the treated branches for months, and it can be repeated without danger. The effect usually lasts a long time, but whether a permanent cure may result remains to be proved. The Offerhaus method is favored, because it is easily performed without previous practice. It is without danger, and may be employed to obtain anesthesia for the performance of operations in the trigeminus regions.—*Mitt. a. d. Grenzgeb. d. Med. u. Chir.*, per *Amer. Journ. Med. Science.*

Hints, Queries, and Comments.

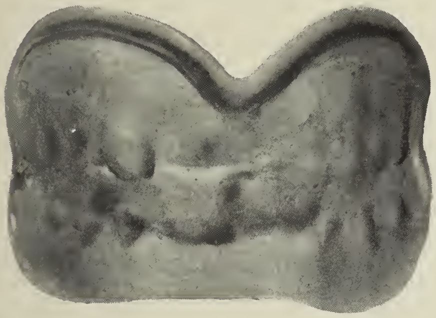
APPLIANCE FOR THE PREVENTION OF MOUTH-BREATHING.

The following describes a clinic given before the Northeastern, New Hampshire, and Vermont dental societies:

Although much is being said and written today about the evils of mouth-breathing, surprisingly little is being done to prevent it. Two methods with this object are prevalent, viz, the halter or sling, which goes under the chin and buckles at the top of the head, and the surgeon's adhesive plaster, which is applied to both lips at night, thus keeping the mouth closed. Either of these methods is very uncomfortable, and does not accomplish the end proposed.

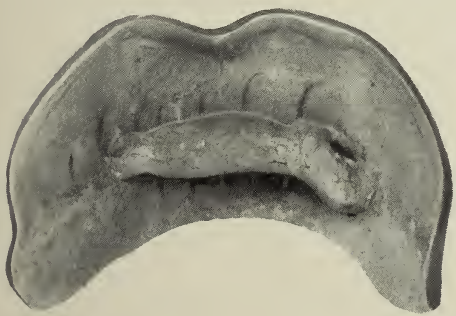
The apparatus to be described was devised by the writer three years ago, and has never failed in any of the cases where it was applied. The mode of construction is as follows: A piece of base-plate wax is cut in such a manner that it will fit into the vestibule of the oral cavity, viz, the space between the lips and the teeth. Notches are cut in the wax so as to make it fit the upper and lower frena. The wax is then slightly softened, and placed in the vestibule of the mouth. The operator then requests the patient to draw in his breath, while he manipulates the lips and face in such a way as to obtain an impression. The wax impression thus obtained is chilled, and a small piece of soft yellow wax is added to its inner surface. The patient is then requested to bite into this yellow wax to within one-eighth of one inch of his usual articulation. The upper ridge of the wax model is then reinforced with a single layer of base-plate wax, as shown in the accompanying illustration. The wax model is then invested in an ordinary vulcanite flask, with the inner surface bearing the yellow wax portion down-

FIG. 1.



ward, leaving all the outer surface of the wax model exposed. Separating fluid is applied, and the other half of the flask is poured. After the plaster is fully set, the flask is opened, the wax is washed out, both surfaces

FIG. 2.



of the mold are covered with tinfoil and soaped well.

For the bulk of the apparatus, excepting the upper ridge, Doherty's velum rubber is used, while for the reinforced ridge ordinary plate rubber is employed, in the following manner: A piece of No. 29-gage gold wire is conformed to the ridge with contouring pliers. This wire is then covered with ordinary plate rubber and set into the upper portion of the model. The flask is then closed, and the case is vulcanized at 280° F. for three hours. After cooling, no finishing will be necessary except the polishing of the hard rubber ridge.

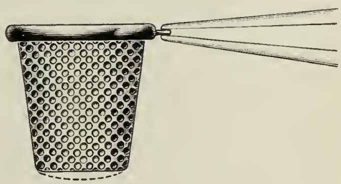
With this appliance, attrition also can be prevented, and the habit of thumb-sucking broken.*

HARMAN NEWELL, D.D.S.

Claremont, N. H.

HEATING ALCOHOL BEFORE APPLYING TO TEETH.

ONE of the most painful sensations is that following the application of cold alcohol to a cavity. This can be avoided by warming the alcohol, using the following method:



An aluminum thimble is placed in a vise and the tip is flattened out as shown by the dotted line in the drawing. This prevents it from falling over when placed on the table. The end of the rim is also flattened out at one end, forming a projection for grasping with tweezers.

The empty thimble is held over the alcohol flame for about ten seconds. It is then set on the table and a few drops of alcohol are poured into it. In a short time the alcohol is sufficiently warm to be used on a pellet of cotton for wiping out the cavity without pain.

BERNARD FISCHLER, D.D.S.

Brooklyn, N. Y.

* [A similar appliance, invented by Dr. Frank B. Darby of Elmira, N. Y., was described in COSMOS, vol. xxii, March 1890, p. 214.—ED.]

Obituary.

DR. NORMAN W. KINGSLEY.

Died, at his home, Warren Point, Bergen co., N. J., on Thursday, February 20, 1913, Dr. Norman W. Kingsley, in his eighty-fourth year.

The funeral of Dr. Norman William Kingsley, dentist, sculptor, artist, and author, and founder of the New York College of Dentistry, who died at his home, Warren Point, N. J., was held on Saturday, February 22d, from the "Little Church Around the Corner," in East Twenty-ninth st., Manhattan. Interment was in Woodlawn Cemetery.

Dr. Kingsley was the son of Nathaniel and Eliza Williams Kingsley, and was born in St. Lawrence county, New York, October 26, 1829. He was a direct descendant of one Ranulph de Kingslea, a Saxon keeper of the king's forest, in 1166, through John Kingsley, who came to America in 1634.

Receiving his early education in the Troy Academy, Dr. Kingsley, after his graduation, became a clerk in a store at Elmira, N. Y. He began his dental studies with his uncle, Dr. A. W. Kingsley of Elizabeth. Later he took a course at the Baltimore College of Dental Surgery, and in 1852 began practice in New York.

In 1853 Dr. Kingsley was awarded the highest prize for porcelain teeth at the World's Fair, held at New York, and two years later he was similarly honored in Paris. In 1859 he invented an artificial palate for aiding the speech of persons with harelip, a device that is still used. For this invention Dr. Kingsley was awarded a gold medal by the American Dental Convention at Saratoga in 1863, and later another medal was given him by the Odontographic Society of Pennsylvania.

Dr. Kingsley went in 1864 to London, where honors were bestowed upon him by various societies and by the French Academy of Medicine. In 1865 he founded the New York College of Dentistry, becoming dean of the faculty and the first professor of dental art and mechanism. He was a member of a score of dental and surgical societies of this country and Europe, and in 1881 was a member of the International Medical Congress in London.

Dr. Kingsley was the author of "A Treatise on Oral Deformities," the first text-book ever published on the scientific treatment of irregularities of the teeth.

As an artist Dr. Kingsley achieved considerable fame, principally in sculpture. His most notable work was a portrait bust of Whitelaw Reid, which was cast in bronze, and is now in the Lotos Club, New York, of which Dr. Kingsley was long a member.

In 1850 Dr. Kingsley married Miss Alma N. Shepard, who, with two daughters, survives him.

Brief Necrology.

Dr. Louis S. Berdelon of Moreauville, La., on December 23, 1912.

Dr. Elon G. Douglas of Lapeer, Mich., on January 1, 1913, in his seventy-fourth year.

Dr. Wm. G. Smith of Salisbury, Md., on January 30, 1913. Deceased was a graduate of the Pennsylvania College of Dental Surgery.

Dr. Marshall B. Dennis of Port Huron, Mich., on December 5, 1912. Deceased was a graduate of the College of Dental Surgery of the University of Michigan, and at one time member of the state board of dental examiners.

Dr. Thomas Western Pritchett of Whitehall, Ill., on January 20, 1913, in his seventy-second year. Deceased was a member, and at one time president of the Illinois State Dental Society, for several years member of the Illinois State Board of Dental Examiners, member of the Madison County District Dental Society, honorary member of the St. Louis and the Morgan County Dental Societies, and a veteran of the civil war.

Dental Legislation.

DENTAL LAW OF VERMONT (1904),

INCLUDING

Amendments of 1912.

An act to Regulate the Practice of Dentistry

Approved November 30, 1904, Together with Amendments Exacted by the General Assembly of the State of Vermont and Approved December 14, 1912.

It is hereby enacted by the General Assembly of the State of Vermont:

Section 1. The state Board of Dental Examiners shall consist of five dental practitioners of good standing, who have practiced in this state for a period of five years or more. Each member hereafter appointed shall hold office for a term of five years from and including the first day of January in the year following his appointment and until his successor is appointed, and no member shall serve for more than two full terms. The governor shall annually, in the month of December, appoint an examiner to succeed that member of the board whose term expires on the first day of January following. A vacancy in the board shall be filled by the governor.

Sec. 2. The meetings of said board shall be held annually at the State-house in Montpelier, or oftener on the call of three members, and thirty days' notice of such meetings shall be given in at least three dental journals circulating in this state. Said board shall annually, at its first meeting after the first day of January, elect from its members a president, secretary, and treasurer, and shall make annual reports to the governor and to the Vermont State Dental Society.

Sec. 3. A person above twenty-one years of age, of good moral character, and who is a graduate of a reputable dental college or school, or of a college or school authorized by law to grant diplomas in dentistry, and who is a graduate of a high school or academy of the first class approved by the superintendent of education, or who furnishes evidence of an education equivalent to that of a high school of the first class, shall upon the payment of a fee of twenty-five dollars, be entitled to be examined, and, if found qualified, shall be licensed to practice dentistry, dental surgery, and medical dentistry, and shall receive a license signed by the members of the board of examiners. The examinations shall be elementary and practical, but sufficiently thorough to test the applicant's fitness; they shall be wholly or in part in writing, in the English language; and shall embrace the subjects of anatomy, physiology, chemistry, materia medica, therapeutics, metallurgy, histology, pathology, bacteriology, anesthesia, oral surgery, operative and prosthetic dentistry, orthodontia and crown and bridge work, with demonstrations by the applicant in operative and prosthetic dentistry. An applicant who fails to pass a satisfactory examination shall be entitled to a re-examination at any future meeting of the board without payment of a fee, but for any subsequent re-examination a fee of five dollars shall be paid. Rules relating to qualifications of applicants and to conduct of examinations and to the granting of licenses may be made by the board of examiners.

Sec. 4. Said board, in its discretion, may, without examination, issue a license to a dentist who has been lawfully in practice in another state for at least five years upon the payment of a fee of twenty-five dollars, provided such applicant presents a certificate from the board of dental examiners or other like board of the state in which such dentist has practiced, certifying to his competence and good moral character, and provided further that such state maintains a law of requirements equivalent to our own and grants a like privilege to dentists licensed to practice in this state.

Sec. 5. Any duly licensed dentist of this state who is desirous of changing his residence to that of another state shall upon application to the board of dental examiners receive a certificate which shall attest that he is a duly licensed dentist in the state of Vermont. The same shall be given without fee.

SEC. 6. The board of dental examiners shall keep a book in which it shall enter the name of each person licensed as provided for by this act.

SEC. 7. A person who receives a license from said board shall, within thirty days from the date thereof, cause it to be recorded in the office of the secretary of state and shall pay him fifty cents for recording the same. Such license duly recorded by the secretary of state or a duly certified copy of such record shall be evidence of the authority of the person therein named to practice dentistry.

SEC. 8. If a person does not cause his license to be recorded within the time required by the preceding section, he shall forfeit the same, and shall not be re-licensed until he has paid the board a fee of twenty-five dollars.

SEC. 9. Whoever engages in the practice of dentistry in this state shall keep his license displayed in the room or rooms in which he practices, in such manner as to be easily seen and read. A person who practices dentistry under a fictitious or assumed name, or who, not being licensed, practices dentistry or advertises or holds himself out to the public as a dentist, or assumes the title of "Doctor of Dental Surgery" or "Doctor of Dental Medicine," or appends the letters "D.D.S." or "D.M.D." to his name, not having the right to assume such title by a degree conferred upon him by a college or school empowered by law to confer such title, or who shall wilfully make a false material statement in his application and license, or who changes or alters a license issued by said board, shall be fined not more than one hundred dollars nor less than twenty-five dollars, or imprisoned not more than three months, or both. A license granted to a person not entitled thereto may be revoked by the board, and a license may be revoked for immoral or unprofessional conduct of a licensee; but such revocation shall be upon notice to the licensee and a hearing at which he shall be given an opportunity to be heard, and when a license is revoked such revocation shall be recorded with the secretary of state. Nothing in this act shall be construed to interfere with the rights and privileges of physicians and surgeons licensed under the laws of this state; nor to any person who is now practicing dentistry under a license granted under the existing laws. Nor shall it apply to the mere extracting of teeth by a person who has been engaged in that work for a period of five or more years in this state; provided, however, that such person file in the office of the secretary of state previous to February 1, 1913, an affidavit that he has been so engaged for such period.

SEC. 10. The treasurer of the board, or the person whose duty it is to receive all moneys for examinations and certificates, shall quarterly make a report to the state treasurer of all examinations given and certificates granted, and pay into the state treasury all moneys received by him for such examinations and certificates.

SEC. 11. Each member of the board of dental examiners shall receive four dollars a day for services rendered and necessary expenses.

SEC. 12. This act shall take effect from its passage.

SOCIETY NOTES AND ANNOUNCEMENTS.

DENTAL SOCIETY MEETINGS:

April, May, and June.

APRIL.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA. Philadelphia. April 22d.

ARKANSAS STATE DENTAL ASSOCIATION. Little Rock. Five days: April 7th to 11th.

CONNECTICUT STATE DENTAL ASSOCIATION. Waterbury. Two days: April 15th and 16th.

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES. Boston, Mass. Two days: April 22d and 23d.

FIFTH DISTRICT (N. Y.) DENTAL SOCIETY. Syracuse. Three days: April 3d to 5th.

ODONTOLOGICAL SOCIETY OF WESTERN PENNSYLVANIA. Pittsburgh. Two days: April 8th and 9th.

MAY.

DENTAL SOCIETY OF THE STATE OF NEW YORK. Albany. Three days: May 8th to 10th.

INDIANA STATE DENTAL ASSOCIATION. Indianapolis. Three days: May 20th to 22d.

IOWA STATE DENTAL SOCIETY. Davenport. Three days: May 6th to 8th.

KENTUCKY STATE DENTAL ASSOCIATION. Lexington. Three days: May 26th to 28th.

LAKE ERIE (PA.) DENTAL ASSOCIATION. Cambridge Springs. Three days: May 15th to 17th.

MASSACHUSETTS DENTAL SOCIETY. Three days: May 8th to 10th.

NATIONAL DENTAL PROTECTIVE ASSOCIATION. Washington, D. C. May 20th.

NEBRASKA STATE DENTAL SOCIETY. Omaha. Four days: May 19th to 22d.

NORTH DAKOTA DENTAL ASSOCIATION. Fargo. Two days: May 16th and 17th.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION. Los Angeles. Four days: May 26th to 29th.

SUSQUEHANNA (PA.) DENTAL SOCIETY. Wilkes-Barre. Three days: May 20th to 22d.

TEXAS STATE DENTAL ASSOCIATION. Temple. Three days: May 15th to 17th.

VERMONT STATE DENTAL SOCIETY. Burlington. Three days: May 21st to 23d.

JUNE.

CALIFORNIA STATE DENTAL ASSOCIATION. Oakland. Four days: June 2d to 5th.

COLORADO STATE DENTAL ASSOCIATION. Manitou. Three days: June 19th to 21st.

GEORGIA STATE DENTAL SOCIETY. Columbus. Three days: June 12th to 14th.

MAINE DENTAL SOCIETY. Portland Harbor. Three days: June 25th to 27th.

MISSISSIPPI DENTAL ASSOCIATION. Meridian. Three days: June 24th to 26th.

NORTHERN OHIO DENTAL ASSOCIATION. Cleveland. Three days: June 5th to 7th.

SOUTH CAROLINA STATE DENTAL ASSOCIATION. Isle of Palms. June 25th to 27th.

TENNESSEE STATE DENTAL ASSOCIATION. Nashville. Three days: June 5th to 7th.

WASHINGTON STATE DENTAL SOCIETY. Seattle. Three days: June 16th to 18th.

Examiners' Meetings.

ARKANSAS BOARD OF EXAMINERS. Little Rock. April 7th and 8th.

ILLINOIS BOARD OF EXAMINERS. Chicago. June 4th.

MARYLAND BOARD OF EXAMINERS. Baltimore. May 29th and 30th.

NORTH CAROLINA BOARD OF EXAMINERS. Winston-Salem. May 26th.

PENNSYLVANIA BOARD OF EXAMINERS. Philadelphia and Pittsburgh. June 11th to 14th.

SOUTH CAROLINA BOARD OF EXAMINERS. Isle of Palms. June 20th.

TEXAS BOARD OF EXAMINERS. Houston. June 23d.

WASHINGTON STATE BOARD OF EXAMINERS. Seattle. May 22d.

WISCONSIN BOARD OF EXAMINERS. Milwaukee. June 16th.

NATIONAL DENTAL ASSOCIATION.

THE 1913 session of the National Dental Association will be held in Kansas City, Mo., July 8 to 11, 1913. The Local Committee of Arrangements have selected the Baltimore Hotel as headquarters, and have made the other necessary arrangements for this meeting. The officers and committees are planning to present an exceptionally interesting program, the details of which, together with the other arrangements, will be presented in later journals.

FRANK O. HETRICK, *President*,
Ottawa, Kans.,
HOMER C. BROWN, *Recording Sec'y*,
185 East State st., Columbus, Ohio.

N. D. A.—SOUTHERN BRANCH AND VIRGINIA STATE DENTAL SOCIETY.

THE fifteenth annual meeting of the Southern Branch of the National Dental Association will be held at the Chamberlin Hotel, Old Point Comfort, Va., July 22 to 25 inclusive, 1913. The Virginia State Dental Society will meet conjointly with the Southern Branch at that time.

THOS. MOORE, JR., *Cor. Sec'y, N.D.A.So.Br.*

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

THE next annual meeting of the Dental Faculties Association of American Universities will be held at Harvard Dental School, Longwood ave., Boston, Mass., April 22 and 23, 1913. The meeting will be called to order on the morning of April 22d, at 11 o'clock.

EDWARD C. KIRK, *Sec'y-Treasurer.*

NATIONAL DENTAL PROTECTIVE ASSOCIATION.

The annual meeting of the National Dental Protective Association will be held at the Fredonia Hotel, Washington, D. C., May 20, 1913, at 7.30 P.M., for the election of trustees and transaction of business.

E. P. Dameron, *President*,
M. F. Finley, *Sec'y*,
1928 "I" st., N. W., D. C.

THE PANAMA PACIFIC DENTAL CONGRESS.

As one of the attractions of the Panama Pacific International Exposition, a dental congress, international in character, to be known as the Panama Pacific Dental Congress, is to be held in San Francisco, California, beginning on the last Monday in August 1915, and continuing for ten days.

A Committee of Organization has been perfected, including representatives from the Pacific Coast states—California, Oregon, Washington, Utah, Idaho, Colorado, and Arizona.

This committee is now actively engaged in perfecting the work of organization, including the establishment of executive committees in every state of the United States and in every foreign country where dental organizations are known to exist, which will be empowered to promote the business of the congress by bringing it to the attention of their national, state, and local societies, and securing memberships and contributions to the program.

The American Society of Orthodontists and the National Dental Association, of the United States of America, have already made arrangements to meet in San Francisco in 1915 as a part of the congress, and invitations will be extended to other dental societies to take similar action.

The Panama Pacific Dental Congress is the first organization to apply to the Exposition management for space for exhibits, and to ask that a definite time be set aside for its meeting.

Manufacturers of dental goods have signified their intention to maintain during the congress the greatest exhibition of dental supplies ever held. Ample space for this purpose has already been promised by the Exposition authorities, and we are assured of their hearty co-operation in all things pertaining to the success of the congress.

The membership fee has been fixed at ten dollars, and the finances of the congress are being cared for by a corporation, formed within the Committee of Organization, and known as the "Pacific Dental Congress Commission of 1915."

Over $8000 has already been subscribed for promotion purposes by the dentists and dental societies of the Pacific Coast states, and this fund will be increased by many thousands of dollars before the congress meets.

Ample funds for promotion of the congress are assured, and in due time Committees on Local Arrangements, Transportation, Exhibits, Clinics, Program, etc., will be appointed, and everything possible will be done to insure the success of the congress and make it in attendance and scientific and professional interest the greatest dental congress ever held.

The whole world is coming to San Francisco in 1915 to participate in and enjoy the Panama Pacific International Exposition, which will commemorate the completion of the world's engineering masterpiece, the Panama Canal.

Never in the history of the profession has there been so auspicious a time for holding a great dental congress, and the Panama Pacific International Exposition Company and the Committee of Organization of the Panama Pacific Dental Congress unite in a cordial invitation to the members of the dental profession to come to San Francisco in 1915 to attend the congress and view the wonders of the Exposition and the Pacific Coast of the United States of America.

Frank L. Platt, *Ch'man*,
Committee of Organization.

ODONTOLOGICAL SOCIETY OF WESTERN PENNSYLVANIA.

The thirty-second annual spring meeting of the Odontological Society of Western Pennsylvania will be held at Hotel Henry, Pittsburgh, Pa., April 8 and 9, 1913. Practical papers and instructive clinics will predominate. Ethical practitioners are cordially invited to attend.

King S. Perry, *Sec'y*,
719 Jenkins Bldg., Pittsburgh, Pa.

CONNECTICUT STATE DENTAL ASSOCIATION.

THE next annual meeting of the Connecticut State Dental Association will be held in Waterbury, April 15 and 16, 1913.

A. V. PRENTIS, *Sec'y*,
New London, Conn.

FIFTH DISTRICT (N. Y.) DENTAL SOCIETY.

THE forty-fifth annual meeting of the Fifth District Dental Society of the State of New York will be held at the Onondaga Hotel, Syracuse, N. Y., April 3, 4, and 5, 1913. Papers and clinics of unusual merit have been secured, and it is confidently expected that this will be the largest and most instructive meeting ever held by the society. A most cordial invitation is extended to all ethical practitioners.

J. N. GARLINGHOUSE, *Sec'y*.

ARKANSAS STATE DENTAL ASSOCIATION.

THE Arkansas State Dental Association, instead of having papers and clinics by its own members as heretofore, will hold a Post-graduate Course, in Little Rock, Ark., April 7 to 11 inclusive, 1913.

This course will be under the direction of Drs. John P. Buckley, Hart J. Goslee, and J. H. Prothero of Chicago. All ethical dentists are eligible, and a membership fee will be charged.

For further information address

I. M. STERNBERG, *Sec'y*,
Fort Smith, Ark.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

THE regular meeting of the Academy of Stomatology will be held on Tuesday, April 22, 1913, at the College of Physicians, Twenty-second st. above Chestnut st., Philadelphia, Pa., at 8 P.M. Dr. F. L. Stanton of New York will read a paper on "Mendelism and Its Relation to Some Dental Problems."

A special meeting of the Academy will be held on Thursday, April 10th. There will be three papers, giving a Symposium on Dental Histology, by Drs. W. T. Addison, M. T. Barret, and J. D. Appleton; also a paper by Dr. S. M. Dorrance entitled "The Oral Cavity as an Etiological Factor in Cervical Glandular Enlargement."

All members of the dental profession are invited to be present.

NORMAN L. JAMESON, *Sec'y*.

VERMONT STATE DENTAL SOCIETY.

THE next meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 21, 22, and 23, 1913.

P. M. WILLIAMS, *Sec'y*,
Rutland, Vt.

NORTH DAKOTA DENTAL ASSOCIATION.

THE eighth annual meeting of the North Dakota Dental Association will be held at Fargo, N. D., May 16 and 17, 1913.

E. N. HEGGE, *Sec'y*,
Hatton, N. D.

NEBRASKA STATE DENTAL SOCIETY.

CHANGE OF DATE OF MEETING.

THE thirty-seventh annual meeting of the Nebraska State Dental Society will be held in Omaha, Nebr., May 19, 20, 21, and 22, 1913, instead of May 12, 13, 14, and 15, as formerly announced.

For programs and any information address

WM. A. MCHENRY, *Sec'y*,
Nelson, Nebr.

IOWA STATE DENTAL SOCIETY.

THE fifty-first annual meeting of the Iowa State Dental Society will convene at Davenport, Iowa, May 6, 7, and 8, 1913, beginning Tuesday, May 6th, at 9 A.M. Elaborate clinics and lectures and a large exhibit will be presented.

Further information will be furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

Exhibitors desiring space should apply to Dr. Wm. Finn, Cedar Rapids, Iowa.

C. M. KENNEDY, *Sec'y*,
Des Moines, Iowa.

TEXAS STATE DENTAL ASSOCIATION.

The thirty-third annual meeting of the Texas State Dental Association will be held at Temple, Texas, May 15, 16, and 17, 1913.

The clinics will be in charge of Dr. J. O. Hall, Waco, Texas, who will furnish any information relative to same. Exhibitors desiring space will please address Dr. J. M. Murphy, Temple, Texas. All ethical practitioners are cordially invited to attend the meeting.

Any other information will be cheerfully furnished by

J. G. Fife, *Sec'y*,
Dallas, Tex.

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA.

The fiftieth anniversary meeting of the Susquehanna Dental Association of Pennsylvania will be held at Irem Temple, Wilkes-Barre, Pa., Tuesday, Wednesday, and Thursday, May 20, 21, and 22, 1913.

The Executive Committee is composed of the following members: A. E. Bull, W. E. Davis, T. W. Thomas, B. A. Courtwright, A. J. Heffernan of Wilkes-Barre, A. B. Miller of Kingston, and I. H. Jennings of Danville.

All ethical practitioners are invited.

E. J. Donnegan, *Recording Sec'y*,
Scranton, Pa.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

The forty-fifth annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May, 8, 9, and 10, 1913. There will be the usual reduced railroad rates on the certificate plan.

The first session will open on Thursday at 10.30 A.M. The literary program of the meeting will be rendered in the auditorium of the Educational Building. Headquarters will be at the Hotel Ten Eyck, where the exhibits and clinics will be held.

A cordial invitation is extended to all ethical dentists in New York and sister states. Exhibitors wishing to engage space please address Dr. O. J. Gross, Schenectady, N. Y.

A. P. Burkhart, *Sec'y*,
52 Genesee st., Auburn, N. Y.

MASSACHUSETTS DENTAL SOCIETY.

The forty-ninth annual meeting of the Massachusetts Dental Society will be held at the Hotel Somerset, Boston, Mass., on Thursday, Friday, and Saturday, May 8, 9, and 10, 1913.

A. H. St. Clair Chase, *Sec'y*,
Everett, Mass.

LAKE ERIE (PA.) DENTAL ASSOCIATION.

The fiftieth annual meeting of the Lake Erie Dental Association will be held at Hotel Bartlett, Cambridge Springs, Pa., May 15, 16, and 17, 1913. This meeting celebrates the "golden anniversary" of this society, and the Program Committee have arranged for the best meeting ever held. Entertainment for the ladies; come, and bring them.

C. L. Mead, *Sec'y*,
Union City, Pa.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

The sixteenth annual meeting of the Southern California Dental Association will be held in Los Angeles, on May 26, 27, 28, and 29, 1913.

An excellent program of essays and clinics, as well as a large and elaborate exhibit, is being arranged. All ethical practitioners of dentistry are cordially invited to be present.

Further information will be sent upon request.

Jas. D. McCoy, *Ch'man Publicity Com.*,
708 W. P. Story Bldg., Los Angeles, Cal.

INDIANA STATE DENTAL ASSOCIATION.

The fifty-fifth annual session of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, May 20, 21, and 22, 1913.

The officers of the association recently met at Indianapolis and perfected plans for a three-day "Post-graduate Course." The very best instructors and specialists are being secured for each day. The course will be as follows: Tuesday—"Humanitarian Dentistry." Wednesday—"Preventive Dentistry."

Thursday, A.M.—"Prosthodontia"; P.M., a great table clinic. The clinic will also be held in the hotel.

No tuition fee for the members of the association, or visitors from outside the state who are in good standing in their state associations, but all others desiring to take this course must arrange their tuition fees with the secretary.

Otto U. King, *Sec'y,*
Huntingdon, Ind.

KENTUCKY STATE DENTAL ASSOCIATION.

The forty-fourth annual meeting of the Kentucky State Dental Association will be held at the Phoenix Hotel, in Lexington, Ky., on May 26, 27, and 28, 1913. All ethical dentists are invited to attend.

C. R. Shacklette, *Sec'y.*

NORTHERN OHIO DENTAL ASSOCIATION.

The fifty-sixth annual meeting of the Northern Ohio Dental Association will be held at Cleveland, Ohio, June 5, 6, and 7, 1913.

C. D. Peck, *Sec'y,*
Sandusky, Ohio.

SOUTH CAROLINA STATE DENTAL ASSOCIATION.

The forty-third annual meeting of the South Carolina State Dental Association will be held on the Isle of Palms, June 25, 26, and 27, 1913.

W. Busey Simmons, *Recording Sec'y,*
Piedmont, S. C.

MISSISSIPPI DENTAL ASSOCIATION.

The thirty-eighth annual session of the Mississippi Dental Association will be held at the Great Southern Hotel, Meridian, Miss., June 24, 25, and 26, 1913.

A determined effort is being put forth to make this meeting our best. There will be a fine clinic, excellent papers, a banquet, and a fine exhibit.

L. B. Price, *Sec'y.*
Corinth, Miss.

MAINE DENTAL SOCIETY.

The forty-eighth annual meeting of the Maine Dental Society will be held at the Ottowa House, Cushing's Island, Portland Harbor, Me., on June 25, 26, and 27, 1913.

I. E. Pendleton, *Sec'y.*

WASHINGTON STATE DENTAL SOCIETY.

The Washington State Dental Society meets June 16, 17, and 18, 1913, in Seattle, Wash.

A. D. Remington, *Sec'y,*
Seattle, Wash.

CALIFORNIA STATE DENTAL ASSOCIATION.

The next annual meeting of the California State Dental Association will be held on June 2, 3, 4, and 5, 1913, in the Hotel Oakland, at Oakland, Cal.

E. E. Evans, *Sec'y,*
Oakland, Cal.

TENNESSEE STATE DENTAL ASSOCIATION.

The Tennessee State Dental Association will hold its annual meeting in Nashville, Tenn., on June 5, 6, and 7, 1913, with the following officers in charge: F. W. Meacham, president; W. C. Gillespie, first vice-president; J. L. Manire, second vice-president; C. Osborn Rhea, recording secretary; W. G. Hutchinson, treasurer; C. E. Hines, corresponding secretary.

C. Osborn Rhea, *Sec'y.*

GEORGIA STATE DENTAL SOCIETY.

The forty-fifth annual meeting of the Georgia State Dental Society will convene at Columbus, Ga., June 12, 13, and 14, 1913, beginning Thursday, June 12th, at 11 A.M. Some very interesting lectures and papers will be presented; also an elaborate clinic has been secured.

Further information will be cheerfully furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

M. M. Forbes, *Sec'y,*
Atlanta. Ga.

BRIDGEPORT (CONN.) DENTAL SOCIETY.

At the regular monthly meeting of the Bridgeport Dental Society, the following officers were elected for the ensuing year: J. L. Egan, president; J. J. Myers, vice-president; C. E. C. Atkins, secretary; R. H. Tuthill, treasurer. Executive Committee—W. J. McLaughlin, *chairman*, B. E. Turney, and W. H. Ryan.

Immediately after the business meeting, the annual banquet was served at the University Club.

Clarence E. C. Atkins, *Sec'y*,
Bridgeport, Conn.

TRI-COUNTY (N. Y.) DENTAL SOCIETY.

(Allegany, Cattaraugus, and Steuben.)

In June last, at a regular meeting of the Allegany County Dental Society, held at Cuba, N. Y., it was decided to call a meeting of the dentists of Allegany, Steuben, and Cattaraugus counties in August at Olean, N. Y., for the purpose of organizing a Tri-County Dental Society.

The meeting took place August 24, 1912, when the society was organized, and the following officers were elected: Dr. J. F. Sortore, Belmont, N. Y., president; Dr. R. J. Conway, Hornell, N. Y., vice-president; Dr. E. O. Whipple, Olean, N. Y., secretary and treasurer.

The second meeting of the society was held in Hornell, January 25, 1913. The third meeting will be in Wellsville, N. Y., on May 17th. This gives each county one meeting each year. It is a single society, in which the dentists of the three counties hold membership.

E. O. Whipple, *Sec'y*.

ARKANSAS BOARD OF EXAMINERS.

The next meeting of the Arkansas Board of Dental Examiners will be held in Little Rock, Ark., April 7 and 8, 1913. All applicants are required to pass an examination to obtain a certificate. Examination fee $15.

For application blanks apply to

E. H. Johnson, *Sec'y-Treas.*,
305 Citizen's Bank Bldg., Pine Bluff, Ark.

WASHINGTON BOARD OF EXAMINERS.

The Washington State Board of Dental Examiners will meet in Seattle, Wash., on May 22, 1913, for the purpose of holding the spring examination.

L. B. Manchester, *Sec'y*,
Wenatchee, Wash.

NORTH CAROLINA BOARD OF EXAMINERS.

The next regular meeting of the North Carolina State Board of Dental Examiners will be held in Winston-Salem, N. C., beginning promptly at 9 o'clock on Monday morning, May 26, 1913.

For further necessary information, address

F. L. Hunt, *Sec'y*,
Asheville, N. C.

MARYLAND BOARD OF EXAMINERS.

The Maryland State Board of Dental Examiners will meet for examination of candidates for certificates, May 29 and 30, 1913, at the Dental Department of the University of Maryland, Baltimore, Md., at 9 A.M.

Candidates must pass a written examination in anatomy and physiology, chemistry and bacteriology, oral surgery, operative and prosthetic dentistry and pathology, therapeutics, and materia medica.

The practical requirements consist of the insertion of one gold and one amalgam filling in the mouth, and the submission of a metal plate or bridge of not less than four crowns—two of which shall be of porcelain—the parts being assembled and invested in advance, and soldered in the presence of the board.

Applications, accompanied by the fee of ten dollars, must be filed with the secretary prior to May 29th.

For application blanks or further information, apply to

F. F. Drew, *Sec'y*,
701 N. Howard st., Baltimore, Md.

ILLINOIS BOARD OF EXAMINERS.

The semi-annual meeting of the Illinois State Board of Dental Examiners, for the examination of applicants for a license to practice dentistry in the state of Illinois, will be held at the Chicago College of Dental Surgery, corner of S. Wood and W. Harrison sts., Chicago, beginning Wednesday, June 4, 1913, at 9 A.M.

All applications, together with the fee, Twenty-six dollars, must be filed with the secretary at least five days prior to date of examination. Address all communications to

T. A. BROADBENT, *Sec'y*,
705 Venetian Bldg., Chicago, Ill.

SOUTH CAROLINA BOARD OF EXAMINERS.

THE next meeting for examination of applicants for license will be held Friday, June 20, 1913, at 3 P.M., at the Isle of Palms, Hotel Charleston, S. C.

J. M. QUATTLEBAUM, *Sec'y*.

WISCONSIN BOARD OF EXAMINERS.

THE Wisconsin State Board of Dental Examiners will convene in Milwaukee, at Marquette University, on June 16, 1913, at 2 P.M., for examination of applicants to practice in Wisconsin.

High-school diploma, application, and fee of $25.00 must be filed with the secretary fifteen days prior to above date. Dental diploma to be presented in advance of examination.

F. A. TATE, *President*,
W. T. HARDY, *Sec'y*,
422 Jefferson st., Milwaukee, Wis.

TEXAS BOARD OF EXAMINERS.

THE next regular meeting of the Texas State Board of Dental Examiners will he held in the high-school building, Houston, Texas, beginning Monday, June 23, 1913, at 9 A.M. Official application blanks and other necessary information will be furnished candidates upon application to the secretary.

All applications, accompanied by a fee of $25.00, should be in the hands of the secretary at least five days before the examination.

Address all communications to

C. M. MCCAULEY, *Sec'y*,
Abilene, Texas.

PENNSYLVANIA BOARD OF EXAMINERS.

THE next regular examination of the Pennsylvania State Board of Dental Examiners will be held in Philadelphia and Pittsburgh, on Wednesday, Thursday, Friday and Saturday, June 11, 12, 13, and 14, 1913. Application blanks can be secured from the department of Public Instruction, Harrisburg.

Further information can be obtained from

ALEXANDER H. REYNOLDS, *Sec'y*,
4630 Chester ave., Philadelphia, Pa.

EXAMINATION OF DENTISTS FOR THE U. S. ARMY.

THE Surgeon-general of the army announces that examinations for the appointment of acting dental surgeons will be held at Fort Slocum, N. Y.; Columbus Barracks, Ohio; Jefferson Barracks, Mo.; Fort Logan, Colo., and Fort McDowell, Cal., on Monday, April 7, 1913.

Application blanks and full information concerning these examinations can be procured by addressing the Surgeon-general, U. S. Army, Washington, D. C.

The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-one and twenty-seven years of age, a graduate of a dental school legally authorized to confer the degree of D.D.S., and shall be of good moral character and habits.

Acting dental surgeons are employed under a three years' contract, at the rate of $150 per month. They are entitled to traveling allowances in obeying their first orders, in changing stations, and in returning to their homes at termination of service. They also have the privilege of purchasing certain supplies at the army commissary. After three years' service, if found qualified, they are promoted to the grade of dental surgeon, with the rank of first lieutenant, and receive thereafter the pay and allowances appertaining to that rank.

In order to perfect all necessary arrangements for examination, applications must be in the possession of the Surgeon-general at least two weeks before the date of examination. Early attention is therefore enjoined upon all intending applicants. There are at present a large number of vacancies to be filled.

ARMY DENTAL SURGEONS.

MEMORANDA OF CHANGES.

For the week ending February 15, 1913:

C. B. Seely, J. W. Scovel, and W. A. Squires, ACT.D.S., sailed February 5th, from San Francisco, Cal., for the Philippines.

First Lieut. R. E. Ingalls, left Fort Worden, Wash., February 3d, for temporary duty at Fort Casey, Wash.

B. C. Warfield, ACT.D.S., left Fort Terry, N. Y., February 12th, for Fort Totten, N. Y.

A. R. White, ACT.D.S., left Fort Des Moines, Iowa, February 10th, and arrived at Rock Island Arsenal same day.

For the week ending February 21st:

First Lieut. E. P. Tignor, left Fort Howard, Md., and arrived at Washington Barracks, D. C., February 13th.

B. C. Warfield, ACT.D.S., arrived at Fort Totten, N. Y., February 13th, for temporary duty.

C. E. Sherwood, ACT.D.S., arrived at Presidio of Monterey, Cal., February 10th.

First Lieut. F. P. Stone, left Fort Williams, Me., February 19th, on leave of absence.

For the week ending March 1st:

J. H. Snapp, ACT.D.S., left Camp E. S. Otis, Panama, February 12th, for San Juan, Porto Rico.

A. T. Knoderer, ACT.D.S., left Fort Morgan, Ala., February 19th, and arrived at Fort Barrancas, Fla., same day.

E. M. Kennedy, ACT.D.S., returned to Fort Robinson, Nebr., February 19th, from leave of absence.

For the week ending March 8th:

J. F. Feely, ACT.D.S., *en route* from Philadelphia, Pa., to San Francisco, Cal., and Manilla, Philippine Islands, March 3d.

ORIGINAL COMMUNICATIONS.

THE PROGRESS OF DENTAL CARIES IN RELATION TO CAVITY PREPARATION.

By ARTHUR D. BLACK, A.M., M.D., D.D.S., Chicago, Ill.

(Read before the Northeastern Dental Association, at its annual meeting, Crawford Notch, N. H., October 1, 1912.)

THIS paper will be limited to the discussion of certain phases of cavity preparation in relation to the pathology of caries which seem of most importance at the present time. From the numerous articles and extended discussions which have appeared in recent years, it might seem that this subject had been fully threshed out, yet a critical review of these articles and careful observation of the operations being performed by many practitioners show much variation both in views and practice. So long as these differences exist there will be room for discussion, and the subject should be a live one at our society meetings. It is certainly proper that we should use every endeavor to come to a better understanding in order that our patients may receive the best possible service. With this object in view, there will be presented in this paper certain points regarding which there seems to be considerable difference of opinion.

MODERN PRINCIPLES OF PREVENTION.

The treatment of each disease should be based on our knowledge of its etiology and pathology. As our knowledge of the etiology and pathology of a certain disease becomes more complete, our treatment of that disease should be more effective, and the most thorough knowledge of etiology should often result in the successful use of preventive measures. This is quite as true of dental caries as of any other disease. Not so very many years ago, little attention was paid to the pathology of caries; the carious portions were removed, and the cavity so made was filled. As our knowledge of the pathology has grown, our treatment has been, or should have been, modified to combat the progress of the disease; a better knowledge of the etiology should result in the employment of more effective preventive measures.

PRINCIPLES OF CAVITY PREPARATION.

Our knowledge of the pathology of dental caries is now practically complete so far as the beginnings and the gradual progress of the destruction of tooth structure is concerned. Our knowledge of the etiology is lacking as to some factors which relate to the formation of the gelatinoid plaques. So far as concerns the carious process itself—the condition which renders necessary the preparation of a cavity—we know the full pathology, and our cavity preparations, based on this knowledge, should be the same the world over.

In the preparation of each cavity we should have in mind two ends which we should accomplish: (1) The cavity should be so prepared that the filling will serve to the best advantage in the treatment of the pathological process, not only in order to cure the existing condition by eradication, but to prevent its recurrence so far as possible. (2) The cavity should be so prepared that the filling operation will be the best possible from the purely mechanical standpoint. In connection with both of these principles we should, in many cavities, also have in mind the danger of inflammation and death of the pulp, and should modify the cavity form accordingly. We should, then, consider first the pathological process which we have to treat in the particular case presented, and we should have in mind the conditions under which the carious process began, its progress up to the time of the operation, and the possibilities of a continuance or a recurrence subsequent to the operation. As the recurrence would necessarily involve the surface of the tooth, our consideration of the pathology will determine the outline form of the cavity. We should next consider what form of cavity will give sufficient retention, with the best opportunities for proper adaptation or fit of the filling, modifying this form when necessary, to give the best possible protection to the pulp.

AREAS IN PROXIMAL SURFACES SUSCEPTIBLE TO CARIES OR IMMUNE.

In this paper we will consider proximal cavities only, as the time allowed is not sufficient for a consideration of all classes. The beginnings and progress of the carious process may be easily observed clinically. Anyone who will record examinations of a few hundred cases will observe that these carious processes begin on the surface of the enamel just gingivally of the contact point, between the contact point and the crest of the gum septum. They always begin at this position unless there are abnormal features present in the form, position, or environment of the teeth. The progress of the growth of the colony of micro-organisms on the surface of the enamel occurs in both directions, buccally and lingually, from the contact point, involving a narrow band of enamel just occlusally of the margin of the gum septum. This surface growth does not, except in rare instances, extend as far as the angles of the tooth. As we pass from the contact point buccally or lingually toward the angles, we find the surface gradually less liable to the spread of the growth of the colony and consequently to superficial caries. This is, of course, because the angles of the tooth are thoroughly scoured in chewing, so that a growth could not maintain itself on the enamel; and likewise because the enamel toward the contact is less well scoured in proportion as the opening of the embrasure between the two teeth is broad or narrow. There is, then, in each proximal surface a definite point at which caries begins, a definite area over which a colony of micro-organisms may grow, and there are definite limits beyond which it may not grow. In other words, we may outline on each proximal surface an area that is susceptible to caries and an area that is immune.

THE RULE OF EXTENSION FOR PREVENTION.

It is certainly rational to apply this knowledge of pathology in cavity preparation; in fact, this knowledge should be our guide in determining the outline form of the cavity. If a cavity is presented which has not involved *on the surface* all of the enamel which our observation and records show to be clearly susceptible—enamel on which micro-organisms will grow and cause caries irrespectively of whether we place a filling or not—is it not very clearly our duty to include that susceptible enamel in the cavity outline? I believe practically all will agree with me in this statement, but we may differ in the application of these principles in practice. If I can in this paper make clear the application of this rule of extension for prevention, I feel sure everyone will agree that it is right both in theory and practice.

THREE CASES OF PROXIMAL CARIES, AND TREATMENT.

To illustrate the application of this rule I wish to describe three different proximal cavities, with the treatment adapted for each. The first is a small area of superficial caries *which has not spread over the full area of susceptibility;* the caries has penetrated the enamel, and there is an area of dentin involved which is *less wide* than the involved surface of the enamel. The treatment of this carious area requires that the remainder of the susceptible area of enamel be cut away so that the margins of the filling will be in immune areas. *That is extension for prevention.* (See Fig. 1.)

The second case is one of caries *which has spread over the full area of susceptibility* on the surface of the enamel, and the area of dentin involved is *less wide* than the involvement of the enamel. The treatment of this case requires that the cavity include all the affected enamel, which here comprises all of the susceptible area. It would not therefore be necessary to cut away any sound enamel; the outline of the cavity would, however, be exactly the same as in the first case. *Extension for prevention would be unnecessary, and would not apply in this case.* (See Fig. 2.)

The third case is one of caries *which has spread over the full area of susceptibility on the surface,* and the area of dentin involved is *considerably wider* than that of the enamel; considerable enamel, unaffected on its surface, has been undermined by lateral caries in the dentin. In this case, the caries in the dentin has undermined not only the enamel susceptible to caries on its surface, *but also the immune enamel* farther toward the buccal and lingual angles, possibly including the angles, or even beyond. The extent of caries in the dentin, therefore, controls the outline form of the cavity and carries it far beyond the position demanded by the rules of extension for prevention. *Extension for prevention is not practiced,* therefore, in the treatment of caries of this type. (See Fig. 3.)

These three cases are cited to emphasize the fact that extension for prevention applies to but one type of cavities—those in which the surface caries has not extended far enough to include the entire area of susceptibility, and in which the caries in the dentin has not undermined the enamel of this area. Extension for prevention applies to no other cavity, because it involves only the cutting away of sound enamel within the area of susceptibility, and it is obvious that no sound enamel in this area could be cut away if the surface spread of caries, or the lateral spread in the dentin underneath, has rendered it unsound.

DIFFERENTIATION BETWEEN AREAS OF SUSCEPTIBILITY AND AREAS OF IMMUNITY.

The important question which next arises is the differentiation between the area of susceptibility and the area of immunity. This is very simple; it is purely a matter of observing a sufficient number of cases of surface caries to be

Fig. 1.

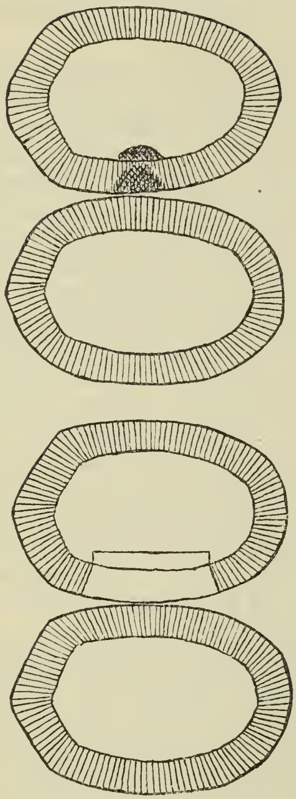

Fig. 2.

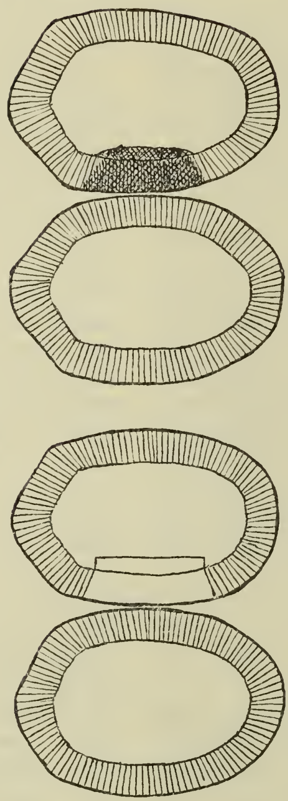

Fig. 3.

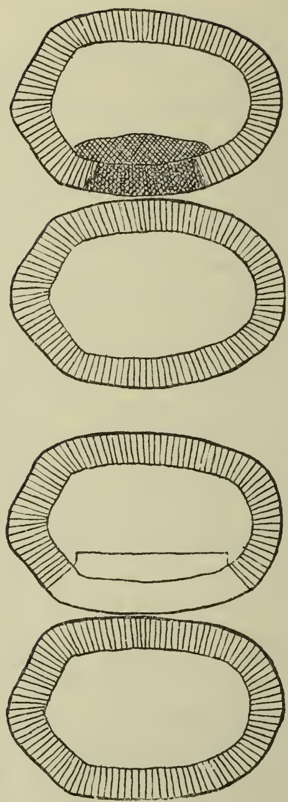

Fig. 1. The diagram above illustrates an area of proximal caries which has not spread to the full limit either buccally or lingually on the surface of the enamel. The caries in the dentin has undermined less enamel than is involved on the surface. The proper cavity preparation requires that sufficient sound enamel be cut away to place the buccal and lingual margins in self-cleansing positions, as shown in the lower diagram. *This is extension for prevention.*

Fig. 2. The diagram above illustrates an area of proximal caries which has spread to the full limit buccally and lingually on the surface of the enamel. The caries in the dentin has undermined less enamel than is involved on the surface. The proper cavity preparation requires no cutting away of sound enamel buccally or lingually, because the caries has already reached the limit to which it may spread in either direction. *Extension for prevention is not required.* The cavity, as shown in the lower diagram, is the same as in Fig. 1.

Fig. 3. The diagram above illustrates an area of proximal caries which has spread to the full limit buccally and lingually on the surface of the enamel. The caries in the dentin has undermined more enamel than is involved on the surface. The proper preparation of this cavity requires the cutting away of all enamel which has been undermined by the caries in the dentin. The margins are therefore carried farther than would otherwise be necessary to reach self-cleansing positions, as shown in the lower diagram. *Extension for prevention is not practiced* in the preparation of this cavity.

able to recognize the limit to which the caries extends buccally and lingually, and the application of this knowledge in the preparation of those cavities in which the caries has not extended to the limit. Especial attention is called to the fact that this limit is not one which includes a definite area or portion of the surface of every tooth, but is determined by the width of the embrasures between the two proximal teeth. If the proximal surfaces are more nearly flat than the average, then the embrasures are narrow and there is less opportunity for food to scour the proximal surfaces; therefore the area of susceptibility will be broader bucco-lingually than in the case where the proximal surfaces are more convex. The most definite rule which could be laid down would be that the cavity should be cut buccally and lingually to a line at which the width of the embrasure is sufficient to insure a self-cleansing margin. Even this width would vary somewhat according to the susceptibility of the individual, but I think we would be safe in saying that a width of 0.8 mm. (about 1/32 of an inch) at the position of the margin would be the minimum, and that a width of 1.2 mm. (about 1/20 of an inch) would be the maximum width necessary. (See Fig. 4.) A good idea of these widths may be gained by using two excavators with blades of these widths for measuring the embrasures as the cavities are prepared.

Fig. 4.

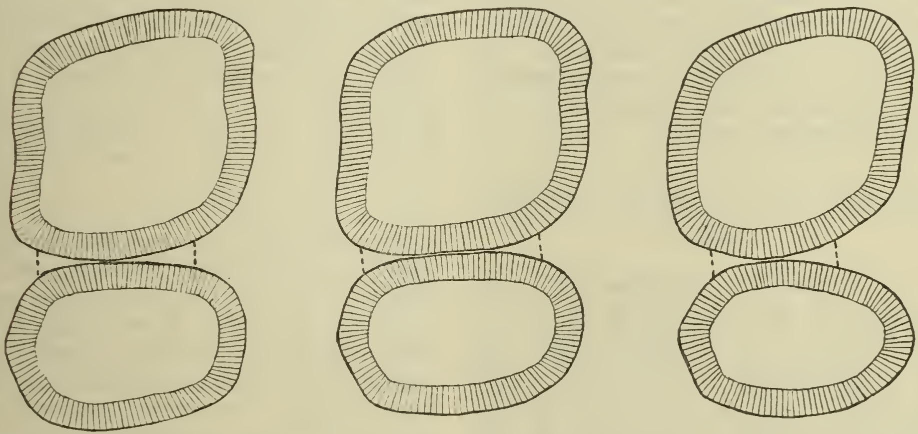

Fig. 4. These three diagrams illustrate the importance of the width of the embrasures in relation to the positions of buccal and lingual margins of cavities. The dotted lines indicate positions of equal embrasure widths in all three diagrams. It will be observed that the more convex the proximal surfaces of the teeth, the less wide must cavities be cut to place the margins in self-cleansing positions.

PREPARATION OF THE GINGIVAL MARGIN.

It may be observed by anyone that surface caries does not extend under a healthy gum margin. Therefore a cavity should be cut far enough in this direction to be certain that the free margin of the gum will cover it. An examination of the gum septum previous to the operation is important in this connection. Particular attention is called to the fact that the surface extensions of caries are parallel to the free margin of the gum, therefore care should be taken to extend the cavity outline far enough at this position both buccally and lingually. This means that the bucco-gingival and linguo-gingival angles should be cut to form right angles, with the exception that the enamel margin may be very slightly rounded. It has been the writer's observation that more operators fail in this one point than in any other. Cavities are cut with the gingival wall in the form of a curve connecting the buccal and lingual walls. This leaves a little triangular area of enamel at each angle that is more susceptible to caries than much of the enamel that has been cut away. It is the writer's belief that if all operators made no other change in their present cavity preparations than to square out these angles, the average life of our proximal fillings would be doubled. I make this statement because these areas are the most susceptible positions on the enamel remaining, as evidenced by the fact that recurrences of caries begin in these positions in the large majority of cases.

RETENTIVE AND CONVENIENCE FORM OF CAVITY.

For purposes of retention and convenience in placing fillings or inlays, the box-like form of cavity, with the surrounding walls nearly parallel and all angles sharply cut, answers all requirements. Such cavities have the best mechanical forms for retention and for resisting the stress of mastication, and the fillings may be started and placed with greater ease and facility than in cavities of more rounded form.

ADVANTAGE OF WEDGING GOLD BETWEEN PARALLEL WALLS.

Another advantage of the parallel walls, which does not seem to be fully appreciated, is the opportunity afforded to take advantage of the elasticity of the dentin by the proper manipulation of gold foil. Gold may be wedged between absolutely parallel walls with mallet blows which are not uncomfortable to the patient, in such a manner that the walls, on account of their elasticity, will be forced apart sufficiently to cause them to maintain a secure grip on the filling. I have tested such fillings, placed between two parallel walls ⅛ inch apart, and not in contact with the other two walls, and have been unable to dislodge them until weights of more than sixty pounds have been attached in a straight pull outward from the cavity.

CONCLUSION.

In closing, I wish to emphasize the fact that, so long as all of the carious area is removed, the inner form of the cavity has nothing to do with the treatment of caries other than to enable us to make fillings which are less liable to come out. Extension for prevention has been charged with all of the accidents which have occurred in cavity preparation because operators have not understood its principle, and it is no wonder that the profession has erred in this, when many prominent practitioners have insufficiently studied the propositions involved and then have led others to believe in their own misunderstandings. The propositions laid down under the maxim of extension for prevention are simple, but it is necessary that an operator study them and apply them with a proper appreciation of the existing conditions in each particular case.

Extension for prevention has nothing to do with depth of cutting in the dentin, it has nothing to do with the possibilities of exposure or nearness of the cavity to the pulp, it has nothing to do with the preparation of cavities in which there has been widespread caries of the dentin. It applies essentially to the treatment of small areas of caries, and never involves the necessity of making a really large cavity. May I ask a careful consideration of all these points, presented with the hope that we may so prepare cavities that the fillings placed will serve better in the preservation of the teeth?

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

PYORRHEA ALVEOLARIS: TREATMENT BY THE OPSONIC METHOD.

By THEODORE CHAPIN BEEBE, M.D., Boston, Mass.,
INSTRUCTOR IN SURGERY, TUFTS COLLEGE MEDICAL SCHOOL; ASSISTANT SURGEON TO THE BOSTON DISPENSARY.

(Read before the Northeastern Dental Association, at its annual meeting, Crawford Notch, N. H., October 1, 1912.)

AN experience of several years in the treatment of pyorrhea alveolaris by the opsonic method—that is, by the use of bacterial vaccines—has led to some revision of the writer's opinions on this subject.

ETIOLOGY.

The consideration of the treatment of pyorrhea alveolaris, as with any other form of disease, presupposes primarily a knowledge of the cause or causes of the malady. Unfortunately, a clear and definite source, applicable to all cases, has not as yet been discovered. The fact that so many various conditions have been suggested seems to the writer to prove that no one of them can be attributed to all cases. Among the diseases and conditions brought forward as predisposing agents may be mentioned diabetes, Bright's disease, syphilis, rheumatism, gout, heart disease, liver affections, and auto-intoxication from faulty metabolism. Certain forms of nervous disorders also, and the presence of localized collections of pus in various portions of the body, have been suggested. The question always arises, also, whether calcareous deposits on the teeth cause pyorrhea, or whether pyorrhea causes calcareous deposits. It will thus be seen that, with so many causes at work, the observer can scarcely say that any given condition is the real reason for the disease in all, or even in many cases. For example, one of the writer's patients was told that the sole cause of her trouble was auto-intoxication from faulty metabolism. She immediately placed herself under the care of an intelligent dietetic expert in New York, where she remained six months. During that time her general condition was greatly improved, but, in spite of careful dental treatment, she lost three teeth, and the progress of the disease was not checked.

OPSONINS AND PYORRHEA.

It will probably be admitted by all that the underlying condition in pyorrhea, from whatever source, is an inflammation of the connective tissue of the gingiva in varying degree, associated in many cases with the presence of pus. Having had considerable experience with opsonic treatment in many other surgical forms of bacterial infection, it occurred to the writer that it might be possible to apply these principles to the opsonic treatment of pyorrhea. Here we have a definite localized condition of inflammation where, theoretically at least, opsonic treatment should be of avail. The question at once arose whether or not pyorrhea in every case might be caused by a deficiency in the normal protective substances found in the blood of the patient. It may not be out of place to review here, briefly, our present knowledge of the rôle of opsonins in the blood.

As you are all probably aware, Wright and Douglas of London discovered several years ago that the serum from normal and immune blood contains substances which they called opsonins, from *opsono,* "I prepare the food for." These opsonins, by their action on bacteria, render them more easily digestible by the polymorphonuclear leucocytes of the blood. They showed beyond question that this process depends upon the action of serum upon the bacteria. Bacteria suspended in salt solution resist this process of phagocytosis by washed leucocytes, while bacteria previously mixed with serum and then washed—that is, freed from serum—are quickly taken up and digested by washed leucocytes. Treated in this manner, bacteria are said to be "opsonified," while there is no apparent change in form, staining reaction, or function. The "opsonic index" means the relative amount of opsonins in the serum of a given patient, compared with the amount in the serum of a normal standard. To find the opsonic index of a patient in regard to a given bacterium, the average number of bacteria taken up per leucocyte under the influence of the patient's serum is divided by the average number taken up per leucocyte under the influence of a standard normal serum under similar conditions. In this way the opsonic indices of all the usual pathogenic bacteria can be found, and the results compared with the clinical and bacteriological findings. The opsonic index cannot be taken as a complete index of the anti-bacterial power of the individual under all circumstances, because opsonins are only a part, though probably the most important, of the protective substances formed in the blood. It must be remembered, also, that the opsonic index alone, without clinical and bacteriological corroboration, cannot be taken as a sure diagnosis of infection, because the index may be high or low according to whether the patient is improving or not.

MAKING A STANDARDIZED VACCINE.

It is now necessary to consider how we can increase the amount of opsonins in the blood. This has been shown by innumerable tests to be possible by the injection into the blood of suitable bacteria in proper amounts after sterilization. This is true in the normal individual, as well as in chronic infections due to the corresponding bacterium. Cultures of the organism causing the infection are grown, usually on agar slants or on blood serum, for about twenty-four hours. The growth is then separated from the medium and churned up in a tube with from 5 to 10 cc. of 0.85 per cent. NaCl solution. The growths in several tubes are emulsified in this manner, and are then sterilized in sealed tubes at 60° C. for about one hour. The suspension is standardized by counting the number of bacteria per cubic millimeter of fluid. After the bacteria have been killed, the tubes are unsealed and cultures are taken and incubated to make quite sure that the bacteria are dead. When the sterility of the emulsion is proved, it is diluted to the proper standard with 0.85 per cent. NaCl solution containing 0.25 per cent. carbolic acid. The "vaccine" is then ready for inoculation. Autogenous vaccines, *i.e.* vaccines made with bacteria obtained from the patient's own lesions, are not always necessary, but are sometimes desirable.

CONSIDERATIONS FOR INOCULATION.

On the inoculation of any vaccine, there is at first a period of diminished resistance, called the "negative phase," lasting normally from twenty-four to forty-eight hours. This is followed by a period of increased resistance, owing to the increase in the protective elements of the blood, called the "positive phase." After several days there is again a gradual decline in resistance, the so-called "secondary negative phase." It will therefore be seen that the next inoculation should be given only during the positive phase, in order that there may be an accumulation of the protective substances of the blood.

Hektoen summarizes as follows the considerations for inoculation:

(1) The power of the injected bacterial substances to stimulate the formation of opsonins and other specific antibodies.

(2) The belief that increased forma-

tion of such substances may hasten healing of the corresponding infections.

(3) The apparent inability of the body under certain conditions of natural infection to produce such substances without special stimulation.

The essential pre-requisites for therapeutic inoculations are:

(1) Correct etiologic diagnosis.

(2) Sterilized, pure culture of the bacterium causing the infection in each disease, or sterile products of such bacteria.

(3) The injection of proper doses at proper intervals, so as not to necessarily lower the anti-bacterial power, or cause other unfavorable disturbances.

ROUTINE OF VACCINE TREATMENT IN PYORRHEA.

The routine of treatment is as follows: At the first visit of the patient, a culture is taken from the gums around the affected teeth, care being taken to press toward the surface any trace of pus which may be present in the gums around the teeth. An autogenous vaccine is made from the bacteria found in the culture, if present, and used in the treatment, or, if thought best for one reason or another, a stock vaccine made from several virulent strains of the same bacteria may be used.

It is my custom to give the injections in the upper arm, having previously sterilized the skin with alcohol. After the injection the needle-puncture is sealed with collodion to prevent the possibility of infection from without. During the course of several thousand injections there has never developed an abscess at the site of the puncture. The dose varies according to the vaccine used. The standard minimum dose of staphylococci is 150 million, while that of pneumococci is 50 million. Our vaccines are standardized at staphylococci $\frac{1}{2}$ cc. = 500 million; pneumococci, $\frac{1}{2}$ cc. = 100 million. These are mentioned as being the two most common bacteria found in inflammatory conditions in the gums. The injections are repeated every three to five days, according to the local constitutional reactions and the experience of the operator.

Bearing this necessarily brief description of opsonic principles in mind, we will now return to a consideration of their application to the disease. First, however, let me state that a complete history of every case is obtained to see what conditions there may be present which may have a bearing on the disease, such as past and present sicknesses, the diathesis, and the mode of life. The urine is also carefully examined for signs of renal diseases and diabetes, and the amount of indican.

BACTERIAL AND OPSONIC FINDINGS IN PRACTICAL CASES OF PYORRHEA.

An analysis of the author's first seventeen cases shows that in six cases the culture revealed a practically pure growth of pneumococci. In all the others the growth was principally one of pneumococci with a small admixture of staphylococci. As compared with cultures taken from normal mouths, and in connection with the opsonic indices, this showing is most significant. We all know that the mouth contains many bacteria normally, but cultures never show growths such as were found in this series. We will now examine the opsonic indices in these cases. In one case the index to pneumococci was 48 per cent. of normal; seven varied from 52 to 59 per cent.; two from 61 to 65 per cent.; four, from 70 to 78 per cent.; one was at 80 per cent., one at 95 per cent., and one at 120 per cent. The indices for staphylococci varied from 36 to 145 per cent., all but four being below 87 per cent. It will thus be seen that the presence of these bacteria in the gums was corroborated by the corresponding opsonic indices, showing that the blood of these patients was deficient in the normal protective substances. The occasional high indices are accounted for by the fact that the blood was temporarily, at least, manufacturing more protective substances than usual. In all cases of doubt, a series of indices, taken at regular intervals, will show whether the high level is being maintained. For the past two years or more it has not been thought necessary to take the opsonic indices, because of the uniform results secured by the writer and other workers in this field.

CONCOMITANT DISEASES.

In but one case was there any sign of renal disease or diabetes. Two patients had an indefinite previous history of rheumatic tendency. Two others had constipation and indigestion to a slight degree. In four there was a precedent family history of pyorrhea. Every case had recession of the gums. Many cases showed active pus which could be expressed on pressure around the teeth. The duration of the disease varied from three to forty years. The presence of the spirochæta refringens was not demonstrated in any case. Except as noted above, the patients were all in good general physical condition. At the time of examination, many of the cases showed red and tender gums about the affected teeth, and most bled easily. Four patients had loose teeth at the time, but two of these four had lost teeth previously from the disease. All cases were referred to me by careful and capable dentists, and all were having thorough dental treatment. One patient had had, in addition, I K I treatment locally during the previous year, without apparent benefit. Whenever it was necessary, as in constipation, rheumatism, or other abnormal condition, appropriate remedies were given. On examination of the urine several cases have shown an increase in the amount of indican, pointing to a disturbance in the digestive processes.

TWO EXTREME EXAMPLES OF EFFECT OF VACCINE TREATMENT FOR PYORRHEA.

The length of time of opsonic treatment varied from four weeks to nine months, with remissions from time to time. The shortest case was that of a lady, sixty years of age, who presented on March 21, 1908. Her gums were red, inflamed, and bled easily. There was recession of the gums but no loosening of the teeth, although she had previously lost one. A culture showed a pure growth of pneumococci, while her opsonic indices to pnemococci varied from 67 to 81 per cent. of normal. Injections of an autogenous vaccine of pneumococci at intervals of three and four days, increasing steadily from 50 to 240 million, were given for four weeks. At the end of this time the gums were of normal appearance, there was no tenderness or bleeding, and there has been no recurrence for four years.

The longest case noted is of an entirely different character: On February 26, 1908, E. G., sixty-five years of age, presented. She had had pyorrhea for forty years. She had lost all her upper teeth, all the lower molars, and two bicuspids. The gums around the lower teeth, which were all loose, were spongy and ulcerated, and pus could be seen around all the teeth. The pain on eating was so great that she had made no attempt to chew meat for many months. Cultures from the pus showed a growth of staphylococci and pneumococci, and the corresponding opsonic indices were 36 per cent. and 58 per cent. There was a definite history of an acute lighting-up of the disease one year previously, following an attack of grippe It seems very probable that, in this case, the infection secured a foothold at that time from which it was never dislodged.

Autogenous vaccines were made, and injections varying from 200 to 500 million staphylococci and 60 to 120 million pneumococci were given every three or four days. There was a gradual, though slow, improvement during the first month. The ulcerations began to heal, the odor was less foul, and the tenderness and bleeding were greatly diminished. During the next month the improvement was more marked, and by the end of the third month the gums were of normal color and texture. There was no bleeding, and the patient could chew with comparative comfort. During this time, however, three very loose teeth, the lower left incisors and canine, which had been held in place by silk from the beginning of treatment, were removed, cleaned, and tied in place again. The lower right canine and first bicuspid, which had been slightly loose, were found to be much more firmly held than before. The indices taken from time to time remained consistently above normal. Owing to the fact that some of the teeth have become almost solid, the patient insists on continuing the treatment from time to time, in the hope that all the teeth will become firm. She has been told many times that, where the alveolar process has been absorbed, there is probably no chance of its regeneration so as to enable the teeth to become very firm. In spite of this she is most hopeful, and insists on having the treatment, saying that at any rate it makes her feel better. The teeth which were taken out and cleaned are now held in place by a gold brace behind the teeth, and there appears to be a slight adherence of the gums around them.

Ranging in severity between these two examples are many types, some of which yielded readily to treatment, while others were more resistant. In the cases where there was no loosening of the teeth the beneficial results were more quickly obtained, as may be imagined. In all cases where there was tenderness, inflammation, and bleeding of the gums, relief was obtained usually inside of one week. In most cases where pus was present there was considerable resistance to treatment, lasting from a few weeks to four or five months. In a few instances loose teeth became markedly firmer.

RÉSUMÉ OF TYPICAL CASES.

A brief *résumé* of typical cases may be of interest.

February 29, 1909, T. B., fifty-nine years. Treated for past ten years for pyorrhea. Has lost two upper molars; has several loose teeth at present. General recession of gums, which are tender and bleed easily. To chew meat hurts him. No pus seen. Treated seven weeks with staphylococcus and pneumococcus vaccines. At end of that time, the gums were in healthy condition. The patient could chew beef easily, and there was no bleeding from use of a brush. The teeth felt firmer, but were still slightly loose.

March 5, 1908, E. C., twenty-eight years. Treated for twelve years. Has lost three teeth. Recession of gums. Several loose teeth with pus around them; is wearing a brace. Gums red, swollen, and painful most of the time. Does not attempt to chew meat. Treated three months with staphylococcus and pneumococcus vaccines with marked benefit. When patient stopped treatment, in order to go away for the summer, there was no inflammation of the gums evident. There was occasionally a trace of pus seen. She was told to return for treatment in the autumn if she still had trouble, but did not appear. In this case there was no evident tightening of the teeth while the patient was under treatment.

October 20, 1908, A. C., forty-seven years. Three years' duration. Two loose teeth at present. Gums slightly inflamed and tender; no pus seen. Gums bleed easily on using a brush. Injections of pneumococcus and staphylococcus vaccines were made for nine weeks, when the patient was obliged to leave town. At that time her gums were of normal color and were not tender or bleeding. The teeth felt much less insecure, and she could chew without tenderness.

November 19, 1908, P. F., forty-nine years. Disease of ten years' standing. Frequent scaling of teeth, and local treatment with I K I for past year without benefit. Patient was sent to me by his dentist as being a particularly difficult case to treat. Has lost several teeth. Recession of gums for many years. Gums red and boggy with free pus around four loose teeth. Cannot eat meat, because of pain on chewing. Given autogenous vaccines of staphylococcus and pneumococcus. By the end of the month the gums were in nearly normal condition, with no redness or tenderness. There has been constant improvement since then. At present the only symptom noticed is a rare trace of pus around one of the lower incisors. The loose teeth have all become markedly firmer, especially the lower incisors.

March 24, 1908, W. G., sixty years. Fifteen years' duration. Has lost eight teeth. Two loose teeth at present. Gums slightly inflamed, but there is no pus present. The loose teeth are very tender and painful on chewing. The patient was given an autogenous vaccine of pneumococcus for five weeks, at the end of which time she discontinued treatment, as she lived at a distance of seventy-five miles. When she stopped treatment there was no inflammation of the gums, and no tenderness or pain in the teeth on chewing. When heard from recently there was no recurrence, and the loose teeth were much firmer.

February 17, 1909, A. H., sixty-four years. Pyorrhea for from ten to twelve years. Has lost two teeth recently, and there are four loose teeth at present. Gums bleed easily, and occasionally become red and tender. Some pus around upper molars. The patient eats no meat because of pain on chewing. Because of looseness and projection of one of the upper left molars, the teeth do not come together well. Culture shows a pure growth of pneumococcus. The patient was given autogenous vaccines of pneumococcus and staphylococcus. In this, as in several other cases, the staphylococcus vaccine was given because of a low opsonic index and for its stimulating effects. Treatment lasted six weeks. At the end of that time there was no redness or tenderness of the gums, and the teeth were not at all painful. There is no discomfort on eating meat. The patient feels much stronger and in better general condition. The upper left molar, which was loose and projecting, has gone back into place and is firmer, so that the upper and lower teeth meet better. Treatment is discontinued, because patient is going abroad.

October 12, 1908, A. K., forty-five years. Duration of three years. Gums receding; are occasionally red, tender, and bleeding. No loose teeth and no pus seen. The patient had been treated for the past year in London by scaling, etc. After opsonic treatment for two months her dentist advised stopping for a while, as in his opinion the condition was entirely relieved. No recurrence.

January 25, 1908, S. S., thirty-eight years. Five or six years' duration. Has had recession of gums from the beginning, and has lost three teeth during the past year. Pus always present as teeth begin to loosen. At present none of the teeth are very loose, but two are just beginning to loosen. Gums are red and tender, and there are small ulcerations about the loose teeth. No especial bleeding except when a stiff brush is used. After two weeks' treatment, there was much less redness, and practically no tenderness. The teeth also felt firmer. At the end of one month the ulcerations were all healed, and the gums were apparently normal. Two weeks later the teeth were quite firm, and treatment was stopped. When seen over a year later, there had been no sign of recurrence.

TWO CASES OF GUM INFECTION.

Two other cases, not pyorrhea, but of infection through the gums, may also be of interest:

November 28, 1908, D. B., twenty-two years. Born and brought up in Ireland, the patient lived there until three or four years ago. Has had hypertrophy of the gums since she was five years of age. Gums are always red and tender, and bleed very easily, particularly when eating. On account of the pain she does not chew her food; is suffering from poor digestion for this reason. Pus is usually present around the upper and lower incisors. Culture shows practically a pure growth of pneumococcus with a few staphylococci. After a week's treatment with autogenous vaccines there was very little redness and bleeding of the gums, and the appetite was much improved. At the end of a month the patient stopped treatment, as she felt so much better. The gums were of normal color, much shrunken from the former condition, and there had been no bleeding for two weeks. She could chew meat easily, had a splendid appetite, and her general condition was excellent.

H. R., twenty-nine years. Two years previously, August 1907, the patient had undergone treatment of left upper canine by a country dentist, who for some reason filled the canal with an arsenical preparation. This was removed later by her regular dentist. One year ago (April 1908) she developed an abscess in the roof of the mouth, near the root of the upper left canine. This abscess was incised, and pus containing staphylococci and pneumococci was evacuated. No bare bone was felt. The patient was given autogenous vaccines for three weeks, during which time the abscess healed. One month ago another abscess in the same location appeared, and was opened. The tooth was removed, and a communication was found between the opening in the roof of the mouth and the socket; bare bone was felt with a probe. It seemed singular that the channel remained open and discharged pus in spite of opsonic treatment, until, two weeks later, a sequestrum one-fourth inch square and one-eighth inch thick, was removed from the palate process. The wound then promptly healed.

CONCLUSION.

It seems probable that, underlying all the various conditions which contribute to the onset and progress of pyorrhea, there is a deficiency in the normal protective substances in the blood. This is shown by the almost invariably low opsonic indices to the same bacteria which are found to be active in the gums. We have found that, whatever conditions may be present, as soon as the blood is stimulated to form new protective substances, there is an immediate improvement in the patient's condition, both locally and generally. It must be distinctly understood—and this point cannot be too strongly emphasized—that in order to secure the best results, the opsonic treatment *must be* combined with careful and thorough dental treatment. The statement is often made that the disease can be held in check, and sometimes cured, by dental treatment alone. This is probably true in some cases, but most of the patients seen by the writer were referred by good dentists, being cases which they were unable to benefit. As a rule, the opsonic treatment is slow, and it may take several months before the gums are free from pus and in a healthy condition. Especially in these cases is it necessary to assist nature by removing calcareous deposits which act as a constant irritation, fastening loose teeth for the same reason, and correcting malpositions. Wherever it is found that some constitutional condition is complicating the case, this must be relieved as far as possible, as in any other disease.

There are many cases which are considered as pyorrhea alveolaris in which there is no pus to be demonstrated, and no evident inflammation of the gums. There is a gradual and chronic recession of the gums, with eventual loosening and dropping out of the teeth. Several of these cases have been treated, with no apparent benefit. In these cases it has been impossible to discover the cause or to stop the progress by dental or other forms of treatment. It is possible that in time these cases may be cured by some means as yet unknown.

The writer is often asked whether teeth that are already loose can become firm again. Patients are told that the cause of the teeth becoming loose is the absorption of the alveolar processes about the sockets, and that in all probability opsonic treatment will not cause a regeneration of the bony structure. In the face of this statement there is absolutely no doubt that in several cases the teeth have become firmer. Another question often asked is as to the length of time the improvement will continue after treatment has stopped. It is too soon to answer that question satisfactorily, owing to the shortness of time which has elapsed since this method of treatment was begun. It is my procedure to tell patients that, when they are relieved once, it is easy, reasoning from results obtained in opsonic treatment of other diseases, to hold the disease in check on the first appearance of further symptoms. It is unfortunate that many of the patients have had the trouble so long, and have suffered so much from it, that unless they obtain immediate results, and are promised future immunity, they easily become discouraged.

Judging from the results so far obtained in all stages and degrees of pyorrhea, it is apparent that we now have at our disposal a method of treatment which, though often slow, is constant in its good results, especially when combined with thorough dental treatment.

CONCERNING THE SCIENTIFIC METHOD OF FILLING TEETH.

By GEO. C. NICHOLSON, M.A.C.D., Melbourne, Australia.

(Read before the Third Australian Dental Congress, held at Brisbane, July 8, 1912.)

BEFORE dealing with the actual operation, it may be well to first speak of the causes of dental caries and to give a brief *résumé* of its etiology. As the study of bacteriology has, within recent years, altered our whole conception of the causes of disease, consequently our methods of treatment have been changed.

ETIOLOGY OF DENTAL CARIES.

The production of caries in teeth depends almost entirely upon the presence of micro-organisms or bacteria in the mouth, and among those isolated and cultivated by Miller, twelve were characterized by the formation of lactic acid, one of the most active agents of dental disintegration.

The late Professor Miller described dental decay as a "chemico-parasitical process consisting of two distinct stages, viz, decalcification or softening of the tissue and dissolution of the softened residue, and liquefication of the gelatinous matrix."

Tomes says—"Caries is an effect of external causes, in which the vital forces of the individual play no part."

Once a breach has been made by decalcification, other organisms, or possibly the same, take an active part in further disintegration. Numerous micro-organisms are always present in the mouth, which, being moist and warm and well supplied with food, is a well-devised incubator wherein organisms may multiply. When food—particularly of a carbohydrate nature—and micro-organisms are left together, fermentation sets in, and acid, chiefly lactic acid, is generated.

First the enamel is attacked, after which the dentin becomes accessible to the above-mentioned chemico-parasitical process, when sufficient destruction of dentin occurs to subject the nerve tissue to irritation and subsequent inflammation of the pulp.

THE RÔLE OF FOODSTUFFS IN DENTAL CARIES.

The various foodstuffs consumed by man are (1) albuminous, or proteids; (2) fats, and (3) carbohydrates (starch and sugar).

(1) *Proteids.* The action of the mouth bacteria upon proteids is such as to give rise to the products of putrefaction with an alkaline reaction. They have no solvent action upon the teeth, but neutralize, to a certain extent, the acids with which they come in contact.

(2) *Fats,* or their products of disintegration, have practically no action, so far as is known, on the teeth.

(3) *Carbohydrates.* These are converted into one or another of the various forms of sugar by certain bacteria and ptyalin, the active principle of saliva. These conversion products undergo further change by the agency of bacterial fermentation, with the ultimate production of acids—viz, lactic, butyric, citric, malic, and tartaric—principally, however, lactic. The focus of infection on the enamel is established by means of a bacterial plaque, or by food settling in a crevice of the enamel, and the calcium salts in the enamel, being attacked by acids thus generated, are dissolved; and with a breach once formed, the fermentative process can proceed uninterruptedly. On the dentin being reached,

bacteria invade the dentinal tubules and complete the work of disintegration.

BACTERIOLOGY OF DENTAL CARIES.

The principal organisms found in carious dentin belong to the order of cocci and bacilli. Those that are the most common are the streptococcus brevis, staphylococcus albus, staphylococcus viscosus, various sarcinæ, leptothrix, and members of the mesenteric group of bacilli. Whereas the cocci are for the most part acid-formers and decalcifiers, the mesenteric group act as liquefiers of the decalcified dentin.

The relation of bacteria to the oxygen of the air is so important a factor in the life of these organisms that it enables a biological division to be made among them. Some bacteria will live and develop only when oxygen is present; these are called (1) *obligatory aerobes.* Other bacteria live and grow only when no oxygen is present. These are called (2) *obligatory anaerobes.*

In still another class the presence or absence of oxygen is a matter of indifference. These may be grouped into—(*a*) those which are preferably aerobes but can be anaerobes, and (*b*) those which are preferably anaerobes, but can be aerobes. As a matter of fact such differences are manifested only in a slight degree, and all such organisms are usually grouped as (3) *facultative anaerobes, i.e.* preferably aerobic but capable of existing without oxygen.

The majority of pathogenic bacteria are facultative anaerobes, and in this class, I think, may be safely included the organisms found in carious dentin. Recognizing the cause of caries and the conditions which are necessary antecedents, the process of filling teeth then emerges from empiricism and becomes a scientific operation.

SHAPE OF FILLINGS.

All fillings must be so shaped that no food will lodge at their edges, and must, of course, be retentive and with no fine edges of enamel left standing. Briefly stated, there should be no marked raggedness. The enamel margins should be smooth, and as nearly as possible at right angles to the surface of the tooth; in the masticating surfaces of bicuspids and molars, however, the margins may be beveled slightly outward, but not sufficiently so to make a ragged edge. The general shape of all cavities should give a curved appearance to the filling, which should have no very pronounced angles. When an approximal surface of a tooth requires to be filled, it is nearly always necessary to contour it, not only to prevent the lodgment of food at the edge of the filling, but also to prevent the change of position of the teeth which will surely take place unless this precaution be taken. This point is called the "point of contact."

FORMS OF CAVITIES.

Various forms of cavities are met with:

(1) Simple cavities in which the enamel and a portion of the dentin is penetrated on one surface of the tooth.

(2) Compound cavities, some involving—

(*a*) One or more surfaces, but not penetrating more than one-third or one-half of the dentin.

(*b*) Others involving an exposure of the pulp, and therefore requiring extirpation.

(*c*) Others, again, occur in which the death of the pulp has already taken place some considerable time previously, and the gangrenous pulp has infected the dental periosteum.

STEPS IN THE PREPARATION OF A TYPICAL CAVITY.

As consideration of the treatment of all the above cases would occupy too much time, I propose to take a typical case, and deal with a simple cavity.

We find the enamel penetrated, and the dentin involved to a considerable depth. The cavity contains a mass of carious débris, and the tubules have become penetrated by and infected with various micro-organisms. First it is necessary to remove the carious matter, after which the cavity must be properly shaped and sterilized. In order to obtain the best results, the rubber dam should be applied to two or more teeth adjoining the tooth under treatment, if practicable. In the case under treatment, we will suppose the cavity to be in the crown of a lower first molar, which will make it a comparatively easy operation. The dam is applied to the molar by the aid of a clamp, and to the second bicuspid by ligaturing it. The removal of the carious matter is effected by excavators and excavating burs, the cavity being finally shaped by wet carborundum stones and disks; when this has been effected, and sufficient of the dentin has been removed, the all-important part of the operation—sterilization of the cavity—is reached.

STERILIZATION OF THE CAVITY.

As we have seen, the micro-organisms which have invaded the tooth structure are "facultative anaerobes," *i.e.* aerobes, but capable of existing without oxygen. If, therefore, any be left in the cavity after the filling is inserted, caries may recur, and this negligence Ottolengui condemns as "malpractice." When, however, bacteria exist in unfavorable conditions, multiplication takes place with difficulty.

The ordinary method of sterilization consists in the use of moist and dry heat at high temperatures. This method is inadmissible and impossible in the mouth, therefore other means must be used to bring about comparative asepsis. The term sterilization is used very often with regard to the cleansing of instruments, cavities, the hands, etc., with a surprising amount of vagueness, as are also the terms germicide, deodorant, disinfectant, and antiseptic.

Perhaps it may not be amiss here to define these several terms:

Sterilization is the destruction of all spores and germs, no matter where situated—as by heat, etc.

Germicide and *disinfectant* are now used synonymously. They are agents employed for the destruction of germs, *e.g.* mercury bichlorid, hydrogen dioxid, formaldehyd, chlorin, etc.

Deodorant. A medicinal agent capable of destroying infectious and fetid odors, but not necessarily a germicide; *e.g.* creasote, thymol, iodoform, etc.

Antiseptic. An agent which prevents or retards the growth of bacteria without necessarily killing them. All disinfectants in weak solutions are antiseptics, *e.g.* carbolic acid, boric acid, iodol, hydronaphthol, the essential oils, etc.

In sterilizing the cavity, therefore, as we cannot employ the necessary heat, it is requisite to employ an effective germicide or disinfectant, such as carbolic acid, silver nitrate, mercury bichlorid, hydrogen dioxid, and to any one of these may be added one of the essential oils as a deodorant.

The cavity may be sealed with gum mastic and cotton for not longer than twenty-four hours; if, however, it be considered necessary to leave the antiseptic dressing for a longer time in place, I consider it should be sealed with an osteoplastic filling, otherwise the beneficial effect of the dressing will be nullified.

Personally, for small simple cavities, I prefer to sterilize and fill on the same day, if possible, considering that thus quite as good, if not better results will be gained than by taking the risk of the cavity becoming reinfected. For that reason, after allowing the germicide to be retained for about five minutes, I remove the dressing, dry, and then dehydrate with absolute alcohol, using a hot chip-blower.

FILLING MATERIALS.

At this stage the cavity is ready to receive the filling, and we may now consider the filling materials at our disposal. These are—

(1) Gold, cohesive and non-cohesive.

(2) Amalgams of mercury with single metals, as copper and palladium; mercury and alloys of two or more metals, mostly silver, tin, zinc, copper, gold, etc.

(3) Osteoplastics, three principal varieties—(*a*) Oxychlorid of zinc. (*b*) Oxyphosphate of zinc. (*c*) Oxyphosphate of copper. 2d. Silicate cements.
(4) Gutta-percha.
(5) Inlays of porcelain and gold.

Of all the filling materials above mentioned, the osteoplastics alone, when properly introduced into a cavity, adhere to the cavity walls. As they are composed of antiseptic materials, cavities should be lined, whenever it is possible, with one of these cements, as by this means the dentinal canaliculi are hermetically sealed against the entrance of micro-organisms.

Cements. Cements may be divided into two classes—(*a*) Osteoplastics, (*b*) Silicates. We will first consider the osteoplastics, which are subdivided into two classes, viz, oxychlorids and oxyphosphates.

Zinc oxychlorid. This is composed mainly of zinc chlorid and zinc oxid. This material is principally used as a root-filling and a lining for cavities. It should not be used in a deep cavity, as it is an irritant, and might cause the death of the pulp. While zinc oxychlorid is an antiseptic filling, it must be regarded as a temporary one when exposed to the action of the saliva, which rapidly disintegrates it.

Zinc oxyphosphate is mainly composed of zinc oxid, magnesia, aluminum, silicate, and phosphoric acid. This material is to be preferred to oxychlorid of zinc, as it is less irritating, and not quite so easily dissolved. It is an excellent lining for cavities, and has proved itself invaluable for setting pivots, crowns, and bridges; but like the oxychlorid it should be regarded as only a temporary filling, the serviceability of which is impaired by an improper method of mixing.

Dr. McCauley has published an interesting table in his paper appearing in the DENTAL COSMOS for February 1912,* which is well worth consideration. When we consider the numerous makes of cement appearing under various names, it is surprising how very few stand the test for expansion, shrinkage, and porosity. As with McCauley's tests of amalgams, however, it must be remembered that these cement tests are made *outside of the mouth.* I have found that, on the whole, when cements are protected from the action of the saliva, the oxyphosphate, in particular, acts very well, and is a means of preventing recurrent caries.

Oxyphosphate of copper. The same may be said of oxyphosphate of copper, which to a marked degree possesses adhesive properties; its color, however, seems to limit its popularity. For deciduous teeth it is an excellent filling material.

Silicate cements. The second class of cements consists of the silicates, or, as they are often termed, translucent, or porcelain cement fillings.

Various makes of this class have been before the profession for some time. The disintegrating action of the saliva condemned quite a number, while others became discolored thereby, rendering them useless for the purpose for which they were inserted. Some, however, have lasted well, and it is to be hoped that the most recent of this class will prove an exception to its forerunners. This material looks remarkably well in distilled water; but, unfortunately, distilled water is not human saliva, and time alone will tell whether we now have the all-to-be-desired filling in our hands. I certainly do not think any cement, translucent or other, should be placed where it has to bear the stress of mastication. It is, of course, absolutely necessary, when inserting *any* cement filling, that the cavity be dry and protected with the rubber dam.

GOLD.

Gold is without doubt the most reliable filling material, and the method of its insertion which I have used exclusively for the last six years was described in the DENTAL COSMOS of No-

* "Amalgams: Their Manufacture, Manipulation, and Physical Properties. Cements: Their Manipulation and Physical Properties." By C. M. McCauley. DENTAL COSMOS, February 1912, p. 174.

vember 1907, by Dr. J. Leon Williams of London.* It is as follows:

The cavity is prepared in the ordinary fundamental way, *i.e.* retentive in shape. The enamel margins being well defined, retaining pits or grooves are unnecessary, as, after the cavity has been dehydrated with absolute alcohol, a small quantity of a quick-setting cement is introduced and placed on the floor of the cavity. This is allowed to remain until it is tacky, after which a fairly large piece of moss fibre gold is pressed firmly into place, as evenly as possible, commencing from the center.

The cement will now be seen to spread itself over every part if a suitable broad condensing plugger be used, care being taken not to allow the cement to reach the enamel margin. Should this occur, it is best not to attempt to remove it until the cement has set thoroughly, when it is easily and cleanly picked off with an excavator.

I usually allow the cement to remain five minutes before attempting to condense the gold. This interval is allowed, because any cement, no matter how rapid in setting, requires at least that time to get reasonably hard and to withstand the pressure necessary for thoroughly condensing cohesive gold. When the cement has set well, the edges of the enamel should be thoroughly examined. This is most important, as, should any cement be allowed to remain there, it will certainly crumble under the mallet and will prove a danger-spot.

When everything is satisfactory, the operator proceeds in the ordinary way, taking care, of course, not to use too large pieces of gold. I have for the last ten or twelve years always finished my gold fillings with heavy rolled gold foils, Nos. 120, 60, 40. I like No. 60 best; three layers of No. 60 rolled gold will make an ideal finish.

The filling is burnished thoroughly with a steel or agate hand or engine burnisher, and, in the case under treatment, reduced with finishing burs or Arkansas stones, and finished with little rubber, moose-hide, or wood points, charged with fine pumice. (For anterior teeth, of course, we use cuttlefish or other strips and disks and little rubber cups.)

I consider that in this way a scientifically correct gold filling is inserted.

At the last dental congress, held in Melbourne three years ago, I gave a clinic demonstrating my method of making a gold filling as above described, and then stated that I did not claim that all gold fillings should be so inserted, but that I considered it one of the best methods of filling. A further three years' experience convinces me that it is absolutely the most reliable and perfect filling I can insert. It will save teeth by reason of its being cemented into place —which, as we have seen, renders it impervious to the ravages of dental caries. It also supports instead of weakens frail walls, and is a filling inside a filling.

The gold and porcelain inlay, which it is here unnecessary to describe, will last—for the same reason, viz, its being cemented into place—until the perfect plastic for which we still hope supersedes zinc oxyphosphate, gold, and porcelain.

AMALGAM.

Amalgam is the filling material next in importance. Here let me speak of the customary method of inserting an amalgam filling.

Unscientific method of introducing amalgam fillings. The alloy is placed in a mortar, and a sufficient quantity of mercury is shaken into it. The two materials are then triturated together, until a pasty mass results; this mass is then "worked up" in the hand—sometimes a moist and not scrupulously clean one—after which the excess of mercury is squeezed out in a dirty piece of chamois leather, and the filling is packed into the cavity as quickly as possible.

I was an articled pupil twenty-five years ago, and this method was largely in vogue at that time; but quite recently I saw a dentist of standing fill a tooth

* "Gold, or Gold and Platinum, Cemented Linings for Amalgam and Gold Fillings." By J. Leon Williams. DENTAL COSMOS, November 1907, p. 1157.

in this way, without even having the rubber dam in place. We are supposed to be practicing as dental specialists, with scientific training, but are those who work on such haphazard lines deserving of being so classified? It was excusable to insert fillings as above related twenty-five or thirty years ago, the science of bacteriology being then but in its infancy, and the practice of dentistry not having at that time reached the high standard which it now occupies. Exactitude in his minutest processes stamps the work of a man of high ideals.

Physical properties of amalgam. Before proceeding to discuss the method of filling teeth with amalgam, it is necessary, first, to consider some of the physical properties of this most valuable agent and its behavior in general practice.

To Prof. G. V. Black we are indebted for the exhaustive investigations he made, the results of which were published in the DENTAL COSMOS as far back as 1895.

He showed that, if a block of amalgam be submitted to stress, and the force be applied rapidly by means of a screw, when the stress reaches a certain point the block of amalgam bursts in pieces with a crash; this point is termed the "crushing stress." If the block be submitted to constant stress, less than the "crushing stress," it is found that the mass gradually yields. This movement is termed the "flow" of the amalgam, and as a result of this flow the whole filling changes shape when under pressure, such as exerted by mastication.

Another point Professor Black showed in his investigations, when considering the silver-tin alloys, is the "aging" of amalgam. Tomes defines this phenomenon as—"the curious fact that, as regards expansion or shrinkage, the same sample of alloy will be found to give different results according as it is used when freshly cut from the ingot, or after a lapse of some time." Dr. McCauley, in his paper before referred to, says: "The best assurance we may have in our amalgam work against recurrence of caries is the certainty that our fillings will not shrink sufficiently to allow micro-organisms to enter between the filling and the cavity wall, and will not permit sufficient flow to disturb the marginal adaptation." Proceeding, he says: "One of the dearest and most widely advertised alloys was tested, and I found, during the first twenty-four hours, 6/10,000 of an inch, or six points, of shrinkage; twenty points, or 20/1000 of an inch of flow, which is nearly one-fourth its volume; and an average strength of only 236 pounds. Such shrinkage is absolutely fatal; the flow is ten times more than it should be, and the strength only two-thirds as much."*

Bearing in mind that when inserting amalgam fillings we believed we were at least dealing with a stable mass, when it was placed in position under proper and scientific conditions, this statement from such an authority is a very disquieting one. If we consider the minuteness of the organisms with which we are contending, and which usually do not measure more than 1 micron (1/25,000 of an inch) in diameter, it will be seen that a force of microbes about seven or eight abreast can march from all positions around our filling which we considered safely stopped.

It will further be seen that the non-recurrence of caries under these circumstances is largely a matter of *luck*—which, it must be admitted, is not what one generally relies on to build up a creditable or lucrative practice!

Lining the cavity. As early as 1883, Marshall Webb recommended that cavities be lined with either oxychlorid or oxyphosphate of zinc, as non-conductors; and Ottolengui, in his book on "The Methods of Filling Teeth," recommends that amalgam be cemented into place—not, however, for its therapeutic value, but for the retention of very shallow fillings. For the last seven or eight years I have adopted the method of lining cavities with cement, with most satisfactory results wherever absolute dryness was obtainable. When, however, these conditions do not prevail, and when

---

* DENTAL COSMOS, vol. liv, 1912, pp. 175 and 176.

the rubber dam will not keep out the creeping moisture, I have adopted a plan of my own, which I have found to work very well, and which I hope my *confrères* will try for themselves.

With the saliva ejector, bibulous paper, cotton rolls, and Stokes' and other clamps, we can do a great deal to reduce moisture, but cannot obtain the requisite degree of dryness necessary when using cement. I therefore use copper amalgam as a lining for such cavities.

Copper amalgam as a cavity lining. Colyer says, "Copper amalgam does not flow under stress; it does not shrink nor expand." The black discoloration is due to the formation of copper sulfid, which has proved itself a valuable germicide, and has been a means of saving very many badly broken-down teeth. In considering copper amalgam it is necessary to state that, while it possesses valuable therapeutic qualities, it has also one very pronounced fault, which must not be overlooked.

The desirable quality in a copper amalgam filling is to have it, after insertion, turn a coppery black when it sets —then all will be well. It very often remains gray, however—the color of a silver-tin amalgam; when this is the case, disintegration rapidly takes place. I am inclined to think that this is largely due to the method of treating after deflagration. I always warm both pestle and mortar and thoroughly triturate, inserting the amalgam fairly dry, using it as a lining only, and completing the filling with one of the harder amalgams, pressing one amalgam into the other.

The union of the two amalgams is perfect. I have made test pieces with copper amalgam and the following well-known alloys, viz, Foster Flagg's Contour and Submarine, Fellowship, DeTrey's, True Dentalloy, Standard, C. A. S.—in fact, any alloy that came under my notice. I may say that when making these test fillings I did not use more force than when filling a tooth in the mouth.

I consider that notwithstanding the liability to disintegration of copper amalgam when exposed to the free action of the saliva, the remedy I have mentioned above should save it from being banished from our surgeries—as doubtless it has been, and is, a valuable tooth-saver.

AUTHOR'S TESTS IN REGARD TO HERMETIC TIGHTNESS OF AMALGAM FILLINGS.

Prof. Black has said that most amalgam fillings contain from 10 to 15 per cent. of air which it is impossible to press out. If an old filling that has been in a tooth be placed in a deflagrating spoon and heated, it will give off a very bad odor, showing that organic matter must be present, which has certainly been the home of microbes. If it is impossible to exhaust the air out of an amalgam filling itself, what amount of air remains between the filling and the walls of the cavity? To this must be added the space created when the amalgam crystallizes, and also the shrinkage that has been proved to take place in almost every alloy. Some makers of alloys assert that their amalgams expand, but my experiments and experience have shown me that there are very few amalgams that, *outside* the mouth, make a watertight plug if left long enough submerged. For a while I used, for experiments, little glass tubes about a quarter of an inch in diameter. I inserted a cork at one end, and filled in amalgam on top of the cork. When the filling had set I removed the cork, and at the opposite end I put in red ink. The result was failure almost every time. I then changed the materials, as I did not consider cork a fair substitute for dentin, and used vulcanite in place of the glass tube. I drilled holes of all sizes and filled into these various amalgams, not using undue pressure in the operation, and, after waiting about a quarter of an hour, I laid the vulcanite into black or red ink. After immersion for some days I cut through the vulcanite and filling with a fine saw, and it was easy to detect the watertight plug. From the result of these rather crude experiments I determined that, if I wished to prevent recurrent caries, the cavities should be lined with either cement or copper amalgam.

I continued the experiments with vulcanite and lined the cavities with either cement or copper amalgam, and inserted the amalgam as before, the result being invariably satisfactory. I then adopted this method in practice—with, certainly, more satisfaction than I had previously obtained. If the amalgam filling still contains from 10 to 15 per cent. of air filled with microbes, and even allowing for a certain amount of flow which may take place under pressure of mastication, micro-organisms have still to pass copper amalgam or cement before reaching the dentin. Ultimately, of course, they may reach it, as cements are not always free from porosity, as we have seen. Copper amalgam does not flow or shrink, and the copper sulfid arrests the progress of the microbe and prevents a condition favorable to further attacks of caries.

Sometimes, if the cavity be extensive, I add to the cement a little chinosol or hydronaphthol, which drugs do not in any way injure the setting qualities of the cement, and are good antiseptics.

Use of matrices. In filling teeth with amalgam in approximal cavities in bicuspids and molars, it is necessary to use the matrix in order to obtain the requisite condensation of the filling material, and also to obtain four walls. In two adjacent cavities it is better to fill the less accessible first.

Although there is no unanimity among authorities as to the use of matrices, especially in regard to the difficulty of obtaining perfect adaptation of the filling to the enamel margins and point of contact, this possible drawback is overcome by subsequently adding a little amalgam to the filling before it has set, after the matrix has been removed; the filling can then be finally contoured.

GUTTA-PERCHA.

Gutta-percha employed in its proper place is very useful indeed. The best results are obtained with it when the cavity is dry, but as it will not bear attrition it should never be placed in an occluding surface. Gutta-percha is useful in cavities caused by denture clasps. These cavities are usually extremely sensitive, and, if they are excavated deeply enough for a metal filling, the pulp may be jeoparded. But with gutta-percha this danger will be obviated largely.

For buccal and lingual cavities near or under the gum, gutta-percha gives more satisfaction than any other material, especially in the case of elderly people. Gutta-percha is not, however, watertight in the ordinary acceptation of the term, and therefore cannot, in my opinion, be classified as a permanent filling. It is a non-conductor, and for this reason is useful as a capping in sensitive dentin.

I am using this material principally as a temporary filling and for root-canals, besides its employment in the above-mentioned cavities. There are several good makes, but I prefer the pink or white base-plate to all others.

My method of inserting gutta-percha is as follows: Having made the cavity as dry as possible, I apply a little oil of cajuput on a pellet of cotton. Then a fair-sized piece of gutta-percha is warmed, dipped in cajuput, and pressed home with a conical warm instrument. Each additional piece is moistened with cajuput, the last piece is placed dry, and the filling is finished off with an instrument that has been dipped into cocoa butter. This imparts a fairly dense surface to the filling.

GENERAL REMARKS.

Of late years manufacturers have devoted special attention to the color of amalgam, with considerable success, but apparently at the cost of the most important quality of an alloy, viz, "the balance"—that is, the greatest number of desirable and the smallest number of faulty physical properties.

In the discussion which followed Dr. McCauley's valuable paper, the suggestion was made that the various alloys at present before the profession should be tested by an independent body of experts, and the results as to their reliability published. At the present time the general practitioner is at the mercy of the manufacturers, and takes for granted the laudatory notices of their products—not only alloys and cements, but other dental requisites. The proposed investigation, therefore, is a matter we should all welcome and heartily support.

CONCLUSION.

We have now considered the cause of dental caries, the method of cleansing the cavity, its sterilization, the preparation of the enamel margins, and the various materials suitable for restoring the contour and usefulness of the tooth, with the object of keeping it in that condition. Whatever the material used may be, whether gold, amalgam, or an inlay, the marginal lines should be too fine to be felt, and the surface of the filling be as highly polished as the enamel of the tooth. The personal equation and attention to exact technique will, of course, depend on the operator.

I desire to express my thanks to Dr. R. J. Bull, director of the bacteriological laboratory, University of Melbourne, for his kindly advice.

A STUDY OF POTASSIUM CHLORATE.

By ALONZO MILTON NODINE, D.D.S., New York City.

IN his paper on "Drug Idolatry in Dental Medicine," published in the DENTAL COSMOS for December 1911, one of the "idols" that Dr. Hermann Prinz attempts to demolish is potassium chlorate, an attempt involving certain misconceptions which it is the purpose of the present article to remove.

PROFESSOR PRINZ' INDICTMENT OF POTASSIUM CHLORATE.

Professor Prinz' unreserved and unqualified indictment of potassium chlorate sounds like an echo of the unreasonable and unsound condemnation of a few medical men.

Evidently this is not Professor Prinz' serious intention, for in a recent book, entitled "Surgery and Diseases of the Mouth and Jaws," by Professor Blair of the University of Washington Dental School, with whom Professor Prinz collaborated, one finds, on pages 288 and 297, potassium chlorate recommended for stomatitis!

"When absorbed [referring to potassium chlorate] by the blood, the greater part of the hemoglobin is either directly destroyed or is changed to methemoglobin,"[1] declares Professor Prinz.

This charge, made without restriction or proviso, is not only untrue but is contrary to common experience and to the common observation of all who for a long time have used potassium chlorate. Were Professor Prinz' statement true, every user of the drug should be dead, and every prescriber of it would be a criminal! Still, such denunciation from a less able and less distinguished man would be passed unnoticed and unprotested.

Before we obey the fiat to "eliminate potassium chlorate from the medicinal armamentarium of the dental practitioner," as we are directed, it is fitting and proper that the drug be judged fairly, squarely, and scientifically; and to that end each man may conduct an investigation of his own, and thus constitute himself his own judge and jury.

REVIEW OF THE THERAPEUTIC USES OF POTASSIUM CHLORATE.

Professor Prinz (on page 1373 of the DENTAL COSMOS, December 1911) declares: "Potassium chlorate is not a specific for stomatitis."

What is a specific? As defined by Dr. J. P. Buckley, "A specific is a remedy which, if used in the proper manner, can generally be depended upon to produce results in certain diseases."[3]

Stomatitis. Potassium chlorate has been used for almost a century by the most scientific men in the medical and dental professions as a treatment for the various forms of stomatitis. It has been used with a success so great that in the majority of text-books in which stomatitis is considered, the one drug recommended as effective in the treatment of this condition is potassium chlorate. Other writers, with but few exceptions, accord it the chief place among two or three other drugs.

Were Professor Prinz' statement true, then the authorities whose books have appeared in the last six or eight years either do not know what a specific is, or what stomatitis looks like, or else the results which they have achieved are due, not to potassium chlorate, but to some mysterious influence peculiarly associated with the use of potassium chlorate!

When Professor Osler of the University of Cambridge,[4] Professor Tissier of the University of Paris,[5] Shoemaker of the Medico-chirurgical College of Philadelphia,[6] Bovaird of the College of Physicians and Surgeons, New York,[7] Holt,[8] Hare,[9] Potter,[10] Roberts,[11] Strumbull,[12] Latham,[13] Fleming,[14] Dayton,[15] Bartholow,[16] and Tuley,[47] declare that potassium chlorate is a specific for the treatment of stomatitis, they come very close to knowing what a specific is, what stomatitis is, and what successful treatment is.

Dr. Prinz says: "Potassium chlorate as a remedy for the various forms of stomatitis is looked upon by many practitioners as a veritable panacea. As someone has said, 'It is one of the most reliable remedies, indeed almost a specific, in ulceration of the mouth, particularly in stomatitis, etc.' "[1]

This is not only the common accumulated experience of over one hundred years' continuous use of potassium chlorate, but forty of the most distinguished writers of England, France, Germany, Austria, and America, in scientific books published within the last six or eight years, declare it to be a specific for stomatitis.

One of these writers states: "For maternal stomatitis it is reported by men of authority as the only remedy worth mentioning."[6]

"Others lauded it as a prophylactic in mercurial stomatitis." (Prinz.[1]) Potassium chlorate is almost without exception the only drug named as a prophylactic for mercurial stomatitis in medical or dental literature. (See bibliography, Nos. 6, 10, 12, 14, 15, 17, 18, 19, 20, 21, 22.) How did it gain this reputation?

Let us turn to the latest books in the English language and published since Professor Prinz wrote his paper—books written by Osler,[4] Latham and English,[17] Stevens,[18] Dayton,[15] Buckley,[19] etc. Are these men hypnotized by a delusion, or are they announcing a scientific truth? If there is any other drug used with the same universal success as potassium chlorate, will Professor Prinz please name it?

"Others claiming that it will prevent salivation." (Prinz.[1])

In the latest and best books are to be found such statements as these: "When ptyalism occurs, the potassium chlorate treatment should be immediately begun."[20 10] "Patients who are taking mercury should use potassium chlorate."[21 6] "As a prophylactic, patients should employ a gargle of potassium chlorate faithfully from the beginning of the treatment, in order to prevent mercurial stomatitis."[12 22]

PHYSIOLOGIC ACTION OF POTASSIUM CHLORATE.

Prinz tells us that "Potassium chlorate has been introduced into therapeutics on the erroneous theory that it will decompose in the body and supply oxygen to the tissues."[1] Whereas potassium chlorate was introduced into therapeutics in 1796 by Fourcroy, on the rather vague theory that acids and oxids have some beneficial effect on the human body, and was first used as a cure for syphilis.[23] Lavoisier first advanced the theory that potassium chlorate gives up its oxygen to the tissues.[23]

"The theory that it will decompose in the body" is not entirely "erroneous," as asserted by Prinz. "Dr. I. Von Mering finds that the chlorate is decomposed in the system with the formation of chloric acid by the action of carbonic acid upon it, and the fact that similar symptoms are produced by sodium chlorate, shows that they are due to the acid rather than to the base."[24] Simon declares: "It is even a stronger oxidizing agent than potassium nitrate, for which reason care must be taken in mixing it with organic matter or other deoxidizing agents."[26] "Chlorates give up their oxygen to the tissues, and it is largely on this account that they have received wide employment in foul conditions of the mouth and pharynx."[27] Wilcox says: "Locally it is easily decomposed by septic tissues, and the nascent oxygen given off acts as a stimulant and antiseptic."[28] Marshall writes: "It is a powerful oxidizing agent."[29]

If potassium chlorate does not part with its oxygen at the temperature of the body, will Professor Prinz please explain by what chemical process it does combine with the red blood cells to destroy them, as has been claimed?

The answer to this question is best stated by Walter E. Dixon, professor of materia medica and pharmacology, Kings College, London, and examiner in pharmacology in the Universities of Cambridge and London: "It is easily shown that chlorates undergo a slow reduction when in contact with putrefying organic matter, and it is known that they are continuously eliminated by the salivary glands, the mucous membranes, and the kidneys; hence it is suggested that, although normal tissue fails to reduce them, the reduction is effected by septic tissue." "Taking man's blood as an example, the addition of 20 per cent. potassium chlorate takes six hours to destroy the hemoglobin!"[62]

Again Prinz says: "It is supposed to be largely excreted by the saliva, and thereby continuously bathe the diseased mouth with its oxygen-laden fluid."[1]

This is not a "supposition." It is an actually demonstrated fact that "Potassium chlorate can be detected in the saliva five minutes after being taken by the mouth."[31]

Other authorities declare that it is eliminated by the buccal secretions, which keep the ulcerated surfaces constantly bathed with the drug, so that its internal administration is recommended. (See bibliography Nos. 9, 22, 32, 33, 34.)

ANTISEPTIC VALUE OF POTASSIUM CHLORATE.

Prinz continues: "It possesses little if any value as an antiseptic."[1] This is diametrically opposed to the views and experiences of the highest authorities in medicine, as a consultation of the following authorities will show: Stevens,[18] Dayton,[15] Kelly,[21] Dieulafoy,[22] Strumbull,[12] Edwards,[34] Forchheimer,[20] Hughes,[35] Taylor,[36] Bovaird,[7] Roberts,[11] Fleming,[14] and many others.

"Its therapeutic effects do not "depend wholly on its salt action," as Sollmann, the only authority whom Professor Prinz names, states,[37] being confirmed by Marshal,[28] and Miller.

"The chlorates have also a disinfectant and local stimulant action which seem to be stronger than would be accounted for by its salt properties, and would therefore appear to be a specific *ion* action."[37]

"This fact" does not "decide its worthlessness as a prophylactic in mercurial stomatitis."[1] Professor Miller states: "It has a distinct and specific antimercurial action." Cushney,[25] Osler,[4] Bovaird,[7] Shoemaker,[6] Buckley,[3] Marshall,[29] Greve,[38] Hall,[17] Tissier,[5] Phillips,[24] Long,[39] Stevens,[18] and many others, declare that it is a specific prophylactic for mercurial stomatitis.

THE QUESTIONABLE TOXIC ACTION OF POTASSIUM CHLORATE.

Prinz says: "It should be remembered that potassium chlorate acts as a dangerous poison."[1]

Holland declares: "If used as a mouth-wash it is harmless, but when taken in large doses it is an irritant, causing abdominal pains, etc."[40]

And Blyth: "No drug has been given more recklessly or on a less scientific basis. Where there were sloughing wounds, low fevers, and malignant sore throat, usually those of diphtheritic character, practitioners administered potassium chlorate in colossal doses. Its too reckless use has led to many unrecorded accidents."[41]

And further, Wittehaus gives a record of 143 poisonings, 116 of which were fatal. "Almost all of these were accidental, caused either (as in 15 cases) by chlorate of potash being mistaken for some other medicine, or, as in a great majority of cases, by its having been administered in overdoses or swallowed by the patient when prescribed as a gargle."[31]

It is such a dangerous drug that one man took 719 grains in thirteen hours and showed no effects![31]

Were we to follow such reasoning, we might as justly condemn the use of common table salt, because a pound of it has killed a man, and because a dentist in Scranton, Pa., has suffered from hyperchloria.

Neither in the U. S., the German, the French, the Swiss pharmacopeias nor in the British Pharmaceutical Index is it classed as a dangerous poison or drug. Other authorities declare: "When taken internally in full pharmacopeial doses it has a saline taste, is generally well borne by the stomach, and usually produces no obvious effects except diuresis." (See Nos. 18, 29, 31, 32, 42.)

Prinz says, however: "When absorbed by the blood, the greater part of the hemoglobin is either directly destroyed or changed to methemoglobin."[1]

We must take this statement together with his other statements that "It does not part with its oxygen at the temperature of the tissues," and that "about 90 per cent. is removed with the urine, the remainder passing out through the salivary glands." Reconcile these three statements if one can!

In the cases that are so often cited as exhibiting the terrible danger (?) of potassium chlorate, most of the adults took from one to two ounces and the children and babies took large amounts. Under conditions such as these, it is quite legitimate to conclude that potassium chlorate is a dangerous drug—*i.e.* when taken by the spoonful or given to children to drink in large quantities.

Prinz continues: "Potassium chlorate in tablet form for throat trouble is in common usage by the laity; such practice should be condemned." Why should it be condemned? Because one man in St. Paul[60] and another in Detroit[61] ate very freely of these tablets—in the former case producing an erythematous rash, in the latter the loss of an eye? Two cases!—only two cases out of the millions who have used such tablets for over a century, and which are sold almost as freely as candy! Truly, a dangerous drug!

THE TASTE OF POTASSIUM CHLORATE.

"Aside from its disagreeable salty taste, the constant use of dentifrices containing potassium chlorate is very prone to produce inflamed and easily bleeding gum margins."[1]

Prinz begs the question when he focuses his attention on the taste of potassium chlorate. When has a therapeutic agent been condemned because of its transient taste? The saline taste remains for only a short time, when it gives the mouth a cool and an unexpected and unusual feeling of cleanliness.

USE IN DISEASES OF THE GUMS.

Further, in regard to its "producing inflamed and bleeding gum margins," the experience of those who have prescribed dentifrices containing potassium chlorate and used them is entirely to the contrary. In addition, for over a century, potassium chlorate has been considered almost a specific for the very condition which it is alleged to create, that is, bleeding gums, and is recommended in such phrases as: "It makes an excellent local application in inflammatory affections of the mouth and throat."[18 25] "It is recommended for bleeding gums concomitant with scrofula."[6] "Potassium chlorate is used as a wash when the gums are inflamed."[27] "For the special ulceration of the gums of scorbutus, the chlorate of potassium is a specific." (See Nos. 4, 9, 24, 17, 43.)

RANGE OF USEFULNESS.

Professor Prinz says: "Potassium chlorate has a very limited range of usefulness."[2] And at page 1374 of his article in the December 1911 DENTAL COSMOS, he says: "Potassium chlorate should be eliminated from the medicinal armamentarium of the dental practitioner."

Before we eliminate it entirely we will explore this so-called "limited range of usefulness," which even Prinz himself admits. It must be borne in mind that potassium chlorate as an ingredient either of dentifrices or mouthwashes is advocated for the treatment and the prevention of a few diseases of the mucous membrane and gums, and as an agent for cleansing the healthy mouth and teeth.

Therefore, when others claim that it produces beneficial results outside of the oral cavity, and has effected cures of diseases other than the ones for which it is specifically suggested, it is "another feather in its cap." When others fail to get the same effects in those cases for which this drug is not especially indicated, this should not detract from or discount its efficiency in the cases for which it is specifically indicated.

In regard to this so-called "limited range of usefulness," it will be found that it is considered and recommended as an antiseptic by Sollmann,[37] Fleming,[14] Latham and English,[17] Taylor,[36] and many others.

A few of the conditions for which potassium chlorate is recommended by the acknowledged authorities in medicine and therapeutics are—*Aphthous stomatitis* (Nos. 4, 5, 6, 9, 11, 13, 15, 16, 17, 21, 22, 24, 25, 28, 30, 32, 33, 39, 42, 44, 45, 51, 54, 57, 65, 67). *Bronchitis* (Nos. 10, 16). *Catarrhal stomatitis* (Nos. 25, 28, 30, 32, 34). *Catarrh of the throat* (Nos. 18, 25). *Diphtheria* (Nos. 5, 10, 24). *Foul ulcers* (No. 42). *Herpetic stomatitis* (No. 47). *Herpes of the buccal cavity* (No. 42). *Leucoplakia buccalis* (No. 59). *Maternal stomatitis* (Nos. 6, 16, 28). *Mercurial stomatitis* (Nos. 3, 4, 5, 6, 10, 12, 14, 15, 16, 17, 18, 19, 20, 21, 22, 24, 25, 28, 30, 36, 37, 42, 49, 66). *Moist eczema* (No. 42). *Noma* (Nos. 11, 20, 30). *Parasitic stomatitis* (Nos. 17, 28, 30). *Pharyngitis* (Nos. 9, 10, 18, 24, 31, 42). *Pharyngomycosis leptothricia* (No. 7). *Prevention of salivation* (Nos. 3, 6, 10, 12, 20, 21, 22). *Simple parotitis* (No. 17). *Scarlet fever* (No. 24). *Scorbutus* (Nos. 4, 6, 9, 12, 13, 24, 34, 38, 43, 53, 56, 66). *Syphilitic mucous patches* (No. 42). *Tonsillitis* (Nos. 10, 16, 28, 31, 44, 58). *Ulcerative stomatitis* (Nos. 4, 5, 6, 7, 8, 11, 12, 14, 15, 18, 20, 21, 22, 24, 25, 28, 30, 32, 33, 34, 44, 45, 46, 47, 48, 51, 54, 55, 59, 64, 67). *Typhoid fever* (No. 10). *Mercurial periosteitis* (No. 63). *Chronic cystitis* (No. 10). *Pseudo-membranous laryngitis* (No. 10). This list is sufficient to show that potassium chlorate has a wide range of usefulness, without going outside of the oral cavity for additional evidence.

RESULTS OF INVESTIGATION AS TO TOXICITY.

To settle the much-discussed question as to the toxicity of potassium chlorate in dentifrices, Bachem of Berlin, at the request of the German government, investigated this question in 1912, and rendered his decision as follows:

(1) "There is no record of any case in which potassium chlorate in a dentifrice has caused any trouble whatever," states Lewin, the toxicologist of Berlin.

(2) It is impossible for the amount of potassium chlorate remaining in the mouth after brushing, when absorbed, to cause any toxic effect whatever.

(3) The amount capable of being absorbed when used as a dentifrice produces no effects on either the stomach or kidneys.

(4) The toxic effect of potassium chlorate on the blood depends upon the amount taken.

(5) Potassium chlorate liberates oxygen in the mouth, as is shown by the rengalit and methylene-blue tests.

SUMMARY.

(1) It has been shown by a vast array of testimony that the charges made against potassium chlorate, and potassium chlorate used in dentifrices, are neither just, true, nor reasonable in either fact or theory.

(2) Potassium chlorate is a specific for the treatment of aphthous, ulcerative, parasitic, catarrhal, and mercurial stomatitis.

(3) It is a prophylactic for mercurial stomatitis, and is recommended by distinguished authorities as a preventive of ptyalism.

(4) It has been successfully used in the treatment of noma and pharyngitis, and in the sore throat of diphtheria and scarlet fever.

(5) It is decomposed in the body and parts with its oxygen at the temperature of the body, as its action in excessive doses proves by its destruction of the red blood cells, by the rengalit and methelene-blue tests, and its effect on septic tissues.

(6) It is largely excreted by the saliva; and because of this,

(7) Its action is continuously antiseptic.

(8) It possesses a decided value as an antiseptic in the mouth because of its oxidizing properties, its *ion* action, and its excretion by the saliva.

(9) It stimulates the healthy flow of saliva, stimulates circulation in the mucous membrane, and because of its salt action, relieves capillary stagnation.

(10) It is, by reason of its effects on alkaline salivary secretion, its effect on the capillary circulation, its tonic effect, its oxygen effect, its saline effect in promoting natural cell activity, very efficient in preventing the multiplication of lactic acid bacteria, and in neutralizing the acids produced during the life-activities of other bacteria and putrefactive processes.

(11) It is effective and efficient in preventing and relieving bleeding and spongy gums.

(12) It is neither a dangerous drug, nor are potassium chlorate dentifrices poisonous compounds when used in mouth-washes or in tooth-powders or pastes, either for adults or for children.

(13) Potassium chlorate has never had an alarming or untoward case recorded against it, when used with even the slightest amount of care as a mouth-wash or as a dentifrice.

(14) *Finally:* Potassium chlorate is efficient and harmless when used as a tooth-paste or tooth-powder and in the treatment of diseases of the mucous membrane of the mouth.

AN OBSTACLE TO ORAL HYGIENE.

By JAMES G. CLUNE, D.D.S., New York City.

IT is an indubitable fact that mental impressions are transmitted from one individual to another through both inheritance and environment; that our conceptions and our sentiments pass from one generation to another, and that, whether right or wrong, some of them gain strength with age, because we are, in a measure, naturally inclined to regard with affection the views held by our forefathers.

THE POWER OF TRADITION.

Just as we observe a similarity of the features of the several members of a family, so do we observe that the beliefs, religious and otherwise, of the consanguinous are, as a rule, alike; and just as family influences tend to perpetuate conceptions and sentiments of a similar character, so do racial, social, and occupational influences tend to prove conducive to the same effect. Broadly speaking, our mental impressions are the product of our ancestors or our associates, for like causes must needs be followed by like effects.

The common propensity to cling to such mental impressions as are handed down from one generation to another accounts, in great part, for the sway of soothsayers and the longevity of most of the current superstitions. It also accounts, in some degree, for the reluctance with which established facts are allowed to replace ancient fallacies.

The disposition to adhere blindly or stubbornly to such convictions as were current in the past or were gained too hastily is not peculiar to the uneducated, for a trait that is common to a race must be common, in some degree, to the individual members of the race; consequently the educated must share, to some extent, the tendency to retain inherited or acquired impressions, whether they be proper or improper.

Regardless of any opinion to the contrary that may be due to "the pride of ignorance," the fact remains that the advancement of dentistry, like that of every other scientific pursuit, is hindered by the common reverence for antiquated convictions; in dentistry, as in every other field of intellectual endeavor, each newborn truth bears the stigma of an antecedent fallacy, or it is received with widespread distrust. Hostility to newly discovered truths prevails because belief in the established order of things is a heritage of our race—the heretic is born, not made.

FALLACIES REGARDING DENTAL HYGIENE.

In no division of present-day dental thought are the evil consequences of this inherent weakness, this innate stubbornness, more generally and conspicuously exhibited than in that which deals with the subject of oral hygiene. Obstinate adherence to the preposterous speculations and irrational deductions of untrained and superficial pioneers has caused many of our profession to remain practically unacquainted with some of the most remarkable developments of skilful research; it has hindered progress; it has exalted the foolish and discredited the wise; it has put asinine phrases into the mouths of the gullible, and savable dentures into the cuspidors of extractors. It has burdened contemporaneous literature with ridiculous inconsistencies; it has retarded popular enlightenment, and it has injured public health.

This inborn inhospitality to such

truths as are revealed by modern methods of investigation is chiefly responsible for the persistence with which many hold to notions that have long since been proved to be entirely erroneous. It accounts for the still prevalent, though totally false impression that oral hygiene means nothing more nor less than caries-prevention; that caries-prevention consists in the employment of alkaline mouth-washes; that all acid substances are highly conducive to carious action, and that oral sterilization is practicable. It also accounts for the continued use of agents that are now known to possess none of the properties formerly attributed to them.

RECOGNITION OF THE IMPORTANCE OF ORAL HYGIENE.

Even to this day, many dentists labor under the false impression that oral hygiene means nothing more than the maintenance of that degree of tooth cleanliness which will either prevent or retard the development of dental caries. Far too many of them fail to understand that so contracted and erroneous a view is entirely out of accord with the present broad scope of dental endeavor, and that it ill becomes one whose knowledge and interest should extend beyond the narrow confines of the oral cavity. In enlightened circles, oral hygiene is now recognized as one of the most important branches of both the dental and medical sciences; we have awakened to the fact that a foul mouth is the preface to many a funerary event, and that a healthy condition of every organ of the body is contingent, in some degree, on mouth cleanliness. We have outgrown the delusion that oral hygiene can be maintained solely by the use of a tooth-brush soaked or swabbed with an alkaline tooth-wash, paste, or powder; we have recovered from the mistaken idea that the use of an acidulous agent in the mouth constitutes a misdemeanor or malpractice; we have evoluted beyond the conviction that chlorate of potash liberates oxygen in the oral cavity.

MODERN KNOWLEDGE OF DENTAL CARIES.

While none but the hopelessly stupid or the incurably conceited will contend that the last truth concerning the etiology of dental caries has been disclosed, the fact remains that the present state of knowledge is such that we can safely abandon many of the convictions that have long been deeply rooted in the minds of the majority, and can deal quite intelligently with carious processes. In spite of the many obstacles that have been interposed through innate reluctance to forsake time-worn convictions, the mysteries concerning dental caries are well-nigh dispelled. We have ceased to take fright at acidulated saliva; we have extended our view far beyond pumice and orange-wood sticks.

Contrary to the popular opinion, which is still shared by a few members of the dental profession, dental caries is not, *per se*, a filth disease. This is evidenced by the fact that it is commonly seen in the cleanest of mouths, and is frequently absent from the filthiest of oral cavities. It is a matter of common knowledge that dental caries is widespread among the better class of civilized races, who, as a rule, make daily use of the tooth-brush; yet it is uncommon among savages, who are practically strangers to the dental toilet. Broadly speaking, teeth suffer decay where the dental toilet is the rule, and escape decay where the dental toilet is the exception. And this is true in spite of the fact that the tooth-brush is a most serviceable, a necessary, article.

CARIES IN MOUTHS WITH ALKALINE OR ACID SALIVA.

Dental caries is not essentially a consequence of tooth-exposure to acid-producing bacteria, for these organisms are, as a rule, quite as plentiful in the mouths of those immune to carious action as they are in the mouths of those predisposed to it. As a matter of fact, dental caries is almost confined to mouths in which the saliva is alkaline, not acid, in reaction. Hence the folly of placing sole reliance on alkaline mouth-washes, tooth-pastes, or powders. It is known, in fact, that the use of vegetable acids, such as cider, vinegar, or the juice of edible fruits, for detergent purposes is productive of much better results than can be obtained by a similar employment of alkaline agents. Paradoxical as it may seem to the unenlightened, vegetable acids enhance the alkalinity of salivary secretions, whereas the alkalis ordinarily used lower it through their inhibitory action on the salivary glands. Acidity of the saliva arises, as a rule, from some perversion of metabolism attended with subnormal alkalinity of the blood. The oral use of alkaline substances cannot possibly affect the underlying cause of this metabolic impairment. One cannot arrest the growth of hair by frequently trimming it, nor can one arrest the output of an acid fluid by frequently applying an alkaline substance to the area of its discharge.

CONCLUSION.

The energy now being expended in an endeavor to acquaint lay minds with the importance of oral hygiene will ultimately prove of incalculable benefit to public health. But it is none the less regrettable that progıessive movements originating in dentistry, like those in medicine, are materially embarrassed through an inherent and widespread disposition to distrust whatever threatens to disprove the validity of convictions handed down from the past.

A NEW METHOD OF TREATING EMPYEMA OF THE ANTRUM.

By VAL. MACDONALD, L.R.C.S.Ed., D.D.S.Univ.Pa., Melbourne, Australia.

THE result of an apparently successful new method of treatment does not render it possible to claim assured success by that method with a record of only one case. Yet in that one case the results so rapidly bore out the hopeful anticipation from a certain line of treatment that I feel some justification in reporting it, if only to advocate its further trial.

HISTORY OF CASE.

On September 23d, the patient came to me complaining of pain and tenderness in the region of the upper right first molar. On examination I found the tooth very tender to the touch, and showing all the signs of a dead or dying pulp, with the inflammation extending to the pericemental tissues, as is usual in these cases. Opening of the tooth from the occlusal surface into the pulp chamber gave immediate relief. A very loose dressing of tricresol-formalin was left in the opening made, to control the septic condition and yet allow the escape of gas, etc.

The next day the pain had gone, but tenderness on biting remained and there were also tenderness and swelling in the apical region. A 1 per cent. alcoholic solution of formalin was vaporized through the pulp as well as possible before removing it, in order to lessen any risk of forcing the septic matter through the apices of the roots, and the tooth was then carefully sterilized and loosely dressed again.

On September 25th there was still much swelling and tenderness in the apical region, and apparently no drainage through the tooth. The patient was questioned as to signs of antral trouble, the pain being suspicious, but there was no discharge.

On September 26th the pain extended all over the right side of the face, and the patient thought there was a slight discharge, but she was not certain, and I requested her to keep for me for examination her handkerchief used on the next morning.

On September 27th I saw the patient at home. She had fainted that morning when dressing, and in falling heavily had bruised her chin, malar bone, and temple—all on the right side. I found her somewhat weak and in bed. There was pain and tenderness in the malar region, and especially over the infraorbital foramen, but this was difficult to differentiate from the pain caused by the injury received. There were signs of a slight discharge on the handkerchief that had been used first that morning, but none after that. I advised extraction, in the hope of thus aborting antral trouble, and on the same evening, under a general anesthetic given by Dr. Lionel Hood, I extracted. I found the roots to be very short, but the anterior buccal one entered the antrum, and I took advantage of that fact to irrigate with a normal saline solution.

On September 28th I saw the patient at her home, and irrigated with normal saline solution again. I also advised a normal saline nasal douche for the next few days.

On October 1st I saw the patient in my surgery. The temperature had risen slightly each evening, but was subnormal now. The socket was closing well, and there was no discharge from it, but some nasal discharge persisted, and there was some slight pain referred to the right eye. On transilluminating no shadow was observed. Dr. Stawell examined the patient for her general condition on Sunday, September 29th, and prescribed a tonic and rest.

On October 2d a slight shadow was perceived. The discharge had slightly increased, and the patient noticed an offensive odor.

On October 3d the pain was less marked, but the offensive odor was still complained of. The shadow was slight. The discharge was examined, and pronounced to be full of pus.

On October 4th there was orbital pain, the discharge had increased, and the shadow was distinctly more marked. At this point I will interrupt the history, in order to explain briefly the rationale of treatment followed to date, and the position arrived at.

TREATMENT.

Although there was pericemental trouble in the beginning, and some slight swelling and soreness over the apex, this was not great, and in the majority of cases it would have cleared up upon the mere opening of the tooth and removal of the dead pulp. The reason why it apparently did not clear up was afterward found to be in the perforation of the antrum by the anterior buccal root, although it was very short. When all efforts at immediate relief failed, I still hoped that careful treatment would eventually lull the inflammatory trouble, and kept an eye open for antral involvement. When this latter was apparent, its effect was sudden and severe, as evidenced by the sudden appearance of pus in the nasal discharge and the probably high temperature which caused the patient to feel weak and faint. When I saw her a few hours after that fainting spell, she was more or less collapsed, and although I then strongly advised the sacrifice of the tooth, I decided to wait until evening, so that, after resting in bed throughout the day, the patient would be in a better condition to tolerate the shock of the anesthetic and the operation. I advised sacrificing the tooth because in three other recent cases I have aborted antral trouble by this early removal of the cause, and I hold that no tooth is worth saving if its loss is likely to avoid the usual necessary surgical treatment that must otherwise be instituted. I explained to the patient and her parents that I did not intend to attempt to drain the antrum through the socket, for it was useless, and tubes or plugs were an abomination and unscientific.

I simply would attempt to abort trouble by an early removal of the cause, and if I should fail, I told them, surgical interference must follow. I extracted, and irrigated with normal saline solution, and, except using normal saline solution as a nasal douche for a few days, instituted no treatment, but waited, hoping for nature to assert itself. On October 4th, viz, six days after the extraction, there was an increased discharge from the right nostril and a distinctly marked shadow on transilluminating, and I abandoned hope of treatment by other than surgical means. I suggested then that surgical interference must be resorted to, but advised first seeing Dr. Stawell.

EMPLOYMENT OF ELECTRIC CURRENT AND NORMAL SALINE SOLUTION.

I then suggested my plan of treatment to Dr. Stawell, who was at once favorably impressed. On the following morning, October 5th, the patient presented with all symptoms more marked, and with additional pain in the region of the frontal sinus. I again opened the socket of the anterior buccal root of the extracted first molar, and carefully enlarged it with an alveolar bur, sufficiently to admit a fine rubber tube. This tube was connected with a syringe and also protected a small bundle of fine platinum wire, which was connected to the negative pole of a battery. The positive electrode, immersed in a 1 per cent. salol solution, was held in position under the chin—as the most convenient place of application—by a special head-gear used by Mr. R. Morse Withycomb in his pyorrheal treatment. The current used was a mild faradic, with the assistance of one dry cell of a galvanic battery; then, with the current turned on, I continually flooded the antrum with normal saline solution from a syringe, and of course wherever this fluid was carried, it acted as an electrode for the current, which was so in turn carried to all parts of the antrum. This treatment I kept up for three-quarters of an hour, and then left the socket entry to close without plug or drainage.

On October 6th, the patient reported by telephone that she was notably free from pain, and feeling better.

On October 9th I repeated the treatment, and then freshened the edges of the wound, which looked very healthy and was granulating well.

On October 11th and 14th I used faradic stimulation about the socket without forcing a passage.

On October 17th transillumination showed no shadow. By request the patient brought the first handkerchief used on waking, so that I might have the discharge examined.

On October 18th Dr. Zwar reported the discharge to be a normal nasal passage.

On November 19th the patient was feeling quite well. The socket was quite closed and filled up, and transillumination gave no sign of a shadow.

When last seen on December 1st, the case was perfectly satisfactory, and the result most gratifying.

CONCLUSIONS.

Frequently, incipient antral trouble may be aborted by an early removal of the cause when it is of dental origin, or a simple saline irrigation may suffice, but I have never seen such an advanced case in which the patient escaped without a radical operation or without a so-called drainage tube attached to a plate, which method is now recognized as being worthy of nothing but unreserved condemnation. I certainly believe that the treatment adopted spared the patient the usual surgical interference.

In explanation of the treatment adopted and the result obtained, I should emphasize that very thorough irrigation must not be forgotten; but it is chiefly to the stimulation of the faradic current that I attribute the result. Dr. Lewis Jones, in his excellent work on "Medical Electricity," says—"A large part of the benefits derived from electrical application can be ranged under the heading of stimulation." D'Arsonval has shown that induction-coil currents, even when so gentle as to cause no muscular contraction, can nevertheless cause modification in the nutritive exchanges of the body, with increased production of heat. Lewis Jones also says—"As well as nutritive exchanges leading to a growth or renewal of the tissues, equally important is the stimulation given to processes of elimination of waste products or toxic substances from the system."

I used the galvanic current in conjunction with the faradic, in the hope that even a mild chlorin ionization would assist the stimulating effects of the faradic current. Dr. De Watteville and others strongly believe that the effects of the interrupted current are enhanced by a simultaneous galvanization. I have been using zinc ionization for some time in the treatment of pyorrheal and other purulent conditions about the mouth, and also the faradic current in the mouth flooded with normal saline solution, as suggested by Mr. Withycomb, and it was the gratifying results attained that suggested the treatment of the present case.

May these notes induce others further to test this form of treatment, and to record their results.

CONSERVATISM IN ORAL SURGERY.

By E. H. CARLETON, M.D., Hanover, N. H.

(Read before the Northeastern Dental Association, at its annual meeting, Crawford Notch, N. H., October 1, 1912.)

THE close relationship between the dentist and the physician is becoming more and more recognized the farther we advance in the study of these professions, or I might better say, in the study of these branches of the same profession, for we can no longer consider dentistry as anything but a specialty of medicine. As we cannot isolate any one region from the rest of the organism or separate its functions and diseases, so neither can the treatment be a separate matter. A fuller appreciation of their common interests should bring the family physician and family dentist together. In recent years we have heard much about the prevention of disease. One of the most efficient factors in this prevention is the dentist; his influence in race improvement ranks with the highest. The study of eugenics and eusthenics—its sister science—is interesting men of every profession, but probably no profession offers a larger opportunity for the betterment of the human race than dentistry.

CONSERVATISM URGED IN ORAL SURGERY.

In the short time allotted me today it is only possible to touch upon a few of the conditions that confront us in the broad field of oral surgery. Both from the standpoint of the physician and of the dentist, mouth surgery is a development of recent years. On this account, as in most methods that have not been long established, we find many advocates of very radical procedures. Fortunately for many of our victims, a decided reaction is now taking place, and leading operators everywhere are advising more conservative methods in this field of surgery. It is true that in our special branches of surgery, as in general surgery, we are prone to applaud the skill of the operator, overlooking the fact that knowledge and judgment might have made the skilful procedure unnecessary.

HASTE IN TONSILLECTOMY CONTRA-INDICATED.

Probably no field of surgery offers more offenders against this recommendation of radical measures than laryngology. The wholesale measures advised by some laryngologists in tonsil surgery can hardly be equaled, unless it be some of our appendix friends. Today the rage for the complete excision of tonsils has become an obsession, which has infected not only the general profession but also the laity. We find parents bringing their children for tonsillectomies, expecting relief from all manner of complaints.

Yet wrong inferences should not be drawn from such statements as these; it is a self-evident truth that there are a host of conditions that call for more or less complete destruction of the tonsils. Conservatism and common sense should be our guide in the selection of cases for operation. Wright of Boston reports an interesting series of 150 cases in which operation on the tonsils was deferred until after the eruption of the molars, not only the first but also the second, and, when dentition had been completely accomplished, the enlarged cervical lymphatic glands disappeared, together with the swelling of the tonsils. Such observations as these teach us the practical lesson that if in infancy and childhood we pay more attention to the neglected nasal cavities and to the hygiene of the mouth and teeth, we will have less tonsillar disease and fewer operations.

Most dentists see more abnormal throats than physicians do; their knowledge should be such that the proper advice can be given with benefit to their clients. We should always bear in mind the few following ideas, which are almost universally accepted according to our present knowledge: That nearly all children at some time of life have more or less enlarged tonsils, that many of these are harmless if not actually physiological, that their removal is only advisable when they interfere with respiration, deglutition, or speech; that in the present state of our knowledge the functions of the tonsils are unknown. Until these functions are known, the final word on their removal cannot be spoken. Therefore, considering the knowledge or lack of knowledge we now have in regard to these structures, we should approach the subject of their complete extirpation with very great conservatism, especially in the throats of very young children.

EMPYEMA OF THE MAXILLARY ANTRUM AND DIAGNOSIS.

In this same state of mind should we approach the other diseases of the mouth requiring surgical interference. Let us take one more example, viz, the management of acute and chronic maxillary empyema. It is a matter of daily observation that, when the exciting cause of a disease is removed, the disease itself frequently disappears. If the normal functions of the part are not too much interfered with, nature effects a cure. This is true of the diseases of the maxillary antrum as well as of disease conditions in other parts of the body. Diseases of the maxillary antrum are almost always secondary to diseases of associated structures, either the nose or the dental organs. Formerly it was considered that 80 per cent. of such diseases were of dental, and 20 per cent. of nasal origin. Many investigators, however, contend that diseased roots are not frequent etiologic factors, as by far the larger number of cases of antral disease are secondary to pathologic conditions in the nose. The experience of the physician in regard to the frequency of disease of the accessory sinuses differs very decidedly from the pathologic findings at autopsy. At autopsy, disease conditions are found much more frequently than were suspected during life. One reason for this is that many suppurative processes of the sinuses cause so little suffering that the patient does not seek the advice of a physician, also in many cases the diagnosis presents many difficulties. In the past few years, aids to the diagnosis of these affections have increased very much, transillumination and the X ray being of great service in many obscure cases. Still more recently the presence of pus has been determined by the suction method.

MAXILLARY EMPYEMA OF DENTAL ORIGIN.

Infection from the teeth usually takes place in these cases in one of the following ways: Caries of extreme degree, extending into the root; apical abscess of a root of a tooth; perforation of the floor of the sinus, with penetration of pus into the antrum, lifting but not perforating the mucosa; perforation of the mucosa. We usually do not find granulations in these dental cases.

POLICY OF TREATMENT IN ANTRUM CASES.

The treatment of acute cases is best described as a policy of conservative non-interference. It is as true of acute antral disease as it is of acute diseases of any of the accessory sinuses, that surgical interference is almost always contra-indicated.

Proper treatment of the nasal conditions will, in the majority of cases, be all that is necessary. The washing out of the antrum through its natural opening in acute cases is too difficult of accomplishment to give much result.

In the treatment of chronic maxillary empyema, it is generally conceded that no methods of treatment except the operative ones need be considered. Opinions differ very widely as to the method and extent to which we shall go in the treatment of such cases. In the European clinics we find a much greater tendency toward the more radical procedures. Consequently, European literature is filled with descriptions, more or less elaborate, of ways and methods of curing maxillary empyema. In doing work of this kind, there is one point that should be kept constantly in mind, and that is, what post-operative discomforts are likely to ensue. We occasionally see cases in which these discomforts seem to the patient greater than the discomforts of the disease itself, and such a condition very seldom increases the gratitude of our patients toward us. In many of the large clinics, considering the class of patients mostly treated, this may seem of minor importance, but certainly to many of us, who have little to do with such clinics, it is a real issue.

METHODS OF ANTRUM OPERATIONS.

After it has been determined that the antrum should be opened, the four best-known routes by which such an opening is made are through the alveolar process, the canine fossa, the hard palate, and the naso-antral wall. In those cases in which the exciting cause of the antral trouble is the penetration of a diseased tooth through the floor of the antrum, the extraction of the tooth and the free opening of the antrum through the tooth socket, with proper irrigation and medication, will generally cure the disease if it has not existed too long. In all such cases, if the disease does not yield readily, other methods should be employed.

It is the contention of most operators in this country that disease of the antrum from this source is the only condition that justifies us in making either a temporary or a permanent opening into the mouth in incipient cases. The opening through the roof of the mouth is only advisable in certain cases for the removal of growths so situated as to make this route the most direct method of reaching them. The route through the canine fossa, the so-called Küster or Danker operation, consists in the removal of enough of the anterior wall of the antrum to permit of a free exploration of the cavity.

Caldwell of New York has described a combination of the external and internal routes, by which an opening is made through the anterior wall sufficiently large for inspection, continuing the opening through the naso-antral wall into the nose; through this latter opening, subsequent treatment is carried out and the external opening permanently closed.

There are a great many methods employed by different surgeons in opening the antrum by the naso-antral route. The simplest method is by penetrating the wall with a trocar and cannula, which instrument can be used both as a means of diagnosis and as a medium for washing out the cavity, which is often sufficient in recent inflammations to effect a cure. In cases requiring more elaborate treatment, success seems to depend a good deal upon the size and position of the opening made. Innumerable instruments have been devised for this work, but it seems best that each surgeon should choose what seems most practical to him and insures him results.

DR. J. O. ROE'S OPERATION FOR CHRONIC CASES.

Dr. J. O. Roe's method seems to offer as much hope of permanent relief as any in these chronic cases requiring more or less radical treatment. He first removes the lower anterior portion of the inferior turbinate, if this body is large enough to interfere with the subsequent steps of the operation; then an incision is made through the periosteum to the bone from behind forward, covering the entire length of the antrum and close to the attachment of the turbinate. At right angles to this incision, two more incisions are carried from either end to the floor of the nose. This flap is then raised from the bone and turned into the center of the nostril out of the way of injury. Puncture is then made anteriorly into the antrum, and the wall is nipped out with forceps. Care should be taken that there be no projection of bone between the floor of the nose and the floor of the antrum. The cavity can then be carefully explored and irrigated. The flap that has been raised is then turned down over the stump of the wall, and held by packing the entire antrum and nose. Dr. Roe claims that this conversion of the antrum into a portion of the nasal cavity is never followed by any ill effects or discomfort. This method certainly has the advantage in the ease with which the cavity can be medicated. Perfect drainage is maintained, and the danger of a recurrence of the empyema is prevented, no matter what the infection be.

These cases tax our skill and knowledge to the utmost. An intelligent survey of all conditions having any relation to these affections will reduce the number of patients who either wish that someone else had done the operation, or that one never had been done.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

PULP CAPPING *VERSUS* DEVITALIZATION.

By L. J. BROWN, D.D.S., Westfield, N. Y.

IN introducing this subject, the first and most important factor to be considered is, in the writer's opinion, the histology and anatomy of the pulp.

HISTOLOGY AND ANATOMY OF THE DENTAL PULP.

We know that the dental pulp is composed of embryonal connective tissue, odontoblastic cells, bloodvessels, and nerves. The odontoblasts, forming a continuous layer over the pulp surface, are everywhere in contact with the dentin by the protoplasmic processes projecting into the dentinal tubules. The odontoblasts also have processes which extend into the pulp tissue, while their lateral processes unite with each other.

The vascularity of the pulp is greater in youth than in old age. The bloodvessels communicate with the general circulation through the small apical foramen or foramina of the tooth. One or more arteries enter, divide into capillaries, and form a plexus around the peripheral portion of the pulp. Although the arteries do not anastomose to any extent, they are generously distributed throughout the pulp tissue.

The veins form a similar plexus, and a central vein, corresponding to the artery, conveys the blood out through the apical foramen. It is claimed by some that these veins have no valves and are non-collapsible. The arteries are without almost any external fibrous and muscular coats, and the veins have only a single layer of endothelial cells to form their walls; the pulp has no lymphatics.

The nerves of the pulp are transmitted through the apical foramen with the bloodvessels. Several bundles of the medullated fibers enter and break up into a plexus of nerves, which are widely distributed throughout the pulp. Those lying just beneath the layer of Weil lose their medullary coat or sheath, and are lost between the odontoblasts.

CONTRA-INDICATIONS TO PULP CAPPING.

So much for the histology of the pulp, which will substantiate the reasons why exposed pulps should not be capped.

(1) *Thermal changes.* There is great possibility of death of the pulp due to thermal changes, especially when gold or amalgam is used in filling a cavity. The action of heat and cold on the very delicate and unprotected nerve fibers causes an irritation from which hyperemia results, and the sensory and perhaps vaso-motor nerve fibers become stimulated, irritated, and then paralyzed. The bloodvessels retain their tonus up to a certain point, but suffer vaso-motor irritation, followed by paralysis, leading to their dilatation and to throbbing pain which is difficult to relieve, and the pulp dies or has to be removed in the course of a short time.

(2) *Death of pulp due to infection.* Death of the pulp may ensue from infection beneath the capping material. Pathologically there is no abrupt line of demarcation between diseases of the dentin and those of the pulp, as the dentinal tubules contain the fibrillar prolongations of the odontoblasts of the pulp. Affections of the fibrils, therefore, cause a pulp reaction, which may lead to a destructive activity by the hyperemia or inflammation set up. A most prolific source of trouble is furnished by dental caries, or the invasion of pathogenic bacteria and the absorption of ptomains. When the pulp is capped, some of the diseased and softened dentin is usually allowed to remain, because its removal in entirety would cause too great an exposure. If any softened dentin is left, it must be thoroughly sterilized, and all micro-organisms destroyed, else caries will advance as before. Sterilization of such dentin is an uncertain and difficult task, for it is almost impossible to find a sterilizing agent which is non-irritating and mild enough in its action to be used in such close proximity to the pulp without setting up an irritation followed by hyperemia. Burchard cites experimental cases upon microscopically sound-looking dentin in which the bacillus gangrenæ pulpæ has been found vital after concentrated phenol and other antiseptics had been sealed in the cavity for months.

We know, too, that infection may travel via the tubules, and that septic inflammation has resulted even before the pulp was quite exposed. The reason for this is that the dental pulp has no chain of lymphatics to remove the products of inflammation, and their removal is as impossible as that of any effusion in the brain. The slightest possible irritation, therefore, will produce a hyperemia or determination of blood in the irritated pulp tissue, and an engorgement of its capillaries; and owing to the absence of the usual venous and arterial coats, the blood-channels at once yield to the pressure. Neither is there the normal vaso-motor system of nerves to control the resilience of the vascular system, and the escape of the elements into the pulp tissue is materially modified. The pulp, moreover, being incased by bony walls, and its only entrance and exit being the small apical foramen, the complications which arise from congestion are enhanced by added pressure against the walls, and a tendency to choke or shut off the entrance of arterial nutriment and the exit of venous impurities, which will soon lead to disease and death of the organ.

(3) *Secondary dentin; calcific deposits; pulp nodules.* There is danger of an over-production of secondary dentin, calcific deposits, or pulp nodules. These result from slight but continued irritation of the pulpal organ, deranged neural currents, and some perversion of nutrition which induces a formation of dentin in abnormal quantities, owing to the undue activity of the odontoblastic cells, and excessive irritation. Our text-books tell us that in pulp capping this secondary dentin is depended upon to heal up the exposure, but in the majority of cases the formation of secondary dentin is not discontinued when this protective layer is completed, but its deposition continues until there is an abnormal amount, which causes very serious trouble, or the pulp may die from the atrophy and degeneration attendant upon the formation of too much secondary dentin. Neuralgia has been caused by this degenerate condition of the pulp, and has been followed by pericemental irritation. In many cases, where the cavity is well up on the tooth or near the cervical margin, the deposit extends into the root-canal, totally obliterating it, producing death of the pulp, and rendering the opening and filling of the root-canal afterward a very difficult operation.

(4) *Uncertainty of success of pulp capping.* The time required for assurance of the success or failure of pulp capping is unduly long. Some practitioners, when asked if they ever cap a pulp, reply, "Yes, sometimes when I make an accidental exposure, and am in a hurry." But do they gain anything by this method? In nine cases out of ten the gain is only temporary, for the operation may not have been successful, and it is only a question of a few days or weeks before the patient returns ready to heap vengeance on the operator, or has become disgusted and has consulted some other dentist. If one ever does cap a pulp, he should never insert a permanent filling at the same sitting, but should resort to a temporary filling, and allow some time to elapse awaiting results.

(5) *Consideration of patient's age and health.* The age and health of the patient are important factors in the success of pulp capping. As has been stated before, the pulp is much more vascular in youth than in old age, and for this reason it is inadvisable to attempt the capping of pulps in the teeth of elderly people. The vitality of the pulp in such persons is so low that the shock of exposure is fatal to the recuperative powers, and trouble ensues. Great attention should be paid to the patient's health and oral conditions. If there is congestion or any evidence of degeneration of the structural components of the pulpal organ itself, it would be futile to apply capping, as would also be any attempt permanently to save a pulp in the mouth of any patient suffering from some systemic derangement interfering with the general circulation, thus lessening vital resistance; for in such cases the pulp would fail to receive from the blood supply the elements necessary for the restoration of its functional activity.

PRECAUTIONS IN THE DEVITALIZATION AND EXTIRPATION OF THE PULP.

Now the question arises, How can we avoid many if not all of the complications and disagreeable features enumerated which so often occur in connection with pulp capping? The answer is: Devitalize, remove the pulp, and fill the root-canals. By this I do not wish to convey the idea that it is advisable to destroy ruthlessly all pulps, for this would be most injudicious. In fact it is the duty of every dentist to save the pulps of teeth, if it can be done with any reasonable prospect of success.

If, in the devitalization and removal of pulps, we observe the three following factors, we are fairly sure of success, and of a just reward for the operation: (1) Establish and maintain asepsis in performing the operation; (2) preserve the color of the tooth, and (3) thoroughly fill the root-canals.

It is needless to go into details concerning the processes of devitalization, for we all know that, by the present methods and new combinations of drugs, this operation has been made almost painless and extremely simple.

PRESERVATION OF THE COLOR OF DEVITALIZED TEETH.

A few words, however, should be said in regard to the preservation of the color of the tooth. The cause for the darkening of a great many teeth after the pulp has been removed can be traced directly to failure to remove blood from the dentin of the crown of the tooth. The prevalent practice of wiping out the bloody canal with a solution of hydrogen dioxid cannot be too strongly condemned. Hydrogen dioxid simply decomposes the blood within the tooth and oxidizes the iron of the hemoglobin, and the gases evolved force this pigment into the tubuli, where, if left—*and it is difficult to remove*—it will cause the tooth to darken in almost every instance.

For the removal of blood from a root-canal, alcohol followed by sterile water applied by a syringe is excellent, or a solution of peppermint water to which two minims of phenol per ounce and a little sodium chlorid have been added will accomplish the desired result.

It is also the practice of many dentists, after removing an arsenical dressing, to flood the cavity with a solution of dialyzed iron, after which the pulp chamber is opened into, thereby usually producing a hemorrhage; then, without removing the blood or the dialyzed iron, tannic acid is applied to toughen the tissue before removal. This application of tannic acid is totally unnecessary, and owing to the fact that tannic acid and iron are incompatible and form iron tannate, which is a form of ink, such practice is another prolific source of discoloration. We should therefore avoid forming, within the tooth structure, a pigment which we know will discolor the tooth. The color of a tooth does not depend upon the life and vitality of the pulp, but upon the array of colors in the dentin, which are reflected through the nearly colorless and transparent enamel. Therefore, unless these colors are changed by our failure to remove blood, or by the use of staining remedial agents in the treatment subsequent to pulp removal, the tooth will not discolor.

CONCLUSIONS.

In conclusion, the arguments advanced may be summarized in three indisputable statements:

(1) The consensus of opinion is that, ordinarily, all exposed pulps should be removed.

(2) There is no certainty that pulps exposed by caries and otherwise will remain vital under capping material.

(3) The inherently experimental character of pulp capping argues strongly in favor of the but little more laborious root-canal treatment.

BAKERS' BREAD AS A FACTOR IN INDUCING DENTAL CARIES.

By ALBERT B. KING, D.D.S., Baltimore, Md.

(Read before the Maryland State Dental Association, at its annual meeting in Baltimore, June 14, 1912.)

I WISH to present a subject that has interested me for some time, and of which I have recorded a number of cases that have come under my supervision. I refer to bakers' bread as a factor in inducing dental caries.

I do not propose to assume an antagonistic spirit to any of the theories that have been advanced in regard to dental caries, but wish to suggest a line of thought on foodstuffs by which, in time, we may be able to determine the best possible diet—especially for the young—that will be conducive to the formation of a perfect normal denture.

I write as a result of some observation, some thought, and some experience, which have convinced me that the dental as well as the medical profession is passing through an era of prevention. While we are impressing upon our patients the importance of oral prophylaxis and are advocating oral hygiene, and, where caries exists, extension of cavity margins to immune areas for the prevention of further ravages, I think it would be well to continue a step farther, and investigate foods that are generally used, and ascertain their susceptibility to lactic acid fermentation.

There is little doubt that the process of caries is affected by the character of our food. This has been fully demonstrated by the comparison of the teeth of different races, those living close to nature being practically immune, while those living on a mixed diet are very susceptible. It has been shown very clearly by Miller that caries of the teeth is the result of decalcification of the tooth substances by lactic acid, and that the carbohydrates, starches, and sugars are the only foods that are capable of lactic acid fermentation. Kirk attributes the prevalence of caries in children to the excess of carbohydrates in their food, which consists mainly of starches and sugars.

This subject was first brought to my attention several years ago. A patient, a man about thirty years of age, presented himself for examination. I found that he had a practically perfect denture, large and well-formed teeth, with perfect occlusion, and a color to denote hard, dense tooth structure. I found two small fissure cavities in the upper first molars, which I prepared and filled. He told me that he had just opened a bakery in the neighborhood.

A year later he came to me again, and upon examining his mouth I could hardly believe that he was the same patient, so great had been the ravages of caries. The central and lateral incisors presented large labial cavities, while the bicuspids and molars had equally as large approximal cavities, and what a year before appeared to be a perfect set of teeth was now a wreck. I questioned him about the care he had given to his teeth since his last visit, and he assured me he had brushed them faithfully night and morning, which statement was corroborated by the almost total absence of calculus.

After questioning him, my suspicions fell upon the bread he was eating; so I determined to investigate along this line and keep a record of the kind of bread used by different patients.

The result has been that of one hundred and thirty-two cases recorded, eighty-seven used bakers' bread exclusively, thirty-one used bakers' bread alternately with home-made bread, and fourteen home-made bread exclusively. The majority of the cases observed were children between eight and fourteen years of age, although some cases ranged in age from twenty to thirty-five years.

After having had most of the cases under my supervision at regular intervals for three or more years, I found caries quite prevalent among the eighty-seven individuals who ate bakers' bread exclusively. With those who alternated with home-made bread, caries was not so prevalent; while for the fourteen who used home-made bread altogether, I have filled but six cavities in over three years. The difference has been so marked that I am convinced that the commercial bread of cities is deficient in bone-producing elements, and is extremely conducive to lactic acid fermentation.

In the DENTAL COSMOS for May 1912 appears an article on this subject by Dr. J. Sim Wallace of England. He says, "No farinaceous foodstuff in general use is less harmful to the teeth than bread when eaten with butter," and that "the different varieties of bread, *i.e.* white, standard, and stone-milled, make no appreciable difference in inducing dental caries."

From my own observations I cannot agree with Dr. Wallace in regard to there being no difference between different forms of bread in inducing dental caries, unless the breads he speaks of were made in the same way and under similar conditions.

I find that when bakers' bread is thoroughly masticated and moistened with the saliva, the bolus formed is pasty and sticky, and therefore adheres more readily to the teeth than the bolus formed from home-made bread, and that feature alone, in my mind, would be more conducive to lactic acid fermentation. Added to this are chemical constituents used for raising or leavening the bread, which also have a deleterious effect on tooth structure.

I therefore believe that while we are advising oral prophylaxis and bringing oral hygiene before the attention of the public, we should also advocate proper, wholesome, pure food, especially for our patients of tender years.

AGAIN THAT DENTAL SOCIETY PAPER.

By FRANK W. SAGE, D.D.S., Cincinnati, Ohio.

READERS of scientific papers in dental societies often unwittingly place an insurmountable obstacle in the way of the stenographer's making an intelligible report for the journals. I refer now expressly to the paper accompanied by a chart.

It often happens that the writer of a paper, having in mind to refer by means of a pointer to his chart as he reads, *fails to letter or number* the chart, forgetting that when the said paper, accompanied by the chart, appears in the dental journal, there will be no hand present directing the reader with a pointer indicating the lecturer's meaning. Let us illustrate by actual reproduction of words used by one such essayist:

"At this point you will see [pointing] that the line curves upward toward that point [pointing], thence dropping down to this place [pointing], and finally being lost there [pointing]."

Now, in all this not a point has been indicated in such a way that reporter, editor, or reader of the dental journal can make out its location. The reporter, when he comes to transcribe his notes, is aware that they must be unintelligible; the editor so finds them, and must refer them to the essayist, who must then supply what he in the first place omitted, to wit, letters or figures to accompany the reported words.

Now for the simple remedy: Number or letter your charts, and when pointing, fail not to *mention the number or letter* you are pointing to. This, of course, is as indispensable to an intelligent understanding of the reporter's verbatim rendering of the speaker's words as the numbering or lettering itself—in order that the reporter may hear, for he cannot always raise his eyes to see, and besides, seeing would not help him. If the reader of the paper omits to do this, then the reporter's transcript, as a moment's reflection will show, will fail to convey an intelligible idea to the reader of the dental journal. And do not use two sets, large and small, of either letters or figures. The reporter is utterly unable to indicate to the reader a large *A* as contradistinguished from a small *a*.

Our journals employ expert stenographers at great expense, under the impression that a verbatim report must be satisfactory, whereas it may wholly fail of the real requirements of the editor. This *en passant*, by way of adding emphasis to the importance of essayists' helping reporters—and editors—by suitably preparing their papers.

A word in general as to aiding the reporter: Do not leave your sentences uncompleted. Many otherwise excellent speakers break off in the middle of a sentence, and begin another. This leaves to the reporter a choice of omitting your speech altogether, or else supplying what you omitted. Some who have perhaps noticed that their remarks were omitted in the published discussions may now understand how it probably happened. The reporter cannot supply what you omitted to say, having only vague surmisings to depend on. The wonder is that professional reporters do as well as they do.

THE DENTAL DEPARTMENT OF SING SING PRISON.

By CHAS. W. FARR, M.D.,
MEDICAL DEPARTMENT, SING SING PRISON.

BRIEF HISTORY.

THE dental department of Sing Sing prison was organized about five years ago, at which time an old Yale chair was purchased, together with sufficient instruments to carry on the work; this consisted of the extracting and filling of teeth, and when absolutely necessary the making of dentures. Previous to that time all extractions were made by the prison physician, and any other work was done by a dentist from the village.

The inmates paid for their work at rates such as they would have had to pay in the outer world, the operator naturally charging for the material and his time, which, in many instances, was more than most of the convicts could afford.

Just subsequent to the appointment of Jesse D. Frost as agent and warden of the prison, a prisoner was received who had been a practicing dentist previous to his incarceration. Warden Frost, knowing the need, saw the advantage of having an inmate dentist who could do the work for his fellow prisoners, the state paying for what material was necessary to carry on the work that was then being done, and he assigned this prisoner to the hospital, where he continued to do the same class of work as had formerly been done by the visiting dentist.

Later the field of work was broadened, to include crown and bridge work, and inlays, etc., were made for the patients—who, however, paid only for the actual cost of the gold and whatever other material entered into the manufacture of the specific work accomplished. This arrangement continued in force for about four years, when another dentist was received at the prison. Just about this time the new prison at Great Meadows was made ready for occupancy, and as a dentist was needed, the man who had been doing the work at Sing Sing was transferred there, and the new arrival was assigned to the Sing Sing hospital to carry on the work.

PRESENT CONDITIONS.

To understand the manner in which the dental work is conducted in Sing Sing prison at the present time, it is first necessary to know something of the arrangements for the daily hospital clinic, as the dental department is carried on in conjunction with the general hospital work. Each morning on the arrival of the various companies in their shops after breakfast, all inmates desiring medical treatment have their names and prison consecutive numbers entered in the hospital book by the company clerk, and later they are marched in squads to the hospital on the top floor of the administration building. Entering the clinic room one by one in order, they state their various complaints to the attending physician, Dr. Henry E. Mereness, Jr., who is assistant physician to Sing Sing prison and whose duty it is to take the morning sick call, and are prescribed for, receiving immediately whatever treatment is indicated. Among these men are those who desire to have dental work done, and on so stating to the physician they are referred to the dentist. A superficial examination is made at once by him, and the patient's name, number, and shop location recorded. An appointment is made and the patient returns to his shop with the squad. The sick call being over, the dentist makes a list of appointments for that day, and the same is sent to the office of the principal keeper, where it is placed on file. After the midday meal, as the men file out of the mess-hall, they are called from the ranks and marched to the hospital. Upon arrival there they are summoned in order to the dental operating room, and the work begun, or continued if it has been started at some previous time.

The present warden of the prison, Hon. John S. Kennedy, is very much interested in this department, and has recently purchased for use therein a new dental chair of the latest pattern, and a complete new outfit of instruments, which enables the present operator to accomplish more work for the inmates and is largely conducive to the general health of the convict body. It may be stated that the discovery has been made that in excess of ninetv per cent. of the new arrivals at the prison have disease conditions of the teeth to a greater or less extent.

All simple work, such as extractions, cement fillings, amalgam fillings, etc., together with the treatment of the diseases of the mouth, are provided by the state free of charge to the prisoner. When, however, the mouth is shown to be in such a condition as to demand artificial teeth in the form of plates or bridges, the inmate pays for the same from the money he may have on deposit with the clerk. In the event that he has no such account, he is permitted to use the amount necessary from the "earnings account," a sum of money with which the state remunerates him for his labor, and which is only available for certain purposes according to law. A form of contract is signed by the inmate in such cases, and is witnessed by the officer attending the hospital. This contract is filed with the clerk of the prison, who puts a stop check against the prisoner's account, so that the amount represented thereby cannot be expended in the interim between the signing of the contract and the arrival of the material and the finishing of the work. When the work is completed, the prisoner signs a voucher to the effect that he has received value for the amount, and the transaction is thereby closed.

When a case presents itself, as sometimes happens, in which the patient has not sufficient funds on deposit or to his earnings account to cover the cost of the proposed work, and the need is absolute for a rubber denture, the attention of the prison physician is called by the dentist, who takes up the matter with the warden, explaining the need, and the necessary expenditure is made from the state funds.

The whole work is carried on under the supervision of the prison physicians, the dentist taking to them all matters which are out of the ordinary, and receiving from them instructions to proceed as he deems proper for the best interest of the patients.

The report appended is a copy of the one made to the Prison Department for the fiscal year ending September 30, 1912. An examination of the same will show the great amount of work accomplished by the department, and its variety, all branches of dentistry being practiced:

MEDICAL DEPARTMENT SING SING PRISON—DENTAL CLINIC.

Annual report of the work accomplished in the Dental Department for the fiscal year ending September 30, 1912.

Applicants for treatment during entire year	2878
Applicants treated	2854
" not treated	24
Teeth extracted	639
" devitalized	122
Fillings—amalgam	242
" cement	128
" gutta-percha	44
Inlays—gold	16
" porcelain	7
Teeth crowned with gold	69
Porcelain crowns (Logan, Davis, and Richmond)	32
Miscellaneous gold bridges put in	116
Full upper dentures	17
Partial upper dentures	23
Full lower dentures	6
Partial lower dentures	4
Applicants' teeth cleaned	180
Gingivitis treated	61
Pericementitis treated	36
Pyorrhea alveolaris cases treated	192
" " " improved	168
" " " not impr.	24
Alveolar abscesses treated	85
Full upper dentures repaired	19
Partial upper dentures repaired	11
Full lower dentures repaired	8
Partial lower dentures repaired	3
Gold bridges repaired	18

Bridges re-cemented	4
Crowns "	12

PROCEEDINGS OF SOCIETIES.

NORTHEASTERN DENTAL ASSOCIATION.

Eighteenth Annual Convention, held at Crawford Notch, N. H., October 1, 2, and 3, 1912.

TUESDAY—*Afternoon Session.*

THE eighteenth annual convention of the Northeastern Dental Association was held at the Crawford House, Crawford Notch, N. H., October 1, 2, and 3, 1912.

The first meeting was called to order by the president, Dr. A. J. Sawyer, Manchester, N. H., at 3.30 o'clock, Tuesday afternoon.

The first order of business was the reading of the minutes of the last meeting.

Motion was made and carried that the reading of the minutes be dispensed with, in view of the fact that they had been printed in full in the Transactions and were in the hands of each member of the association.

The next order of business was the report of the Committee on Necrology.

Dr. KINSMAN, secretary, reported that a memorial page had been set aside in the program on which a notice was given of each deceased member, and this practically constituted the report of the committee.

Dr. KELLEY asked if the committee had received any correspondence in regard to the death of Dr. Stockwell.

Dr. KINSMAN reported that he had received a letter from Dr. A. J. Flanagan in regard to the matter, stating that he thought the society should take some special action on the death of Dr. Stockwell. Dr. Kinsman further explained that at the last meeting, on resolution, the association bowed in silence for a few moments in respect to the memory of Dr. Stockwell, and that also his name had appeared on the memorial page.

Dr. RIDER moved that the Committee on Necrology of the association formulate a suitable resolution of sympathy, to be sent to the members of the family of any member of the society who dies. The motion was carried, and the report of the Committee on Necrology was on motion accepted.

Dr. KELLEY moved that a committee of three be appointed to bring in a list of nominations for officers for the ensuing year. (Motion carried.)

Motion was then made and carried that the association adjourn until the evening session.

Evening Session.

The meeting was called to order at 8.30 o'clock, Tuesday evening, October 1st, by the president, Dr. Sawyer.

Dr. Murlless having been called to the chair, the president, Dr. A. J. SAWYER, read his annual address.

Dr. Sawyer resumed the chair, and announced as the next order of business for the evening session the reading of a paper by Dr. ARTHUR D. BLACK, Chicago, Ill., entitled "The Progress of Dental Caries in Relation to Cavity Preparation."

[This paper is printed in full at page 469 of the present issue of the COSMOS.]

Discussion.

Dr. N. A. Stanley, New Bedford, Mass. New England has been rather loath to accept Dr. Black's method of cavity preparation. We all know that success in filling teeth is dependent upon the proper preparation of cavities, which is of the same importance as the foundation under a house; if the cavity is not properly prepared, the filling will not stand. We have had a most scientific demonstration of cavity preparation, and the profession is indebted to Dr. Black's father for giving to us this truly scientific method. I want to give my testimony to the weak point to which Dr. Black calls attention, that is, the buccolingual aspect of approximal cavities in which the gingival portion is curved rather than straight, leaving a little triangle of enamel which is susceptible to recurrence of caries. It is nearly always at this precise spot that I have observed this recurrence; not in platoons, but now and then, just to remind me. I acknowledge this, and am going to adopt the method described. Of course, with the use of ordinary common sense and judgment in any given case, as Dr. Black says, we should make self-cleansing margins, which the process of mastication will keep polished and immune from caries.

Dr. W. I. Brigham, South Framingham, Mass. I have heard many papers read upon the Black preparation of cavities, and I am generally ready to discuss such papers. No paper is of much value unless the ideas contained therein are demonstrated, and I came here to give a clinic tomorrow entitled "Anti-Black Preparation," and I suppose there are other clinicians who will insert fillings by the Black method.

Dr. Black has said this evening that extension for prevention has nothing to do with the interior portion of the cavity. If a cavity is prepared according to the demands of extension for prevention, then the interior of the tooth has a great deal to do with extension for prevention. I have from the beginning opposed the Black preparation, and I was one of the first who was willing to stand up, denounce it, and demonstrate that it had but little value. After many years, many writers are denouncing the Black preparation, so that I feel encouraged in my objection to that method. Why do I object? Because it involves unnecessary cutting for the preservation of a tooth. I object to its being taught in dental schools as the ideal preparation, because the student thus prepared is not equipped to fill teeth as they are presented to us for treatment. At this point I would like to refer to that portion of Dr. Sawyer's address where he spoke about the colleges. Some society ought to take a stand in regard to what the colleges are teaching their students. The dental student today, when he is graduated, is a very poorly equipped operator. Otherwise, we should not see glittering gold crowns on teeth that should have been filled. This is not all done for mercenary reasons, but because the student has never been taught to fill these teeth properly. Very few operators would do inferior work if they knew how to do good work. It is surprising how little really esthetic dentistry is being taught in the dental schools. How much porcelain work is being taught in our schools? I remember reading not long ago a catalog of one school in which it was stated that within one year in that school thirty-three porcelain fillings had been inserted. Think of it! A whole class made thirty-three porcelain fillings. Can one expect students to graduate and do esthetic work with that preparation? Thirty-three porcelain fillings a week would have been too small a number. If we think of the different instructors we had in college, how few of them ever taught us anything! The great trouble is, as I stated in a paper which I read in Boston, that many of the students who are graduated today are tomorrow back in the colleges as instructors. In the editorial in the September Cosmos, in which Dr. Kirk speaks of educating men to become teachers, this same thought is expressed.

While these remarks do not pertain

strictly to cavity preparation, they emphasize how poorly students are being equipped today in our colleges for operative work. I claim that there are men today teaching the Black system who cannot demonstrate it, and others, as I discovered in conversation with one not long ago, who have never read Black's book.

I want to ask the essayist a few questions. Does he advocate the preparation of cavities as laid down in Black's "Operative Dentistry"?

Dr. Black. Yes, sir.

Dr. Brigham. Then, if you follow the preparation of cavities as laid down in Black's "Operative Dentistry" and as demonstrated to the student, the preparation of the cavities which you have shown is tame indeed. There is no comparison, to my mind, between the illustrations in that book and what we have seen here tonight.

The essayist said that the cavity always starts at the contact point. In this, I think, he is generally correct. Once in a while we see a cavity on or near the approximal surface which did not start at the contact point. If the cavity begins at the contact point, why shall we extend the cavity awav out here [illustrating], in order to carry out the principle of extension for prevention, if caries never commences there? If in the cavity a tight and properly contoured filling is inserted, why is that tooth not as perfect as it was in the beginning, if caries never starts except at the contact point? This is a reason, then, why it is not necessary to extend a cavity to these wide extremes to preserve the tooth.

In a cavity like that [illustrating] the essayist carries the gingival margin under the free margin of the gum. If the cavity begins at the contact point and never at the free margin of the gum, why is it necessary to carry the cavity under the gum line, if caries never begins there? The essayist says that the gold must be packed in the cavity with such force that the elasticity of the dentin would be sufficient to hold the filling in place. How many of us wish to have a filling inserted in that way? If the cavity margins are perfect and smooth, it is not at all necessary to carry them out to an angle. I may appear dogmatic. I admit that I am positive, but I have the right to be so, because I am willing to demonstrate my ideas practically and have the results compared with those of any operator who wishes to follow Black. A filling can be inserted as well if the margins are curved, provided the gold is packed in very tightly. What do we see at conventions where operators are demonstrating the Black cavity preparation? At a convention in Boston not long ago, a man—one whom I am sure Dr. Black would be willing to have demonstrate his ideas anywhere—demonstrated cavity preparation and the filling of a tooth. It was a cavity, or he said it was a cavity, although I could not see any, on the mesial surface of a molar, in which he wished to demonstrate his cavity preparation. In the same mouth were several large or medium-sized cavities temporarily filled with gutta-percha. Why did he not select these cavities? Simply because the Black preparation of cavities is not applicable to all carious teeth. It is only applicable to teeth in which the advocates of the Black method can demonstrate extensive cutting. What did we see at the convention at the Weirs? One of the clinicians selected a lower bicuspid with a little imperfection in a woman of about fifty years, and he prepared a large cavity with undercuts, which it required more gold to fill than would have been necessary if the cavity had been properly prepared.

Another point in this connection. The Black followers always select bicuspids or molars to demonstrate their principle of cavity preparation on. Why? Because their preparation of a cavity in an incisor or canine would be very difficult to follow indeed, and I venture to say few of them could ever insert a perfect filling in an incisor and have it last, unless they had produced a wide separation beforehand. In bicuspids the extension of the cavity into the coronal surface greatly weakens the tooth, if the sulcus is a perfect one, and is seldom necessary. In a bicuspid Black extends the filling from the cervical wall to the coronal surface, exerting enough pressure to have the gold spread out and come in tight contact with the approximal walls. As the gold becomes hardened by malleting, it is difficult to obtain close adaptation to any of the walls, and that is the vulnerable point in many of these fillings. If that wall is perfect, with proper manipulation of the gold it is as easy to fill as any other portion of the cavity.

Dr. Stanley. The filling is just as tight there as anywhere else.

Dr. Brigham. You may think so.

Dr. Stanley. I know it.

Dr. Brigham. That is rather difficult to say. I make mistakes, and sometimes find fillings give way that I assumed I did not have tight there. Many of these may not be tight there, and that is why they have failed. But why should we cut in the longitudinal direction of the tooth when caries does not progress that way? A cavity in a tooth of that type should be filled from the approximal side, and as the gold comes down it becomes tighter and tighter.

Speaking of the retentive form of the cavity, I think too much stress is laid upon retentive form in bicuspid fillings. But little retention is required if the gold is placed properly. If we have a cavity in a bicuspid, it should be cut so that it shall be wider at the cervical than at the occusal border; then, as we insert the gold, and come down here [illustrating], in packing the gold with the mallet we are driving it in from a larger to a smaller space.

As to the illustrations shown on the board, I seldom see the gum line so high up as has been illustrated. If the cavity extends below the gum line, we must prepare it accordingly, but if it does not extend under the gum line, I should be very loath to extend it there. With a very small undercut along parallel walls [illustrating] all the retention necessary is obtained, whether there is a flat base or whether it is beveled to the extent of the outer surface.

I hope to find a patient tomorrow for a clinic, and to demonstrate to the satisfaction of almost anyone that this ruthless cutting of tooth structure is unnecessary.

Dr. G. A. Bowers, Nashua, N. H. I did not come prepared to discuss this paper, and I do not think that Dr. Black needs any indorsement. Dr. Brigham certainly has taken a very positive stand in regard to extension for prevention. I have been on the New Hampshire Dental Board for fifteen years, and in that time it has seemed to me that the real purpose of about every one of the students was to go just as quickly as he could to the pulp of a tooth in order to find a retention place to hold his gold. About two years ago we had eleven applicants, most of them from the Baltimore schools, some from Harvard, some from Tufts and other schools, and out of this number of applicants, five or six prepared and submitted to us for examination the most beautiful cavity preparations that I have ever seen, and some of the most beautiful fillings. These were the only students I ever saw that seemed to treat a tooth with any clear understanding. Most of the students we come in contact with seem afraid to use the chisel. One of the men in question took an old rocker as an operating chair, placed his patient in it, and went at the tooth as if he knew his business. The point that I am driving at is that these men had been taught the Black system of cavity preparation.

It was my pleasure some years ago to attend a meeting of the National Dental Association at Buffalo, and I met there Dr. Wedelstaedt, Dr. Conzett, Dr. Searl, and a number of other representatives of the Black Club. It was one of the greatest inspirations of my life to see the work demonstrated by these men. I think the operations of Dr. Cooke, as far as I can remember, were done about fifteen or sixteen years ago almost on the same lines as have been advocated here tonight. I might say they were composite fillings of the three "B's"—Black, Brigham, and Bowers—combined, perhaps, with horse sense.

I have nothing but the highest commendation for Dr. Black's paper, and I honestly feel that, if students were taught some system, this would tend to produce very beneficial results.

Dr. G. A. Maxfield, Holyoke, Mass. I was very much interested in this paper and in the modified views presented, which were so well illustrated by the tooth passed around by the essayist which showed his principle of cavity preparation. The cavity in that tooth evidently was originally small, and he has not made it an exceedingly large one. I believe and have always advocated the theory that the less metal we can use in filling a cavity, the better it will be for the tooth.

The reason why many colleges are teaching the Black method, I understand, is because it is the only system that has so wide an application, and it is so difficult to instruct the students in all the various methods of filling teeth. There is an old Yankee expression, which probably many of you have heard —"That man has no gumption," meaning he lacks common sense and the proper way of applying it. The majority of dentists who are practicing today and teaching the Black system are not using any gumption. I do not think that small approximal cavities in incisors, canines, and bicuspids should be made any larger than is necessary for the thorough removal of carious portions, and for giving them a retentive form and perfect edges. Fillings placed in such cavities and thoroughly polished, I think, are much the best means of restoration.

I have seen fillings inserted according to the Black method, some of which failed in five years, and then had to be reinserted with very little tooth structure left. If these cavities had been prepared and filled after the manner which I have just advocated, and had then failed after five years, there would still be a large amount of tooth structure left, and even after reinsertion the filling would not be as large as many of the practitioners of the Black method would extend a small pinhead cavity to. I believe that we should conserve tooth structure, and should not sacrifice any more than possible.

There is another instance where we should use gumption, that is, in considering the texture of the teeth and the conditions of the patient's mouth. We know that at times the teeth decay very rapidly, and again in the same mouth the teeth seem to have changed and there is very little caries. We must consider these conditions; every patient that comes to us must be treated individually. We should not try to adapt the Black system to every one, but treat each case as appears best for that individual.

In my own practice, whenever it is possible, I like to shape cavities so that I can use soft gold, filling the cavity two-thirds or more with soft gold, and finish with cohesive. I believe that in this way I can make a much better filling, which is better adapted to the walls of the cavity than if I had used cohesive gold altogether. I also save my own time and strength, and do not tax the nerves of my patient. This cannot be done in using the Black system.

There is another point to be considered, that is, the question of compatibility between the tooth structure and the material used for filling. Tin is much more compatible with tooth structure than gold, and a cavity filled with tin covered with gold makes an excellent filling and also preserves the tooth better than an all-gold filling. I would not, however, advocate this method for the anterior teeth, for tin discolors and appears dark through the thin walls of the incisors, though it does not discolor the tooth. It is favorably indicated in the bicuspids and molars. I hardly think, however, that a cavity could be filled with this combination of gold and tin if it had been prepared by the Black method.

Dr. Henry A. Kelley, Portland, Me. I am not a student of Dr. Black's book, nor of his system, except as I have seen it demonstrated at conventions by many different operators. I should say, however, that there is nothing that Dr. Black has said or shown on the board that I would not indorse. His teachings appear to be sound and scientific. It is when it comes, however, to extension for approach and extension for retention, points which Dr. Black has not touched upon, that I would probably differ with him. I have no doubt that I can indorse his theories as explained here today. The first lesson that I received from the gold inlay cavity preparation was how much better I could preserve the teeth by the inlay system than with fillings, because previously I had not cut away enough tooth surface. The inlay method necessitates a good deal more cutting of tooth substance, and I believe that is one advantage in favor of the inlay method. In a certain way, being neither old nor young, I bridge the space of time between the older and the younger operators, and of course I have been influenced by both schools. I think if Dr. Maxfield were more conversant with the teaching force at Harvard Dental School, he would not have said that it was so difficult to teach all the different methods. They have there a great number of different operators, and the different methods are taught, so that the students leave with a knowledge of many ways of filling teeth.

Dr. Black's paper has been instructive and useful; and he seems to have carried out in a scientific way what many of us have noticed in a clinical way. It occurs to me, as a believer in prophylaxis, that if these teeth always start to decay at the contact point, why is it not possible for us to keep that point clean? Also, why is it possible for us, instead of extending these surfaces to immune areas, to extend the immune area farther into the approximal space, so that there would be no necessity for a great amount of cutting of the tooth. I believe with Dr. Maxfield in the incompatibility between metal and tooth structure, and I think that proper prophylactic care of the mouth can do a great deal to make large extensions of the cavities, with the resulting large metal fillings, unnecessary.

I was pleased to see Dr. Black's drawings on the board, and realized at once that what they showed was not what I had supposed to be the Black system, nor what many so-called exponents of the Black system have taught. I had supposed that much more cutting was necessary than his drawings showed. I have no criticism to make of Dr. Black's presentation of his views. As to his opinion regarding the question of extension for approach and retention, however, I might radically differ.

I admire Dr. Brigham's courage very much, and I know that he can do all that he claims. I also know that Dr. Gerrish can show pinhead cavities that have retained fillings as many years as any inserted by the Black system; this, however, does not disprove any theory. It seems to me that Dr. Brigham's criticism pertains rather to what he thought Dr. Arthur Black might say—viz, upon his father's book and the theories propounded there—than upon Dr. Arthur Black's paper. As a conservative operator, I am much pleased with the conservatism which Dr. Black has exhibited.

Dr. Brigham. The point I wish to make is that the cavity preparation as shown here tonight is not as I understood it from Black's "Operative Dentistry." I spoke of what I saw demonstrated at one of the conventions by one of Dr. Black's disciples. This operator selected a small cavity in a molar and prepared it so that it required about five sheets of gold to fill it. While he was giving this clinic, two other clinics were going on in the room. These other clinicians had finished their work an hour and one-half before this Black advocate completed his filling. It required about three and one-half hours to insert the filling, the patient being subjected all that time to ruthless cutting and hammering, although this filling could have been completed in three-quarters of an hour, and would have preserved the tooth probably indefinitely, because the patient was no more than thirty-five years of age.

Dr. Stanley. I saw that clinic, and the reason why it took so long was because the clinician had a large audience and was lecturing during the clinic.

Dr. Brigham. The other operators were doing the same.

Dr. W. P. Cooke, Boston, Mass. I had not seen the Black cavity preparation until a few years ago, when it was my privilege to view one of the cleanest preparations of a compound cavity that I ever saw. I was brought up in dentistry under Dr. Shepard, whose great maxim was that, if the cavity was of reasonable depth, two parallel walls were sufficient to hold a filling, and that undercuts were not necessary; and that is the principle according to which I have filled teeth ever since.

Demonstrators choose certain cavities instead of badly decayed teeth, because they prefer to select a cavity that can be seen by the audience, and in which they can make a clean cavity preparation and demonstrate the principles of filling.

The principles laid down here tonight are, in my opinion, the proper ones for inserting amalgam, gold, porcelain, or gold inlays, and I do not think they can be controverted, since the more we think over them and the more closely we come in contact with the men who practice these principles, the more firmly we believe in them.

Dr. W. H. Rider, Danbury, Conn. We have always been taught to conserve tooth material, taking due care, however, to obtain firm, sound margins, in the preparation of cavities. A certain percentage—say fifty per cent. for argument's sake, though I would not admit of anything like that amount—of approximal, labial, and buccal fillings we are, in time, compelled to extend slightly or to a greater extent, and sometimes to replace. Can Dr. Black give good, adequate reasons why we should condemn the other fifty per cent. to that loss of enamel and dentin? There are tendencies in certain mouths to marked forms of cavities of decay, idiosyncrasies of the teeth, as of general temperament. Should we not study those idiosyncrasies rather than treat all teeth alike by the rigid rule of a positive system? Would Dr. Black dispute it, in general actual practice? There is a certain percentage of criminally inclined individuals. Shall we treat all of them as criminals? There are many consumptives, many insane or incompetent, others with peculiar tendencies to many forms of diseases. Shall all be isolated, confined, or treated alike the instant a symptom shows? It seems to be almost criminal to teach so indiscriminate a system in a dental college. There is one very essential point, however, that I would like to emphasize particularly. It must be remembered that Dr. Black is teaching this system to inexperienced men, that is, young students, and is sending them out with but little actual experience but with a knowledge of a certain very radical system. He says the cavities should be extended below the gum margin. This margin we know is the weakest at the junction of the cementum and enamel, and more easily fractured than any other portion of the tooth, yet he sends these boys out—for they are boys yet, not dentists—without experience, and many, not a small percentage but a large majority, without even the knowledge that the slightest blow against the enamel causes a fracture at that point, resulting in subsequent failure of the operation. This also accounts for the failure of many fillings the cavities for which have been prepared in the old way.

Dr. Cooke. I would like to ask how a fracture would occur there, if the large mass of gold was there to be condensed over the margin?

Dr. Rider. You need but a slight blow there, and you know also that it requires an expert, not a novice, to hold and properly condense even a small mass, as you term it, of gold under the most favorable conditions.

Dr. Cooke. It is simply a question of packing the gold properly.

Dr. Rider. But these boys have not had sufficient experience to do it even approximately correctly in most cases. Would you allow one of them to undertake it in your own mouth?

Dr. John F. Dowsley, Boston, Mass. I must take issue with Dr. Brigham in one particular criticism he has made. He claims that the young men who are being graduated from our colleges at the present time are poorly prepared, intimating that they are more poorly prepared now than before we knew or heard of the Black method. On the contrary, I have been examining the product of our colleges throughout this country for even a few more years than my friend Dr. Bowers. I have examined hundreds of candidates, and I and my colleagues have been impressed by the amazing improvement of the student body in regard to cavity preparation. The improvement has been simply wonderful, and it was noted not in one or two men of a class, but in nearly all of them. This is due, I believe, to the teaching of the Black system. I wish to emphasize the fact that *a system* is being taught, and that every student is being taught that system. These men not only prepare beautiful cavities, but do it in very much less time than was spent by students previous to the adoption of this particular method. This might have been the case if any other method had been taken up; but it happened to be the Black method, and we can, in our examinations, recognize the young men who have received that particular instruction by the clean-cut cavities they present.

It has also been said that it is not good to teach the young man a system. I believe, however, it is better to give him some definite system. Then, after starting to practice, he can improve on that system, and acquire better knowledge and judgment as he goes along. I think if the Black method has done nothing else, it has done a great deal for the colleges in their teaching of a definite method of cavity preparation.

Dr. Rider said also that these young men are not dentists when they are graduated. I do not agree with him. I believe that many of them are expert operators after a year or so of practice and are far in advance of those not having received a college training.

Dr. Brigham. We speak of a cavity as being nicely prepared. Do we know whether the filling which is placed in such a beautifully prepared cavity will preserve the tooth? We are not always able to say whether a filling is a good filling or not, by its appearance. I have seen students insert fillings which any expert would have declared good fillings, yet in a little while they failed. I know of a young man who went before a state board in a certain state and passed, and the filling he made at that time did not stay in the tooth three weeks. This filling, however, seemed to be a good filling when it was inserted. I know of another case where a young man, before a state board, inserted a gold filling in the distal surface of a lower canine, and did not pass, but I saw the filling seven years afterward, and it was preserving the tooth perfectly. The proof of the pudding is in the eating. I venture to say that there are not five men in this room who can fill a tooth and have it last under the Black preparation. That is a pretty bold statement, but I will pay for their time if they can do it. I have seen fillings fail that were made by the Black system, and only a little while ago I took one out from the mesial surface of an upper molar, that had been inserted only a short time, and that filling never can have been tight, because otherwise there would never have been so much recurrent caries. So we cannot tell always by appearance how well a filling is going to last. I can show fillings that have been inserted for years and are preserving the teeth perfectly, although this heroic cutting was not resorted to.

Dr. Black (closing the discussion). We are tonight considering especially the shape which we should give to the cavity in order to treat certain pathological conditions which present. One should not judge a thing by what anyone tells him; one should look into these things and study them out for himself, and do that which my father did when he developed this system, viz, take a paper and record what he saw. He observed thousands of small proximal cavities and found that they were practically all in the same place in relation to the contact point, and as a result he was justified in saying that caries begins there. This all can do; it is simply recording facts.

If we would take other thousands of teeth which have extensive proximal carious surfaces, and note how far the caries has spread on the surface and make records thereof, we would know something of the tendency of the progress of dental caries on proximal surfaces. If there were found in this examination not more than one or two in which caries had spread around the angle, then would it not be sound reasoning to say that, as a rule, caries does not extend there, and that the area near the contact point is the most susceptible point, and the condition gradually changes as the angles are approached? This is simply a plain fact that no one can get away from, and which anyone who goes to the trouble of making observations cannot possibly deny. It is not anyone's theory that I am trying to bring out, it is just a plain fact.

I would not agree with Dr. Maxfield that we should make a small filling, and when caries recurs, fill the cavity again. I would just as soon do as a dentist, whose respect for the code of ethics was questionable, said he did in placing fillings in the occlusal surfaces of the molars. Speaking of the lower second molar, he said he would not cut out the fissures in the occlusal surface and make one large cavity in the shape of a Greek cross, as others had advocated, but would make a small filling in the central pit, and then within a year or so the fissures would be affected by caries, and he would make four more fillings, and thus charge for five fillings altogether, instead of one. This quack understood dental pathology, but he was applying it to his own advantage. We are doing the same when we do not extend small proximal cavities, although we know that the tooth will again be affected by caries in the course of a few years. What happens after such a filling is placed in a tooth? Let us suppose that the filling is as smooth as the surface of the tooth was in the beginning; what is the result? If there is a slight space where the gum septum has receded from the contact point, micro-organisms will attach themselves to the filling or to the gold or porcelain inlay, in the same way as on the tooth itself in the first place. The colony grows on the filling in the same way as on the tooth, because there is nothing to prevent it, and it grows out beyond the margin of the filling in the same way as if the filling were not there; then there is a recurrence of caries on the surface of the enamel beyond the margins of the filling. It seems, therefore, common sense to extend the cavity so that it includes the area on which the colony will grow, thereby preventing recurrence of caries. It is not necessary to make a big cavity to do that.

Dr. Brigham spoke of cavities being shown in Dr. Black's book which appeared much larger than those that I showed in the drawings here. There are illustrations showing methods of preparing various kinds of cavities, and in many cases the cavities shown are extremely large, because extensive caries in the dentin had undermined large areas of enamel, but that has nothing to do with extension for prevention.

As to the elasticity of the dentin, it does not require a hard mallet blow to get good results in securing a grip on the filling by the dentin. A fifteen-pound blow on a one-millimeter plugger point will do it. Gold may be malleted in teeth with healthy peridental membranes with a blow of fifteen pounds without harm to the tissues and without discomfort to the patient. It is only necessary to apply the force in the proper direction in order to wedge the gold in and force the dentin back.

Dr. Kelley. Is there not also elasticity in the gold?

Dr. Black. Yes, but it is practically *nil* if compared with that of the dentin.

There is evidently quite a little misunderstanding in regard to recurrence of caries. There are two conditions which cause fillings to fail. In the one case the cavity has not been extended sufficiently; enough of the tooth surface has not been cut away in preparing the cavity, and caries recurs on the surface where the colony of micro-organisms has grown beyond the margin of the filling on the surface of the enamel. Such caries occurs no matter how perfect the filling, because the tightness of the filling has nothing to do with the recurrence of the growth of the colony of bacteria on the surface of the tooth. In the other case, the failure is due to the fact that the filling is not adapted to the walls of the cavity. In the first case, caries begins on the surface of the tooth; in the second, between the filling and the cavity wall. This statement must be kept distinctly in mind, because it refers to two types of recurrence of caries due to absolutely different causes.

Dr. Kelley spoke of prophylactic treatment of caries. If caries begins in a certain place and extends from that point, Dr. Kelley raised the question as to why we should not prevent it by prophylactic methods. There is one area of predilection of caries which can be effectively dealt with in this way, and it is situated in the region of the gingival third. Any patient can prevent such caries by brushing these areas thoroughly twice a day, but for proximal caries, I do not consider such treatment practicable, for the reason that in the constant effort to keep the surfaces clean, the gum septum is often injured to such an extent that additional recession occurs, and the patient is worse off than before.

The association then adjourned, to meet again on Wednesday afternoon at 3 o'clock.

Wednesday—*Afternoon Session.*

The meeting was called to order on Wednesday, October 2d, at 3.30 P.M., by the president, Dr. Sawyer.

Election of Officers.

The Committee on Nominations, Dr. Boardman chairman, then presented the following list of nominations for officers for the ensuing year:

President—F. T. Murlless, Jr., Hartford, Conn.

First Vice-president—G. A. Maxfield, Holyoke, Mass.

Second Vice-president—F. H. Brown, Lebanon, N. H.

Secretary—E. O. Kinsman, Cambridge, Mass.

Assistant Secretary—Charles F. Kreppel, Forest Hills, Mass.

Treasurer—David Manson, Burlington, Vt.

Librarian—D. W. Fellows, Portland, Me.

Editor—I. B. Stilson, Providence, R. I.

Motion was made and carried that the report be received, and the secretary be instructed to cast one ballot for the list of nominations for officers.

The society then adjourned to meet again at 5 o'clock.

The society re-convened and was called to order by the president, Dr. Sawyer, at 5.30.

The first order of business, as announced by the president, was a paper by Prof. E. H. Carleton, Hanover, N. H., entitled "Conservatism in Oral Surgery."

[This paper is printed in full at page 502 of the present issue of the Cosmos.]

Discussion.

Dr. F. H. Brown, Lebanon, N. H. This subject came to my attention very forcibly about two years ago. I was unfortunate in having the process left much exposed in the extraction of my upper left first molar. The process failed to cover even by a clot. I remonstrated with my friend who performed the extraction for not trimming with excising forceps the protruding alveolus, and predicted trouble. In about two weeks I began to have peculiar sensations. I suspected the trouble, and consulted several of my professional friends, but was assured that I had no indication of antral abscess, to which I could not agree. The next day I consulted a specialist in Boston, who asked me to wait two days for developments before he would venture a diagnosis. Three days later I went to the Mary Hitchcock Hospital at Hanover, and was operated upon by Dr. Carleton for antral abscess. Dr. Carleton told me afterward that the case had run on to the danger-point. From my personal experience, therefore, I want to emphasize the importance of removing all exposed alveolar process after extraction, as it is dangerous to leave it.

This operation impressed me as being so simple that I believe any qualified dentist could perform it as well as the specialist, if he had the courage to attempt it.

I wish that Dr. Carleton would state a few details of his method of diagnosing an antral abscess, as this seemed particularly difficult in my case.

Dr. G. A. Maxfield, Holyoke, Mass. I used to treat antral cases and was very successful, but after considerable experience and close study I found that so many other parts are liable to be involved that I concluded it was best to send these cases to the rhinologist. A case illustrating this difficulty was one that was sent to me last fall from a neighboring town. The patient, a woman, had been suffering from neuralgia for several years, and it had become so severe that her physician had sent her to the hospital. After eight weeks she was discharged, because they could not do anything more for her. A patient of mine, a superintendent of one of our paper mills, for whom this woman had worked several years, sent her to me to see if I could find anything wrong about the mouth. She said she was suffering severely, and at times the pain was so intense that she almost went insane. She located the pain on top of the head just to the left of the median line. On examination I found three roots decayed to the gum line, but no teeth that would cause this reflex pain. I at once thought of antral trouble, and, upon questioning her, was told that when she stooped over to pick up anything from the floor, there always was a dull heavy pain over the left side of the face. Whenever we note this symptom, we may feel quite certain that some antral trouble is present. I extracted the roots, and passed a probe into the antrum through one of the sockets, confirming my diagnosis. I told the patient that I had given up treating such cases, and advised her to consult Dr. Hopkins of Springfield. The next day I received a letter from him saying: "Transillumination shows shadow in region of left maxillary sinus and left frontal sinus. The use of the pharyngoscope does not show pus coming from the sphenoidal sinus, although the symptoms would lead one to suspect that this sinus is involved. She has hypertrophy of both middle turbinated bones, and this hypertrophy interferes with drainage from the frontal sinuses. I suggest the removal of the anterior end of the middle turbinated bones, and the opening and washing out of the left maxillary sinus." Upon his direction she went to the hospital, but was in such a nervous condition that she had to be kept in bed three days before the operation could be performed. She remained in the hospital two weeks, and subsequently had several treatments in Dr. Hopkins' office. Since then there has been no pain on the top of the head, and the neuralgia has gradually passed away.

This patient had been under the observation of several physicians for many months, and none of them had suspected that the trouble was due to conditions in the oral cavity. I cannot understand why so many physicians overlook the conditions of the oral cavity in making their diagnosis, and in the treatment of neuralgic conditions.

Dr. W. H. De Ford, Des Moines, Iowa. In my opinion Dr. Maxfield has struck the nail squarely on the head. The dentist should not undertake to treat any of these cases unless he is satisfied that they are due to some mouth or tooth lesion. If the essayist had undertaken to operate in the case mentioned, he would have removed the teeth and made an entrance through the alveolar process into the antrum, while the trouble was probably in the frontal sinus, and the patient would not have recovered as the result of this operation.

It is very difficult to enter the frontal sinus, and we do not have the proper instruments suitable for this operation; but dentists can take care of antral troubles that arise from teeth, and this is best, because physicians are not so apt to observe these affections as dentists.

The essayist has stated the subject clearly, and I wish to compliment him on his paper.

Dr. W. A. Brigham, South Framingham, Mass. I should like to cite a case in which the physician advised against the removal of the tonsils. A member of my family suffered considerably with tonsillitis, consulted a specialist, and, after being questioned somewhat as to the trouble, she was advised not to have the tonsils removed. In questioning the patient, the physician found that the most severe attacks of inflammation in the region of the tonsils followed the eating of candy, of which the patient was very fond. He advised that she avoid candy, and there was no recurrence of the trouble. The explanation of this difficulty was that, in eating candy, enough sugar was caught in the folds of the tonsils to facilitate the growth of bacteria. The inflammation did not return when the patient stopped eating candy, and with a little care has been easily controlled since. In this case many physicians would have advised the removal of the tonsils, but the trouble was overcome without an operation, and the patient is probably better off.

Dr. David Manson, Burlington, Vt. I recall a practical case that may be of interest in this connection. It was a case of antral trouble in a man approaching middle age, and with a syphilitic history. He came to me because of the loosening of his teeth, saying that he had removed with his fingers the upper right first molar and first and second bicuspids. On examination I could readily see that the case was a syphilitic one, although of some years' standing. I cleansed out the sockets with a saline solution, and advised the patient to see me again in a few days. During the intervals between treatments he was troubled in smoking his pipe, in that he was unable to create proper suction on the pipe, and the smoke would pass up through the nose. On examination I found that the sockets of the teeth opened into the antrum and that quite a large piece of bone was loose. I removed this piece, leaving an opening of a size to admit my thumb, resulting in a ready access to the antrum. At this time I referred the patient to a specialist, with whom I discussed the case. The patient came back to me for cleansing and treating, and was given proper directions as to keeping the opening clean. The final result was that more teeth became loosened, and one after another were removed with the fingers until only the left second molar remained. This tooth was quite firm, and I hesitated to remove it with the forceps because of the frailty of the whole process, fearing that the antrum on the left side might also be opened. I allowed this tooth to remain in position and made for the patient a vulcanite denture. At the open point of the antrum I built of velum rubber a bulbous portion, which goes into the antrum, covers the opening, and aids somewhat in the retention of the plate, and by this means I have given the patient comparative comfort. He can use the denture, is saved the annoyance of fluids passing into the nose, and is able to smoke his pipe with a comparative degree of comfort. This is a somewhat unusual case, but possibly interesting in this connection.

Dr. Carleton (closing the discussion). I think that the comment of Dr. Maxfield that physicians are not careful in their observations of the conditions of the mouth is very true. I have recently had a case in which a patient was sent to me with a terrific pain in the ear, and we naturally thought that she was suffering from an abscess in the middle ear. On examination, I found almost normal conditions of the drum, but possibly, if I had exercised my imagination at all, I might have been convinced that a little congestion was present. The patient said she could not hear anything through the affected ear. I could not, however, discover anything wrong about this ear, but it finally occurred to me to ask her if she had had anything done to her teeth recently. She said she had recently had one tooth filled, but had suffered no inconvenience therefrom. After examination of the mouth, I advised her to consult a dentist. In removing this filling which had recently been inserted, the dentist found that pressure had been brought to bear on the pulp of the tooth, and the relief of that condition caused the cure of the trouble in the ear without further treatment.

There are, however, many cases in which the trouble is not so well marked as in this case. I have recently had under treatment a child of ten years of age with inflammation of the cornea and vascular infiltration of the coat of the eye. This was a child of lowered vitality and with bad teeth, every one of which was a focus of infection. Our treatments of the eye mean little in a case of that sort, if teeth remain untreated. Many minor inflammations of the eye and disturbances of the conjunctiva undoubtedly have their origin in the teeth. The throat specialist, of course, now knows that many of the affections with which he has to do come from mouth conditions. It is to be deplored, however, that so many physicians examine the mouths of patients without regarding the teeth and the condition of the oral cavity, etc., seeing only the condition of the throat. I am convinced, however, that the more intelligent and progressive practitioners are noticing these conditions, and this practice, we hope, will become more general in the future.

In regard to dentists' treating affections of the antrum of Highmore, I think many of them would be in the same position as many young surgeons are who operate on the appendix. You know everywhere now we find physicians, young men especially, who like to perform the appendix operation. I have a good many friends among the medical profession, who I know can perform the appendix operation perfectly, and whom, if it were within human ability to say that the trouble was confined strictly to the appendix, I would as soon have operate on me as to engage some other surgeon with far greater skill and knowledge. But there are complicating conditions that we are not absolutely certain of. It is very much the same in treating the antrum. We know from examination and experience that the accessory sinuses are likely to be involved. I think, however, as Dr. Brown has said, that when it is possible to diagnose with certainty a case as empyema of dental origin, there is no reason why the dentist, under proper antiseptic precautions, should not treat it. Of course, we must take into consideration the fact that many of these cases do not turn out as favorably as that cited by Dr. Brown. I know a physician whose alveolar process was perforated for twenty-five years, and who washed the antrum through that opening twice a day all that time. Of course, if a case can be diagnosed with certainty, and the dentist wishes to take the chance, I do not see any reason why he should not attempt the treatment. I am not of the opinion that the dentist cannot do as well as the surgeon; but if there are other conditions involved, it would seem rather wrong. There are two factors to be considered: One is, not to be too hasty in curetting the cavity, because, as I pointed out in my paper, granulations are seldom found in these cases of dental origin, and, second, the use of simple alkaline washes. Even in those cases of long standing where there is more or less thickening of the mucosa and loss of vitality, it is surprising, after a certain length of time, how much we can accomplish by the use of mild washes and stimulation of the parts with silver nitrate.

The diagnosis of these cases is sometimes easy and sometimes difficult. The case of Dr. Brown's was shown up perfectly by the aid of transillumination the day I saw it, while it may not have been possible to see the conditions as perfectly on the day when the patient was examined in Boston. By the application of cocain and adrenalin in the nose around the normal opening of the antrum, which has become congested and swollen so that it is closed up, drops of pus can sometimes be produced from the region of the anterior turbinate bones. If it is not possible to use the X ray or transillumination on account of the smallness of the opening into the antrum, as is found in many cases, the results are not satisfactory even with the use of cocain. Under such conditions the case is very difficult to diagnose. I wish to emphasize chiefly that too early opening of the antrum should be avoided, because, as one of the speakers said, neuralgic conditions are frequently set up as the result of various affections of all the sinuses.

I see no reason, however, if the dentist is willing to take chances with a case of several weeks' or months' standing—because lots of these cases run that time, and they are just as likely to occur in the dentist's as in the physician's practice—I see no reason why, if the dentist is willing to take these chances, he should not operate on such cases.

The next order of business, as announced by the President, was the reading of a paper by Dr. T. C. Beebe, Boston, Mass., entitled "Treatment of Pyorrhea Alveolaris by the Opsonic Method."

[This paper is printed in full at page 475 of the present issue of the Cosmos.]

The meeting was declared adjourned after the reading of Dr. Beebe's paper.

Thursday—*Morning Session.*

The meeting was called to order Thursday morning, October 3d, at 10 o'clock, by the president, Dr. Sawyer.

Dr. Kinsman moved that a vote of thanks be extended to the hotel proprietor, to the essayists, the clinicians and exhibitors, and others who had contributed to the success of the meeting.

The motion was carried.

Dr. Boardman moved that an appropriation of $25.00 be made for the coming year for the use of the secretary in addition to his regular salary.

The motion was carried.

There being no further business before the association, the President declared the meeting adjourned until the next annual session.

NATIONAL DENTAL ASSOCIATION.

Sixteenth Annual Meeting, held at Washington, D. C., September 10 to 13, 1912.

(Continued from page 429.)

THE CLINICS.

MISCELLANEOUS.

Dr. C. M. McCauley, Abilene, Texas. "The Use of the Black Micrometer and Dynamometer for Testing Amalgams."

A duplicate of the amalgam micrometer invented by Dr. G. V. Black was exhibited, together with fillings made from twenty-five of the most popular alloys used by the profession. Some of these fillings showed shrinkage sufficient to render them worthless, while others showed expansion, some as high as 300 points and over. Only a very few remained unchanged in the cavity—*i.e.* showing neither shrinkage nor expansion.

Dr. D. H. Young, Attica, N. Y. "Surgical Treatment of Prominent Alveolar Process Before Introducing Artificial Dentures."

The advantage of this treatment is that it enables the dentist to get rid of all objectionably prominent portions of the process and undesirable undercuts, this operation, in many cases, not only transforming the patient's appearance from an unsightly to a pleasing and intelligent one, but adding much to the credit of the dentist's operation.

If a case of this kind is treated without some such surgical intervention, the dentist is sure to be criticized for the ill appearance of his patient.

Dr. W. F. Andrews, Springfield, Mass. (I) A Simple and Effective Method of Restoring Worn-down Teeth and Replacing Missing Ones." (II) To Replace a Missing Tooth."

(I) To restore worn-down teeth, the cutting edge of an incisor or canine is ground to a smooth surface, then two holes, of 22 gage, are drilled parallel with the pulp without encroaching on it. Gold of 22-karat is burnished to the surface, after having fitted platinum pins in the drilled holes; the gold and the pins are fastened together with hard wax, removed, and soldered. Next the piece is applied in the mouth, given a second burnishing and trimmed to the tooth. It is then removed, sufficient solder is added to restore the length, and the appliance is finished and fastened with cement.

(II) The occlusal surface of a molar or bicuspid is ground so as to allow sufficient space for gold, then the same procedure is followed as for a worn-down tooth, or pins are inserted, a wax model is made, and an inlay cast. This is placed in position, removing the appliance with the impression, and then the usual procedure for fastening to it the missing tooth is followed.

Dr E. A. Schillinger, Lee, Mass. "Gold Fillings in Artificial Teeth."

The first step in the preparation of the cavity is to grind a concave depression with a large-sized carborundum stone. Following this, grooves are cut on the margin of the cavity with small-sized stones. On the lingual side of the tooth dovetailed grooves are ground at obtuse angles to the cavity.

The filling is started by placing a small portion of cement in the bottom of the cavity. While this is still soft, a piece of gold is inserted, waiting until the cement sets before finishing the filling.

To hold the tooth to work on, a hole is cut in a large cork, and around it waxable rubber is built.

This work is done entirely without the use of diamond drills.

Dr. J. M. Levy, New York, N. Y. "Radiography as a Regular Part of Office Practice, and as an Aid in the Extraction of Impacted Third Molars."

The case presented for impacted third molar operation was one of simple maleruption of the lower left third molar. In regular practice the operator would most certainly not extract such a tooth. The patient's dentist, who accompanied her, however, and the patient herself, insisted upon its extraction. The tooth was extracted under local anesthesia with alypin 2 per cent. and adrenalin 1:1500, by the use of ordinary cowhorn forceps.

Dr. Levy also showed a new film-holding device for making radiographs, and explained his method of taking and developing radiographs.

Dr. A. H. Corbett, Atkinson, Nebr. "Scalers for Personal Use."

The clinician demonstrated a method by which a person can thoroughly scale his own teeth by the use of a set of scalers, such as Nos. 3 and 4 of Dr. King's set made by the S. S. White Co. These instruments, he said, are especially indicated when the patient cannot return for subsequent treatments. The patient is instructed in the use of the scalers, which are to be used in conjunction with a good antiseptic mouthwash.

OPERATIVE DENTISTRY.

Dr. L. S. Breed, Boston, Mass. "Removing Pulps, Preparing and Filling Root-canals."

The pulp is first removed under pressure anesthesia. Extremely small canals are enlarged to a size which will allow of their being properly filled, and the canal is filled by first pumping it full of chloroform with the aid of a broach, after which properly selected, stiff gutta-percha canal points are inserted.

Dr. C. G. HUGHES, Pittsburgh, Pa. "Painless and Quick Removal of Pulps and Immediate Canal Filling."

The tooth operated upon in this clinic was an upper right third molar, with a saucer-shaped cavity and slightly exposed pulp, though the tooth had never ached. The cavity was washed out with dioxid, after which the pulp was anesthetized by the use of a half-tablet of cocain and adrenalin. The preparation was first worked over the cavity with a pointed explorer, and an opening made directly into the pulp. Another application of the cocain and adrenalin was made directly to the pulp, producing pressure anesthesia by the aid of soft plate rubber. Proper opening was then made, and the pulp removed from the chamber and canals. The canals were next reamed, and after drying properly, the upper fourths of the roots were filled with Oxpara, being pumped up into the root-canals with a broach. A small pellet of cotton was next inserted, and the Oxpara forced to the apex of the root. The canals were then filled with gutta-percha, and a permanent filling was placed over this.

Dr. ROBERT PURVIS, Camden, N. J. "Ascher's Artificial Enamel."

This clinic consisted in the insertion of two artificial fillings, one being a large contour filling in an upper lateral, placed over a capped pulp, the other a restoration of the labial cusp and surface of an upper bicuspid.

Dr. SIMON SHAPIRO, Brooklyn, N. Y. "A Method of Separating Teeth by the Use of Silk Ligatures."

By means of dental floss, a double ligature of French silk or very thick darning silk is drawn through the interproximal space below the point of contact, and tied over the morsal edge, forming a loop lingually and a knot labially. The swelling of the French silk, caused by the absorption of moisture, will in the course of a day or two separate the teeth, and afford sufficient space for almost any dental operation.

Dr. F. E. BALL, Fargo, N. D. "Treatment of Putrescent Pulps."

The cavity is first flooded with the following preparation:

Creasote (beechwood),	
Formaldehyd 40 per cent.,	
Alcohol,	āā ℥j
Thymol,	
Menthol,	āā ʒss
Lysol,	gtt. xxx

The canal is then carefully excavated and prepared, keeping the medicament in advance of the instruments. A portion of the medicament is sealed in the tooth for forty-eight hours. At the next sitting this dressing is removed, then a paste is made by adding powdered zinc oxid to the liquid prescription, and as much of this paste as possible is carried into the canals of the tooth, forcing it to the end of each canal and filling the latter with gutta-percha points.

This paste formula is useful in all canal work, and is heartily recommended by the clinician.

Dr. JOHN H. KENNERLY, St. Louis, Mo. "Filling Root-canals with an Improved Paraffin Compound."

The root-canal is thoroughly dried with acetone, bibulous paper cones, and a hot wire. The canal is then coated with a very thin film of pure paraffin oil and a cone of the prepared paraffin compound is melted into it by means of the electrically heated root-dryer. The source of electricity may be obtained from the electric light supply current, after it has been passed through a suitable switchboard, or from a series of from 6 to 8 dry-cell batteries. This method is fully described in a paper by Dr. Hermann Prinz entitled "Filling Root-canals with an Improved Paraffin Compound," published in the DENTAL COSMOS for October 1912, p. 1081.

Dr. J. W. Bryan, Nashville, Tenn. "A Method of Treating Pulpless Teeth."

Treatment of pulpless teeth by the use of equal parts of cresol and formalin is recommended, in the following cases:

(1) When the pulp has been extracted, regardless of the method of anesthetization or devitalization employed.

(2) When the pulp has died and but little, if any, apical pericementitis is present.

(3) When there is decided apical pericementitis, or when pus is present but no fistulous opening has formed or can be made as yet.

(4) When there is a fistulous opening, or when such can be made.

The clinican discussed the subject according to the above analysis, and gave reports of the most satisfactory results following the treatment demonstrated.

Dr. John H. Bristor, Mansfield, Ohio. "Three Helpful Hints."

A pulp capping for filling deciduous teeth where the pulp is close, and for fillings where metal is not indicated, may be made by adding one or two drops of beechwood creasote to the liquid of the oxyphosphate cement, mixing the liquids together before incorporating the powder.

A stainless counter-irritant consists of—Tinct. iodin, 3 parts, tinct. aconite, 3 parts, aqua ammonia, 1 part. (The first two form the official preparation.)

Glass saliva tubes, glass cement slabs, and all pieces of glassware are easily cleaned by immersing in a dilute solution of muriatic acid, then rinsing in clear water.

Dr. J. E. Tibbetts, Rockland, Me. "Filling of Mesio-bucco-distal Cavities, under the Gingival Margin, Extending Too Far for Ligatures or Clamps."

The rubber dam is applied without ligatures or clamps over the teeth of a human skull. The dam is held in place above the cervical margin by an elevator, the cutting edge of which has been altered, by one hand of the operator, while he manipulates the filling material with the other hand. The advantages of this method are saving of time, less pain to the patient by less laceration of gum tissue, and preservation of the gingival margin.

Dr. J. Austin Dunn, Chicago, Ill. "An Improved Method for Cleaning Teeth by Means of Rubber Cones."

These rubber cones are submitted to the dental profession as an improved means of cleaning the teeth, and for the purpose of meeting the modern requirements of prophylaxis and sanitation.

The fine feather-edge on these cones will admit of a close contact and thorough cleaning of the gingival borders and angles of all the teeth, and they are sanitary because, having been once used, they are thrown away.

Their use on the right-angle handpiece is especially new and satisfactory for cleaning the buccal and lingual surfaces of the teeth. These cones are very easily and quickly mounted on a crosscut fissure bur No. 4.

Dr. Frank J. Ryan, Chicago, Ill. "Amalgam Fillings."

The clinician showed six cards of amalgam fillings, fifteen to each card, showing—(1) Amalgam fillings as they are after failure, the defects being easy to see and avoid; (2) amalgam fillings as made by the clinician in cavities in human teeth and ivory blocks, all made under ideal conditions, showing the reasons for failures of amalgam fillings; (3) a card of fillings made by other operators, showing that some operators do better work than others, but that none can make even a good filling with amalgam alone; (4) a card of fillings made in glass tubes, some with soft cement linings that looked splendid, and others with amalgam alone that did not look as though they would arrest caries in a tooth.

Dr. Edward S. Gaylord, New Haven, Conn. "Rapid and Positive Method of Obtaining Gold and Platinum Matrices."

The gold or platinum is placed between a fold of thin China silk, which is immersed in water to make the silk and metal better conform to each other. With ball-nosed foil-carriers the combination is held over the cavity, while with a round-ended instrument in the other hand it is carried promptly to the floor of the cavity, and held there. With foil-carriers the folds are pulled out until a pellet of wet cotton, spunk, or bibulous paper can be packed in so as to swage the matrix and make it conform to the cavity. The silk is then removed carefully from the cavity, then the partially formed matrix is returned to the cavity for completion, by packing dry pellets of cotton, spunk, or bibulous paper firmly into the cavity until the matrix is perfectly adapted to it. The margins are also carefully adapted by a burnisher or roller, Pierson's rollers being preferred. The cotton or spunk is removed, the matrix in the cavity is filled with softened wax or gum camphor, and with a small heated copper wire, inserted in the wax, the matrix is removed from the cavity. It is then invested in Jenkins' or Pelton & Crane's investment No. 1, a pellet of absorbent cotton is placed on the wax, which, on heating slowly, is taken up in the cotton. The matrix is then ready to receive the porcelain for the bake.

Dr. V. M. Rundle and Dr. H. I. Beemer, Newton, N. J. "Preparing and Inserting a Gold Filling in a Cavity in the Approximal Surface of a Bicuspid by Dr. Black's Methods."

The cavity filled was in the distal surface of an upper right first bicuspid. It was prepared after Dr. Black's method of extension for prevention. The buccal, lingual, and gingival margins were extended to areas of greatest immunity, and an occlusal step was made for anchorage. The gingival and occlusal seats were made flat, and all opposing walls parallel.

The gingival third of the approximal portion of the cavity was filled with unannealed gold cylinders, specially rolled for this purpose as taught by Dr. Black, and the rest of the filling was made of annealed gold pellets, also specially prepared for this use after the methods of Dr. Black.

The hand mallet was used for condensing the gold, and special cutting instruments were employed for preparing the cavity; the pluggers were also specially designed for this work. All the instruments used were manufactured from models made by Dr. Black, Dr. Wedelstaedt, and Dr. Conzett.

Dr. W. R. Clack, Mason City, Iowa. "Gold Foil Filling in the Disto-occlusal Surface of an Upper Bicuspid or Molar by Dr. Black's Method."

In preparing his operation, Dr. Clack removed two amalgam fillings, one from the occlusal, the other from the mesial surface of an upper right second bicuspid. He then squared the cavity as much as possible without going to the full depth of the center, or pulpal wall.

After the cavity had been completely prepared, the first step in the operation consisted in placing three cylinders of gold against the cavity margins, one on the buccal, one on the lingual, and one on the gingival wall, the last binding the former two in place. These pellets or cylinders consisted of one-quarter sheet of No. 4 soft gold, the same quality of gold being used for the entire gingival third of the filling. At this point, the clinician began to anneal his gold, which thereafter consisted of loosely-rolled pellets containing from one-sixty-fourth to one-sixteenth of a sheet each. The entire work of placing the filling was done either by hand pressure or hand mallet, the latter being wielded by an assistant.

The points that Dr. Clack desired to emphasize in his finished filling were the production of an accurate contact point and the shaping of the filling so that food, in its excursion from the occlusal surface of the tooth toward the gum, would be brought in contact with both the buccal and lingual margins throughout their length, thus mechanically assisting in keeping the margins polished. This condition was produced not so much by extensive cutting as by the shaping of the filling and a narrowing of the contact points.

[This report was made at Dr. Clack's request by Dr. Alfred P. Lee, Philadelphia. Pa.]

Dr. C. L. Brininstool, Rochester, N. Y. "Vapor Bleaching."

Vapor bleaching is accomplished by the use of 25 per cent. pyrozone, the vapor being generated by the application of heat.

For bleaching the marginal or cement line of a porcelain inlay, the rubber dam is applied to protect the surrounding tissues, as in all cases where this method is used. Then a pledget of cotton moistened with the solution is placed over the margin, and heat is applied in order to vaporize the solution by means of a flat instrument or one that conforms as nearly as possible to the surface to be bleached. The electric wax spatula answers this purpose nicely, as it generates just about the proper amount of heat.

For bleaching an anterior tooth the moistened cotton is placed in the cavity, and the heat is applied with an instrument that closes the cavity as nearly as possible, the object, of course, being to retain the vapor so that it will be forced into the tubuli of the dentin. Care should be taken to seal the point of the root carefully, so that no vapor will be forced through the apical foramen. If the opening be only a small and round one, where the pulp-chamber has been entered, it is quite a simple matter to vaporize the pyrozone with a short, tapered root-canal drier, which can be made to close the opening quite effectually. Care should be taken not to use an instrument that is too hot, or the vaporization will be so rapid that a mild explosion will take place. Other methods of applying this principle will suggest themselves, the object being to confine the pyrozone vapor so that it will be forced into the tubuli and be brought in contact with the material to be bleached.

Dr. J. Fremont Burket, Kingman, Kans. "The Filling of Root-canals."

If a patient presents an exposure, the pulp is removed, the cavity and canals are washed and thoroughly cleansed with hydrogen dioxid, and the canals dried with bibulous cones made by cutting little triangles from sheets of bibulous paper and twisting them into cones, made of any size so as to suit the case. This procedure is followed by applications of hot air to the canals. After the canals are thoroughly dried, a little powdered iodoform is placed in the pulp chamber, and with a small plugger a little of it is worked into the canals. Then a gutta-percha point is selected, small enough to be gently carried to the apex of the canal, and if more than one canal is present, a point is placed in each; then, with a small drop syringe, made of a little glass barrel with a platinum point and a rubber bulb, a drop of chloroform is dropped upon the gutta-percha point, which drug will immediately follow the gutta-percha point to the apex and dissolve it. As soon as this point is dissolved, another gutta-percha point is introduced into the canal, thereby forcing the first gutta-percha, which has now been changed to chloro-percha, into the recesses of the canal. This is repeated till all the chloroform is evaporated, and the canal is filled.

If the case is one of a dead pulp, the pulp chamber is opened freely so as to make the opening large enough to allow free access to all canals, and all decayed matter is removed. Then the cavity, pulp chamber, and root-canals are washed out with dioxogen and the canals filled as indicated above.

If the case is one with a fistula, the process described is followed until the pulp chamber and canals are thoroughly cleansed, then a small ball of vulcanite rubber is placed on a "sub Q" syringe point, to cork the cavity in the tooth and prevent back flow, and a syringeful of dioxogen is forced through the canal and fistulous opening. This is repeated till the fistulous tract is thoroughly cleansed, two or three applications usually being sufficient. Then the root-canals are filled as described above.

The clinician demonstrated the method of filling roots as above described by the use of glass tubes, prepared for this purpose, permitting of an accurate observation of the results of the process employed, the tubes being made to approximate root-canals of different sizes.

ANESTHESIA.

Dr. A. E. Smith, Cleveland, Ohio. "Nitrous Oxid and Oxygen for Producing Prolonged Analgesia and Anesthesia."

Deep analgesia was produced in several patients in whom, during this condition, hypersensitive cavities were excavated and prepared without pain. At no time were the patients unconscious, as only the sensory nerves were acted upon. During the analgesic state, patients are fully conscious and can talk, but have no sense of pain. The patients were kept in the analgesic state for from three to thirty-seven minutes.

Dr. R. H. Riethmüller, Philadelphia, Pa. "Local Anesthesia with Novocain-Suprarenin."

The clinician demonstrated the use of novocain-suprarenin for local anesthesia in dental operations, the methods of injection, the preparation of the most serviceable and safe solution, the instrumentarium required and its sterilization; and the prophylactic treatment of patients. Statistics were given as to the very successful employment of local anesthesia by means of novocain-suprarenin in dental as well as in minor and major surgical operations as practiced in European countries to such an extent that general anesthesia has been assigned second rank. The four methods of injection available for dental operations—viz, terminal, conductive, peridental, and intraosseous anesthesia—were demonstrated by means of large anatomical drawings and a natural skull, in which the oral tissues had been replaced in wax. The preparation of an isotonic, so-called "normal" novocain-suprarenin solution, as indicated by Dr. G. Fischer of Marburg, and its sterilization by boiling, was shown, preference being given to the tablet form of the anesthetic mixture over ampules containing ready-made solutions. Precautions necessary for keeping the drugs free from decomposition by air, light, and traces of alkalis, for making an isotonic sodium chlorid solution, and for obtaining absolutely sterile distilled water were pointed out. The instrumentarium demonstrated consisted of several syringes, all-metal and glass-and-metal of various makes, as well as hypodermic steel needles of various diameters, lengths, and makes, a glass jar fitted with a German-silver stand for the convenient preservation of two fully mounted syringes in a 70 per cent. alcohol solution, which is burned off the syringe and needle before use, or in a saturated boric acid solution, for the sake of sterility; a small porcelain pan for boiling and thereby sterilizing the solution to be injected; an electric sterilizer for sterilizing the syringe and needles after use, and a syringe tray for holding the sterilized instruments temporarily. Samples of synthetic drugs most useful in preparing the patient for the injection and divesting the injection of even the minutest trace of subsequent intoxication—viz, pyramidon, trigemin, and bromural—and precautionary preparations for the counteracting of possible shock in mild form—viz, strong black coffee, camphorated validol, and amyl nitrite—were exhibited. The advantages of novocain—the fact that it is not a nostrum like innumerable other substitutes for cocain, its low toxicity, which is from seven to ten times less than that of cocain, the confinement of the anesthesia to a small area produced by the admixture of suprarenin, its low price, its sterilizability by boiling, its compatibility with vital tissue, the absence of after-pain, inflammation, and necrosis following its employment, and its universal usefulness in dental practice, ranging from the desensitization of hypersensitive dentin and devitalization of pulps to the painless resection of the whole mandible—were emphasized. To prove his absolute faith in this ideal local anesthetic, the clinician had Dr. Potter of the Harvard University Dental School make a buccal and lingual injection for the anesthetization and subsequent excavation and filling of an extremely hypersensitive cervical cavity in an upper second bicuspid, the vitality of which has been fully preserved.

Dr. E. O. WHIPPLE, Olean, N. Y. "Cocain Anesthesia Without Pressure."

After removing the loose carious portions present, a pellet of cocain and adrenalin is placed as near the pulp as possible, sealing it in with hot temporary stopping. It is left for from fifteen minutes to one hour, depending on other work to be done. Then as much of softened dentin and of the pulp is removed as is possible without pain, and the operation is repeated, leaving the dressing for fifteen minutes more. If at the end of that time the pulp is not thoroughly anesthetized, the process is repeated a third time.

As a rule, other work is to be done for the patient, so no time is lost. Otherwise the patient can wait while the operator works on another patient. The more the pulp is inflamed, the more time is required for the production of thorough anesthesia.

Dr. J. A. BLISS, Ruthven, Iowa. "Instruction in Somnoform Analgesia Induction, Using the DeFord Appliance."

A number of patients were put into an analgesic state, also several dentists inhaled the somnoform for the sake of personal experience as to the amount necessary, the depth of analgesia required, and the technique involved. Some who had cavities which elicited pain upon the slightest touch of a toothpick or instrument volunteered to take somnoform. Two or three inhalations were found to be sufficient to render the dentin insensitive to pain when touched with instruments.

Stress was laid upon the small amount of somnoform vapor necessary in inducing the analgesic stage as compared with the air used. In one case only was anesthesia induced for the purpose of showing that the anesthetic stage is but a step from that of analgesia and can be induced with no discomfort whatever to the patient. Several dentists who had never had an analgesia appliance in their hand before, and an assistant of one of the local dentists, induced analgesia in patients without difficulty. The DeFord appliance is so constructed that the anesthetic agent can be controlled absolutely and scientifically.

Dr. H. E. TOMPKINS, New York City. "Anesthesia in Oral and Dental Surgery."

The clinician presented an anesthetic apparatus with which it is possible to administer any combination of anesthetics in any desired proportions. Its particular use in dentistry is realized in analgesia, for any desired percentage of air, N_2O, and O, either singly or in combination, may be administered with this apparatus. It also presents a regulating feature by which the flow of gas is under absolute control, ranging in pressure from zero to 10 pounds. Because of the lack of material, this apparatus was not put to a practical test at this meeting.

There was also presented a new capsule of aromatic ammonia, containing 10 drops, which is wrapped in a layer of absorbent cotton, this in turn being wrapped in a sheath of silk cloth. The preparation is known as Vaporole Ammonia, and is useful in all cases where a disposition to faintness is manifested.

Dr. FRANK L. PLATT, San Francisco, Cal. "Peridental Anesthesia."

The clinician demonstrated a method of injecting a local anesthetic into the cancellous tissue of the alveolar process, thus anesthetizing the peridental membrane and rendering the tooth insensitive to operative procedures. The anesthetic used was a preparation of novocain and adrenalin.

The region to be operated upon is first thoroughly cleansed by means of any good antiseptic mouth-wash applied with an atomizer, particular attention being paid to the interdental spaces and the free margins of the gums.

The point on the gum where the puncture is to be made is then painted with tincture of iodin and well swabbed with a pledget of cotton saturated with the antiseptic used in the atomizer.

An all-metal hypodermic syringe with a short, sharp 28-gage needle is used. Pressure is made on the gum with the finger to render it somewhat insensitive, and the needle is inserted slowly and gently, beginning the injection of the anesthetic as soon as the needle touches the tissue, in order to keep the anesthetic always ahead of the needle.

No pain need be inflicted in this or any subsequent part of the operation.

The needle is inserted until it reaches the bone of the interdental septum next to the tooth or between the teeth to be operated upon, and just above the base of the interdental flap. It is then driven through the hard outer plate of the process by light taps on the piston of the syringe, stopping between blows to exert pressure and inject the anesthetic into the tissue. Should the needle become clogged, the obstruction may usually be removed by withdrawing the syringe and striking sharp, heavy blows on the head of the piston.

After the needle has been cleaned, or a new one has been adjusted, it is again inserted in the previous puncture, and the process is repeated. When the cancellous tissue is reached, the injection should be made slowly and gently, with but little pressure.

From one to two or even three teeth may be anesthetized with one injection, though more than one puncture may be required for a single tooth, in portions where the bony tissue is more than ordinarily dense. Where difficulty is experienced in driving the needle through the hard outer plate of bone, the latter may be punctured by means of a No. 1 half-round bur in the engine handpiece, after anesthetizing the gum at the spot where the puncture is to be made.

The bur must be sterile and dipped in vaselin to avoid winding the membrane on it, and should be revolved slowly and with little pressure to avoid heating. The outer plate of bone having been punctured, the syringe is used with a conical needle, which may be made from an ordinary hypodermic needle by grinding the reinforcement down to a long tapering point, and cutting the needle off close to the point of reinforcement. After this conical needle is inserted in the puncture made by the bur, the syringe should be held firmly in position, and the anesthetic deposited in the tissue by slow, gentle pressure.

When the bur is used, the puncture should be made between the teeth, if they be single-rooted, or between the roots if the teeth be molars, from one-half to two-thirds of the way from the gingival border to the apices of the roots of the teeth.

In the case exhibited, the needle was driven into the process between the upper right first and second bicuspids, and the pulp was removed from the first bicuspid "without a bit of pain"—as the patient remarked. This intra-osseous injection of an anesthetic will render any dental operation, even the extraction of impacted third molars, positively painless, and marks an important advance in modern, ethical painless dentistry.

Dr. Emerson R. Sausser, Philadelphia, Pa. "Subperiosteal Injection of Novocain in Preparing Two Hypersensitive Cervical Cavities. (According to Dr. Guido Fischer.)"

The patient presented two intensely sensitive cervical cavities of the erosion type, the affected teeth being the upper left lateral incisor and canine.

The technique employed by the clinician was as follows:

Complete sterilization of the field of operation and the instruments used, and the solution then injected.

One cubic centimeter or sixteen drops of distilled water was prepared, in which one of Prinz' novocain tablets was dissolved. The formula of this tablet was suggested by Dr. Hermann Prinz, and is as follows:

Novocain,	gr. 1/3
Thymolated adrenalin,	gr. 1/1500
Sodium chlorid,	gr. 1/8

This tablet, when dissolved in the above amount of distilled water, gave a 2 per cent. isotonic solution of novocain. The Parke-Davis dental syringe improved, with a short hub and a medical Schimmel hypodermic needle, was filled with the above solution.

The mucous membrane was painted with iodin and the needle was inserted directly over the root of the upper left central at a point between the gingival and the apical regions, where one drop of the solution was injected, after which the needle was passed under the periosteum in a direction toward the apex of the lateral, viz, the tooth to be anesthetized, where six minims of the solution was injected. After fifteen seconds had elapsed, the needle was withdrawn and the finger quickly placed over the point of insertion to prevent the escape of the solution. After a few seconds the parts were massaged.

The mucous membrane on the palatal side in the apical region of the lateral incisor was painted with iodin and an injection of four drops of the solution made into the subperiosteal tissue at this point; the needle being withdrawn, the finger was placed over the point of the insertion and the parts were massaged. In three minutes complete anesthesia was established and the tooth was ready for painless excavation of the cavity and extirpation of the pulp.

In anesthetizing the canine the same technique was followed, excepting that the point of inserting the needle was midway between the gingival margin and the apex of the lateral incisor, and the needle was advanced toward the apex of the canine.

Dr. S. G. Wallace, Lakewood, N. J. "The Immediate Cutting and Grinding of Hypersensitive Dentin in Dental Operations."

The clinician demonstrated the use of his obtundent in the preparation of an upper second bicuspid for a jacket porcelain crown in a male patient of about twenty-five years of age and nervous temperament. Dr. W. A. Capon of Philadelphia, who later applied the crown, directed and assisted in the preparation. The hypersensitive tooth structure and the stones and burs were kept wet with the obtundent during the operation, and the grinding and shaping of the tooth was completed in about twenty minutes. After the application of the obtundent, the tooth structure was completely desensitized, and the patient stated that he experienced no pain during the operation. While cutting the tooth under the gum with an Evans' tooth trimmer up to the alveolar ridge, there was not the slightest indication of pain. This method also afforded a great saving of time.

The two succeeding demonstrations showed the use of the obtundent in removing hypersensitive dentin and in cavity preparation. The first patient to be operated on was a young man of nervous temperament, who presented a large, extremely sensitive cavity in the occlusal surface of the lower right second molar with a nearly exposed pulp. After carefully removing the débris, a pledget of cotton saturated with the obtundent was placed in the cavity and allowed to remain for ten minutes. The operation proceeded then without delay, the burs being kept wet in chloro-carbolin while in motion. The fully prepared cavity was examined and found to be thoroughly excavated even in the portion overlying the pulp chamber, without an exposure having been produced. The pulp was then capped with one part of chloro-carbolin and two parts of Harvard liquid, rubbing up the two and drawing in powder to make a cream-like paste. The entire operation was completed in less than one-half hour; the patient showed no signs of pain, and stated that he felt no discomfort whatever in the operation.

In the other case, the cavity to be excavated was situated in the disto-approximal surface of an upper right bicuspid, the tooth structure being broken down around a gold filling near the gingival margin. This cavity was unusually sensitive and difficult to work on without a right-angle attachment. Cotton saturated with the obtundent was placed around the gold filling and held there for ten minutes; the gold filling was removed in the usual way, and, as sensitiveness presented, the use of the obtundent was repeated. This operation was performed on a dentist who was attending the convention, and who expressed himself as being delighted with the absence of even the least discomfort, as he had expected to be hurt unmercifully.

PYORRHEA ALVEOLARIS.

Dr. R. G. Hutchinson, Jr., New York City. "Surgical Treatment of Pyorrhea. Final Scaling and Curetment."

This surgical treatment was applied to nine lower anterior teeth which were greatly involved. The treatment was completed at one sitting, with the exception of final polishing with pumice.

Dr. Elbert J. Weaver, Milwaukee, Wis. "Surgical and Systemic Treatment of Pyorrhea Alveolaris."

The clinician showed a method of instrumentation in two lower centrals affected with pyorrhea pockets. He also gave an exhibition of urinalysis charts, showing constitutional conditions to be found in pyorrhea cases, with suggestions as to the improvement of these abnormal conditions, in conjunction with the surgical treatment. The clinician also showed results obtained in one case particularly.

Dr. J. M. Gompertz, New Haven, Conn. (I) "Bacteriology and Vaccine Therapy of Pyorrhea Alveolaris." (II) "The Making of Autogenous Vaccines."

The clinician showed pure cultures of from 24 to 48 hours' growth in agar, milk, and potato, of staphylococcus albus and aureus, streptococcus, and pneumococcus, with cultural features. He also showed fifty pure cultures of different bacteria found in pyorrhea alveolaris cases, on slides stained by the Gram method, as seen under the microscope, also suspensions of definite quantities of bacteria killed by heat in a 0.9 solution of sodium chlorid. He demonstrated a method for the determination of bacteria by the Thoma-Zeiss blood-counting chamber, also the initial step in the making of an autogenous vaccine, the finished product, and the method of inspection.

Dr. Clyde M. Gearhart, Washington, D. C. "Pyorrhea Case."

This clinic consisted in the exhibition of a well-defined case of pyorrhea, the patient having been dismissed only three months previously by a dentist who had completed the operative work, but neglected the manifest pyorrheal condition, assuring the patient that his mouth was in a healthy condition. The clinician treated the upper and lower left side, and presented the results obtained by him in comparison with the opposite neglected side.

Considerable stress was laid upon the fact that, as in this case, many mouths that are in a similarly precarious condition are being slighted by dentists, and patients are being dismissed under the impression that their mouths are in a normal state.

Dr. Moore Stevens, Atlantic City, N. J. "High-frequency Current in the Treatment of Pyorrhea Alveolaris and Congested Conditions of the Oral Cavity."

In May 1911, the clinician, not receiving as quick results as he desired in the treatment of pyorrhea alveolaris, applied a high-frequency current directly upon the gums, thinking that the stimulating results, if the patient could tolerate them, might be beneficial in more quickly healing the gums. The patient and the operator were more than pleased after a few treatments, as the excessive stimulation of the gums removed all congested blood in these tissues. As the patient was using care to keep his mouth in a sanitary condition, it was restored to a healthy state in much less time than was possible with the medicinal treatments previously used.

High-frequency currents possess therapeutic power in passing through tissues in which vitality has almost been exhausted. These currents appear to promote circulation, increase metabolism, and more or less completely restore general harmony in the part.

With the proper application of this current, relief from pain can also be brought about in the treatment of toothache, tic douloureux, painful eruption of teeth, gangrene, sensitive teeth during menstruation, ulcerated gums, neuralgia, in fact any congested condition of the oral cavity.

Dr. Jules J. Sarrazin, New Orleans, La. "New Riggs' Instruments. Preventive and Corrective Local Adjuncts."

Dr. Sarrazin demonstrated the use of a new set of instruments for the surgical treatment of Riggs' disease, in which six of the points are original, viz, Nos. 3, 4, 5, 6, 7, and 8. These six instruments are devised for delicate root-scaling, and besides being universal in their reach on roots, they are also capable of entering and scaling at and around the bifurcations of molar roots, both above and below. The other numbers in the set of twenty-four instruments are compiled from other pyorrhea sets, with more or less modification. The aluminum-knob finger-rest No. 21 is an improvement on the use of any perishable material for the purpose of increasing firmness of grasp, and has the advantage of allowing sterilization by boiling. Nos. 22 and 23 are burs especially devised for the convenient removal of carious bone in sockets and at their borders. No. 24 of the set is a sharpening disk, to be used in the dental engine for quickly and accurately edging any instrument in the set.

Three tooth-brushes were also shown, specially devised to facilitate not only the cleansing of teeth, but the massage of gums. The wide-head brush carries a very small head on a very long neck, with ample space between the transverse rows of bristles, terminating in a long tuft. This brush is universal in its access to dental arches, both above and below, brushing from gums to teeth, both lingually and buccally, or labially. Where buccal space is scant at upper molars and distally of the farthest one, this brush is replaced with advantage by a still narrower one, which was also exhibited. The third brush in the set is a double-ender, one head being like a small hoe, and the other head like a small, flat paint-brush, to cleanse under bridges and at crowns forming the abutments thereof, and to reach properly the necks of natural teeth next to gaps, no matter whether those teeth tilt over the gaps or not; also for use lingually of lower incisors and distally of rearmost molars.

Tooth-powders were also demonstrated, and mouth-washes with proper medicinal properties and polishing power, not commercial toilet articles. Powder No. 2 does active oxidizing without danger of irritation, and possesses mild alkaline germicidal properties. It is capable of polishing the enamel without scratching the cementum; it is classed as a preventive powder for general purposes. Powders Nos. 3 and 4 possess medicinal properties necessary in the adjunct treatment of pyorrhea, the only difference between those two numbers being that No. 4 has a perceptible grit to meet conditions which require it. This latter is valuable in office prophylactic work, besides home treatment in Riggs' disease. Mouth-wash No. 5 is a preventive preparation, which is at the same time capable of coping with congestion of the mucosa. It owes its efficacy to the combination of zinc iodid and zinc chlorid with other favorable drugs. It is also prescribed as a daily mouth-wash with preventive properties.

The clinician also exhibited flat dental flosses charged with antiseptic polishing powders supplying the different grits necessitated by the various conditions to be cared for, including the cleansing underneath bridges.

Dr. T. Sydney Smith, Palo Alto, Cal. "Pericemental Diseases."

This clinic is an effort to show that by early diagnosis, prevention, and cure of pericemental diseases—so-called pyorrhea alveolaris—we may not only keep the gums strictly normal, but also keep all the teeth in excellent condition to extreme old age. This brings about a new and wonderful era in dentistry, for it is the highest standard we can ever reach. The clinician wishes to contrast this statement with the teaching of the past age as voiced by many of our leading writers, viz, that the loss of these dental structures is a physiological event to be expected. Today we know that nature does not remove the gingival and septal tissues which she placed for essential purposes, but that their destruction is due to pathological actions, and always preventable simply by keeping the teeth highly polished and clean under the free margins of the gums.

The clinician also wishes to show that even though deep pockets are present and the teeth have become very loose, the gum tissues can be reattached to vital teeth by first intention—the blood-clot method—just as rapidly as a clean cut will heal in some other part of the same body, and the bone will also be reconstructed at the point where the soft tissues have been reattached. This rapid healing by first intention can only be secured by perfect surgery and nature's forces; we must therefore emphasize the value of the blood, which should not be washed out of the wound during any stage of the operation. We require it first for cleansing, second for sterilizing, and third for its reconstructive properties. This blood is cleansing because of the tendency for liberated blood to coagulate, thus incorporating the loosened particles of deposit in the fibrin. In this way the instruments bring them to the surface much more perfectly than would be possible by washing, since the tissues act like a sponge to hold them. Blood is sterilizing because the presence of micro-organisms in the pockets for considerable time has fortified the blood with anti-bodies to hold these germs in check. The specificity of these anti-bodies is beyond all human imitation, and these do not interfere with the reconstructive properties of the blood, as they are normal to it; they quickly sterilize the wound when we turn the balance of power on their side by perfect surgery. Lastly, the blood is essential to form the union between the freshened gum tissue and the cementum.

This method of healing has proved that the denuded cementum does not die while the pulp and dentin are vital. Microscopic anatomy has revealed the possible path for nutrition to pass from the dentin, and the easy passage of staining solutions from the pulp chamber to the pericementum has strengthened this theory, but the blood-clot method of reattachment has settled the question by showing that only granulation and close contact can be secured around a pulpless tooth, while the tissues readily unite with a vital one. This difference lies in the cementum, and shows life in the one case and death in the other.

This method of healing has determined another vital question. The fact that all absorption and destruction of bone immediately ceases when the reattachment of the soft tissues is secured indicates that the local seat was not in the bone, but its reconstruction proves beyond any doubt that the seat of the disease is in the pericementum and not in the alveolar process. We must therefore change our terminology. Pyorrhea is never an alveolar disease, but rather, in all its stages, a pericementitis.

(To be continued.)

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

EDITORIAL DEPARTMENT.

ORIGINALITY—PRIORITY.

WE publish elsewhere in this issue the full text of the decision handed down by Associate Justice Chas. H. Robb of the Court of Appeals of the District of Columbia, in the case of Taggart *vs.* Boynton, which in effect nullifies the right of Taggart to the claims of his patent under which suit was brought, and renders them null and void within the territorial limits of the District of Columbia. The case has run its devious course through the judicial machinery of the courts of the District of Columbia, and, after sifting and weighing all the evidence in the light of the law of the land in such cases made and provided, the result is as stated. The present decision cannot be taken as final, for there still remains the possibility of suit upon other Taggart patents, or upon the same patent in other jurisdictions, or the possible right of appeal to the Supreme Court of the United States.

Quite apart from all the material interests directly involved, and the emotionality which is apparently an inseparable concomitant of such an incident, affecting as it has the interests of many individuals, there is the underlying ethical problem that in a certain sense is more important than the material interests concerned, in that it raises a question that should be squared with the conscience of every man who owes allegiance to the ethical standard of the dental profession.

The evidence reviewed by the learned judge of the Court of Appeals clearly shows that the principle involved in the Taggart casting process had been employed in a similar way previous to the issuing of the Taggart process patent, and, for the reason that his invention had been anticipated by others, his patent is declared invalid—which is technically in harmony with the patent law. There remains, however, the well-recognized fact that these desultory instances of application of the process of casting under pressure and with the disappearing model were unknown to the dental profession as such; they attracted little, if any, attention—so little that for the defense of the Boynton suit the securing of direct evidence of anticipation in the use of the Taggart casting process was by no means an easy task. On the other hand, immediately that Taggart made known his invention and published it as a well co-ordinated and practical procedure, with an apparatus by which the process could be put into effective and successful use, it was received with almost instantaneous approval by the whole dental profession, and in every country of the civilized world the cast inlay made a place for itself as an accepted and recognized procedure. Moreover, so enthusiastic was the reception, and so far-reaching were the recognized possibilities of the invention, that the ingenuity of its advocates developed applications of the process to practically every department of dental prosthesis. And further, so fascinating was the fundamental principle of the process that ingenuity directed itself toward the creation of new appliances for utilizing it; and to such an extent did success crown these efforts that casting machines multiplied like rabbits, and seemed to spring up overnight like mushrooms, so that one might buy a casting machine at any price from a few cents to as much as one hundred dollars, as his judgment and fancy dictated.

From all of the indications above referred to, we have for some time held the opinion that the cast inlay in its proper place and usage is a good thing, and has apparently come to stay. That being conceded, we are inclined to ask, How did it get here? What was its origin? Who made it possible and practical? Did any outside of a favored and non-favoring few ever hear of cast inlays before the announcement of the Taggart inventions? If they did, and kept their knowledge to themselves, to what credit are they entitled? Did they do their whole duty to their profession—were they strictly ethical in reserving their information until it was needed to prevent the man who made the method possible from securing the reward to which otherwise, under the law of the land, he would have been clearly entitled? We are well aware of the arguments that can be adduced against the iniquity of "professional patents," but "professional patents" is a very comprehensive term—too comprehensive, in fact, to be justly applicable in all instances—and the factor of iniquity is, therefore, a relative one. But the question here under consideration is not the ethics of patent rights from a legal standpoint; it is the moral responsibility of an ethical profession toward a benefactor.

It is presumed that there is no reasonable doubt that Taggart believed himself to be the inventor, the originator, of the process and the appliance known by his name and for which he secured letters patent. The courts have decided from the historical evidence that he was not the first inventor of the process, and as the legal right to protection in the use of his discovery depends upon priority of invention, his right to protection in its use falls. But notwithstanding the legal aspects of the question, it still remains the incontestable fact that it was the ingenuity of Taggart that made the cast inlay possible and practicable, and it was his introduction of the process that made it an accepted dental operation. Therefore we ask, What does the dental profession owe to Dr. Taggart?

Those who view the matter wholly from the legal standpoint will, of course, decide that they owe him nothing. Others, who down in the depths of their souls realize that they owe him much, will consider the obligation more than canceled by the fact that he tested his right to a reward for his service to dentistry by a suit at law; and yet others, whose ethical sense is not measured nor measurable by the restrictions of a so-called code, but is expressed in the spirit and practice of the "golden rule," will forget the emotionalism and personal friction which the settlement of this case has engendered, and remember Taggart as not the least of the benefactors of our profession, and treat him accordingly; for, apart from the question of the legality of Taggart's right to protection under the terms of his patent, apart from whatever exceptions may be taken to his methods in endeavoring to secure to himself the material benefits of his invention, and apart from whatever of friction, ill-feeling, or antagonism have been engendered in testing the involved issues in the courts, there still remains the fundamental ethical question of the credit due to the man who made the procedure practically possible.

In years to come we believe that the credit will be universally accorded to W. H. Taggart;—and if it shall be due him then, why is it not due now?

SIXTH INTERNATIONAL CONGRESS.

The Committee of Organization is now engaged in the preparation of the preliminary details incident to the holding of the Sixth International Dental Congress in London in 1914. It will be held at the University of London, August 3d to 8th inclusive, 1914. His Majesty King George V has accepted the patronage of the congress. Announcement is made at this early date so that those from America who are expecting to attend the meeting may have ample time in which to make the necessary preparations. For the reason that this great gathering will be one of the most important congresses of the international series, and because of the unusual attractions, both in a professional and a social way, which it will afford to American dental practitioners, it is hoped and expected that a large and representative contingent of American colleagues will arrange to attend the London meeting.

Correction.—Dr. Geo. B. Harris desires to make the following correction in his paper, entitled "The Treatment of Pyorrhea by Bacterial Vaccines," published in the April issue of the Dental Cosmos: Page 392, *for* "(5) Pyorrhea is contagious;" *read* "(5) Pyorrhea is infectious."

Bibliographical.

An Introduction to Dental Anatomy and Physiology, Descriptive and Applied. By Arthur Hopewell-Smith, L.R.C.P.Lond., M.R.C.S. Eng., L.D.S.Eng., Prizeman of the Royal Coll. Surgeons, Lecturer Dental Anatomy and Physiology, Dental Surgeon, and Demonstrator Prac. Dental Histology, Royal Dental Hospital; Member Faculty of Medicine, University of London, etc. Large octavo, 372 pages, with 340 new and original illustrations, including a frontispiece in photogravure and 5 plates. Cloth, $4.00, net. Philadelphia and New York: Lea & Febiger, 1913.

In the preface, the author states the purpose of his book, namely, to furnish the advanced student and the dentist with a knowledge of the anatomy and physiology of the teeth—it being a fact that these subjects have to a certain extent been crowded off the modern dental curriculum. The "mission" of the book is to explain how it comes about that man has a certain number of teeth, to describe their functions, plan of attachment, and the rôle they play in the general economy of man.

After outlining his plan, the author makes a plea for the use of certain terms, most of them being in accord with my own belief. Thus: The terms "central" and "lateral" should be dropped, and "first" and "second" used in their stead. Likewise, "six-year" and "twelve-year" molar should give place to the terms "first" and "second." "Third molar" should be used instead of "wisdom tooth." "Premolar" is more descriptive than "bicuspid." "Deciduous" should be used in speaking of the first set of teeth which man develops. The author also recommends the term "occlusion," where the profession has been in the habit of using "articulation." Certain terms suggested for use in speaking of certain malocclusions, however, I do not consider to be as good as those now employed in orthodontia.

Chapter I is devoted to a general introduction to dental anatomy and physiology, with a view to letting the student know some of the questions and problems that can be better understood if they possess a knowledge of the above subject. Attention is called to the various theories of "tooth eruption," and I doubt if very many practicing dentistry today could name the various theories of such an important part of the dental apparatus, let alone describe and criticize them.

Chapter II is devoted to the classification of the animal kingdom. The Teeth in general are taken up, and a definition of "teeth" is attempted. The definition given is no better than that given by Dr. A. H. Thompson, *i.e.* "Teeth are hard, usually calcified substances placed at the orifice of the alimentary canal." There are, however, structures which resemble teeth, found under certain conditions in other parts of the anatomy besides the mouth. Various examples are cited.

The kinds of teeth among the vertebrates, viz, corneous and calcified, are then described, which description is followed by a section on the functions of the teeth, divided into major and minor, the former being further divided into general and specific. It makes little difference just how the functions of the teeth are divided, but it has been my plan to divide into primary and secondary, which method is much simpler and includes everything which comes under the four heads given by the author. The principal function of the teeth is the securing and preparing of the food. In the fish and in lower animals, the teeth are used to secure the food, and are of little use to the animal in preparing it for digestion.

Then follows a description of the foods of the various animals, and an account of the foods of the various races and nations. Probably not enough attention has been paid in times past to the various foods, and their possible relations to dental lesions. As a function of the teeth is mentioned the development of the face, following which the statement is made that "A study of this quesion is, however, wanting, and definite statements cannot yet be made as to their precise rôle in this respect." It would have been well if the author had been familiar with the work done by the American Society of Orthodontists. Speech as influenced by the teeth is well explained, although the citing of different opinions is liable to confuse the student. Under the head of "minor functions of the teeth" are placed some of those functions which relate to the preparation and securing of the food, viz, prehension and the use of the incisors as seen in the rodents. These functions belong to primary use of the teeth, for they help the animal to secure its food and thereby prolong life.

Chapter III is devoted to the Number of the Teeth and their various shapes in the different classes of animals, the relation of the teeth to the osseous structures, along with the notation of the same. Supernumerary and missing teeth are taken up, and a number of radiographs are shown.

In Chapter IV is treated the Morphology of the Teeth, with the modifications of the cone, flat plate, prism, cylinder, and blade. Fish, reptiles, and mammals are described, with the forms of the incisors, canines, premolars, and molars.

The reasons of the morphological variations are considered as an answer to the question: "What has brought about these variations in dental shape and pattern?" Inheritance is mentioned, and considerable space is given to "adaptive modification," in which examples are cited of different teeth being adapted to certain functions and purposes. The difference between the non-poisonous and the poisonous snakes, and again, the incisors of the kangaroo, are among the good and interesting examples cited. Types of dentition of the carnivorous, herbivorous, insectivorous, and omnivorous animals receive attention.

"Darwinia" is the title of Chapter V, in which is given a short review of Darwin's work and its application to the teeth. Natural and sexual selection are considered: "The males choose the handsomest of females in one class of animals, and the females choose only the handsomest males, and so on. The rise of the human race is largely due to the advanced sexual selection which our ancestors exercised in choosing their mates. It is possible that sexual selection tends to prevent irregularities of the teeth." This is a grateful change from the old theory that sexual selection or mixing of types produced all sort of malocclusions. However, much of the satisfaction derived from the above statement is lost when we read under the title of "A Typical Dental Heredity" the old arguments of the inheritance of supernumerary teeth, altered character of the jaws, and even the most foolish of all, the inheritance of large teeth and small jaws. As is always the case, there is no explanation of how the above conditions could be brought about.

Evidences of the mutability of species, proofs of derivation of species, make other topics for consideration; post-Darwinian theories, the Mutation theory and the Mendelian theory, with the results of experiments, make valuable additions to this chapter. While I could suggest additions and changes in the arguments presented, I believe that the above chapter is one of the most valuable in the book for the advanced student, as it will cause him to think and perchance read and investigate the subject farther, as a result of which a great good will have been done.

Chapter VI contains a consideration of the Implantation and Replacement of Teeth, which have always been considered as "attachment" and "succession" of teeth by the American writers; I doubt if the English terms are better than the American. Each class is considered in its order.

Chapter VII treats of Homology and Analogy, which must have a place in a work of this nature.

Evolution of the Mammalian Crowns is the title of Chapter VIII. This chapter makes interesting reading, as does anything on this phase of dental anatomy. There is, however, one objection as regards a text-book for the student in college; that is, so many different theories are advanced, without the author settling upon any particular one, that the reader will become confused, unless he has a good knowledge of the subject before beginning. The concrescence theory and the tritubercular theory are given, and the objections and proofs in favor of the same are cited. The old terms antero-external, antero-internal, postero-external, postero-internal, and postero-median are used, instead of the more modern much-used terms mesio-buccal, disto-buccal, mesio-lingual, disto-lingual, and distal. I would be in favor of the dental profession adopting the terms protocone, paracone, and metacone for the upper cusps, and protoconid, paraconid, and metaconid for the lower cusps; but never the antero-external, postero-median, etc. The evolution of the teeth can be better understood if the theory of radiation and mutation is also given some consideration.

The Teeth of the Primates and Prehistoric Man are discussed in Chapter IX. Descriptions of the Heidelberg jaw, the Neanderthal skull, the man of Spy, the *Pithecanthropus erectus,* the Galley Hill man, the Ipswich man, the Tilbury skull, and others are given, along with the conditions under which they were found. These descriptions are valuable and serve to show the great age of man, and the conditions under which he lived. The various dental and cranial indices are also taken up in this chapter.

Chapter X contains a description of the Anatomy of the Teeth of Man. In one chapter is considered what would make a book of many pages. The objection to this chapter is that the descriptions of the teeth are entirely too brief. One feature which I heartily recommend is the naming of the teeth in preference to the terms generally used. Instead of the right upper central incisors and the right upper lateral incisors, the author uses "the first right maxillary permanent incisor" and the "second right maxillary permanent incisor." Also the "first right maxillary premolar" is better than the first upper bicuspid. The term "occluding" surface is used, instead of "occlusal," the latter term being the better one and more in keeping with mesial, distal, lingual, and buccal. I am aware that an objection will be raised by some of the profession to the use of "maxillary" and "mandibular" series, on the ground that the patients would not understand the terms; and this may be true, as far as the patients are concerned. However, for the use of the profession they are much better than upper and lower.

Speaking of the surgical anatomy of the first maxillary premolar, Professor Hopewell-Smith recommends the extraction of this tooth before eruption for the correction of irregularities. While some men in this country have advocated the extraction of this tooth for the treatment of malocclusions, I know of none who have gone so far as to advocate the extraction before eruption. It is almost needless for me to say that a large number of orthodontists in America have found that the extraction of the first maxillary premolar is never advisable for the treatment of malocclusions.

In various places in this chapter, the terms "from side to side," and "before backward" are used when the terms "mesio-distally" and "bucco-lingually" would be more descriptive. As a rule, the descriptions of the teeth are fairly good, but better descriptions could be given than by saying that the mesial surface of the first right mandibular permanent molar is "roughly triangular, with its apex considerably reduced, and base corresponding with the neck. Convex in both directions, it is more greatly flattened than the opposite surface. Its upper border is furnished with two cusps, which are part and parcel of the two anterior cusps."

The description of the Deciduous Teeth is briefer than that of the permanent teeth, which should not be. If there is need for a good description of teeth, it should be accorded to the deciduous teeth. Every day I am impressed with the fact that few practitioners could tell, if asked to do so, the difference between the maxillary and mandibular first deciduous molars. It is a mistake to say in a modern textbook, "The configuration of the teeth of the milk series is essentially that of the permanent dentition."

The chapter closes with a consideration of the "age changes" of the teeth.

In Chapter XI are considered the relations of the teeth with the mouth and osseous system, the nervous system, the vascular system, and the lymphatic system.

By the mutual relationships of the permanent teeth is meant the occlusion of the teeth. Here again, the author makes use of the terms antero-external and antero-internal, to which I raise the same objection as before. The occlusion of the individual inclined plane of the cusp is not given with the inclined plane with which it occludes. There are also some errors which I hope have been due to the printer, not the author. On Page 235, under E, we find: "The antero-external [mesio-buccal] cusp of the first mandibular molar occludes with the distal ridges of both cusps of the second maxillary premolar in front, and the antero-external [mesio-buccal] and antero-internal [mesio-lingual] cusps of the maxillary first molar behind—" This is correct, but continuing we find—"while the antero-external [mesio-buccal] cusp of the lower first molar [which is the same as the antero-external cusp of the first mandibular molar just described] occludes with the central portion of the morsal [occlusal] surface of the upper first molar, and the postero-external [disto-buccal] with the posterior portion of the morsal [occlusal] surface of the same tooth." It should read: "the postero-external [or disto-buccal] cusp of the first mandibular molar occludes in the central fossa of the first maxillary molar."

Under F the error is as great. I quote from the text: "The antero-external [mesio-buccal] cusp of the first maxillary molar interdigitates with the central sulcus of the corresponding lower tooth in front, and the postero-external [disto-buccal] with the postero-lingual [disto-lingual] and postero-buccal [disto-buccal] cusps of the first mandibular molar and the antero-external [mesio-buccal] and antero-internal [mesio-lingual] of the second lower molar." It certainly would be very difficult to get the cusps into the positions named, let alone call it normal occlusion. The antero-external or mesio-buccal cusp of the first maxillary molar occludes in the buccal groove of the first mandibular molar—that is, the mesio-lingual inclined plane of the first maxillary molar occludes with the disto-buccal incline of the mesio-buccal cusp of the first mandibular molar. The disto-lingual inclined plane of the mesio-buccal cusp of the first maxillary molar occludes with the mesio-buccal incline of the disto-buccal cusp of the first mandibular molar. The antero-internal or mesio-lingual cusp of the first maxillary molar occludes in the central fossa of the first mandibular molar. The postero-external or disto-buccal cusp of the first maxillary molar occludes in the buccal occlusal embrasure between the disto-buccal cusp of the first mandibular molar and the mesio-buccal cusp of the second mandibular molar.

Under G the occlusion of the antero-external cusp of the second mandibular molar is given correctly. The occlusion of the postero-internal cusp, as given, is the occlusion of the postero-external.

Under H it is stated: "The antero-external cusp of the second maxillary molar occludes with the central part of the crown of the second mandibular molar" [which should read, "in the buccal groove of the second mandibular molar"]—"and the postero-external cusp, with both posterior cusps of the second mandibular molar in front, and both the anterior cusps of the third mandibular molar behind." It is the postero-internal or disto-lingual cusp which has the occlusion stated, and not the postero-external [disto-buccal], as stated by Professor Hopewell-Smith.

I am aware that these errors may be printer's errors, but it is unfortunate that so many should occur on one page while dealing with such an important subject as the occlusion of the teeth.

Under the heading "Variations," some of the terms used to express certain conditions are justly criticized, but the terms suggested have been proposed before, and have not been accepted by those who have more to do with malocclusions than any others. Orthodontists realize that their classification of malocclusions and their terms for denoting positions may be faulty, but the classification and terms suggested by Dr. Angle, with slight modifications, are better and more descriptive than any yet proposed.

The relations of the nervous system, the vascular system, and the lymphatic system are taken up, and valuable knowledge for the general practitioner is found in these pages.

The Gingival Region is the title of Chapter XII, under which is considered the character of the alveolar socket of the teeth of man, and comparison is made with some of the lower animals, which is a great help. In order to show the relation of the socket to the tooth, radiographs are employed to good advantage. A number of good photomicrographs are shown, to illustrate the relations of the gingival tissues.

Chapter XIII is devoted to the Development of the Teeth and Jaws. The development of the embryonic structures is taken up, and the development of the different adult parts explained. As a whole, this chapter is very good. There are several disputed points in the development of the jaws of man, and some of the authorities quoted are contradicted by others equally as high. The question as to whether there is any cartilage ossification in the mandible seems to be decided by Professor Hopewell-Smith in favor of the cartilage theory. He even states that the external alveolar border is developed from cartilage, which hypothesis is contradicted by a large number of investigators. Personally, after having studied a large number of specimens made from embryos of various ages, I have never seen any evidence of calcification of cartilage within the mandible or region of the alveolar process.

A description of the growth of the deciduous teeth and the permanent teeth, illustrated by several good half-tones and drawings, completes this chapter.

A very important chapter is that on the Dynamics of Tooth Eruption (Chapter XIV). The different theories of tooth eruption are taken up very thoroughly and analyzed. If nothing else were found in this section, the following statement would be worth the entire space given to this subject: "The socket is subservient to the position of the tooth, and wherever the tooth may chance to get to, there the socket will be built around it." The following theories are given and considered: The "radicular elongation theory," the theory of "bone currents," the "deposition of bone" theory, the "blood pressure" theory, the "epithelial" theory, "gubernaculum" theory, "epiblastic" theory, the "addition of dentin," and the "influence of nutrition." After all of these have been considered, we are confronted with the fact that not one of them explains everything satisfactorily, that probably several or all of them may play some part in the eruption of the teeth, and that the principal factor in the eruption of the teeth is cell metabolism, or physiological growth. And when this has been said, about all has been said that we know—and that is practically nothing. The time of the eruption of the teeth is taken up, and attention is called to the fact that different tables which have been compiled differ greatly as to the time of age and as to the teeth which erupt first. Anyone who has practiced orthodontia for a number of years and has observed the loss of the deciduous teeth and the eruption of the permanent teeth knows the reasons for the difference. The ages vary, and the teeth vary as to which appears first.

Chapter XV contains a consideration of the Functions of the Dental Tissues. The author gives great importance to the function of Nasmyth's membrane, and seems to believe that it has some protective influence upon the enamel, but he also points out the lack of data upon this much-neglected structure. The enamel, dentin, and dental pulp are considered, and valuable information is offered by the comparative study of specimens. The "periodontal" membrane, cementum, and the gums are next taken up in the order named, followed by a review of the sensitiveness of teeth, and dental pain.

Chapter XVI is devoted to comparative dental anatomy, under the title of "Mammalian Dentitions." The following orders are considered: Cheiroptera, Insectivora, Rodentia, Carnivora, Cetacea, Sirenia, Ungulata, Edentata, Marsupialia, and Monotremata. Each order is described more with a view to giving the details of their dentition than to outlining the principles of tooth evolution and the evolution of occlusion, along with the effect of food upon the jaw movements and the resulting changes. A large number of illustrations are shown which are a great help to those who have no anatomical collection available.

This book is one which I would highly recommend to the practitioner of dentistry who is desirous of becoming familiar with the principles of dental anatomy and physiology. It will repay careful reading, and while some of the theories offered are not proved facts, they are the best known at the present time, and will have the effect of causing thought upon that particular subject which may lead someone to attain the actual truth. Probably the greatest compliment I could pay the book is to say that it has been many days since I have read a book I so thoroughly enjoyed.

MARTIN DEWEY.

A HANDBOOK ON SURGERY. Intended for Dental and Junior Medical Students. By ARTHUR S. UNDERWOOD, M.R.C.S.Eng., L.D.S.Eng., late Examiner Royal College of Surgeons of England, etc., and BAYFORD UNDERWOOD, M.B., B.S.Lond., L.R.C.P., M.R.C.S.Eng. Pp. 244, with 19 illustrations. New York: Wm. Wood & Co., 1913.

As an introduction to the subject of general surgery for the dental student this book has some value, as it outlines briefly the principles of surgical pathology, and also the surgical affections of the mouth, jaws, and neighboring parts, such as the eye, nose, and throat. The few illustrations make no pretense to be anything but mere diagrams, and even as such add little value to the book.

R. H. I.

SURGICAL OPERATIONS WITH LOCAL ANESTHESIA. By ARTHUR E. HERTZLER, M.D., Surgeon to the Halstead Hospital, Halstead, Kan., and to the Swedish Hospital, Kansas City, Mo. Pp. 205, with 104 illustrations. New York: Surgery Publishing Co., 1912.

This work covers in a compact manner the subject of local anesthesia. Each drug used for the purpose is taken up in detail, and its advantages and disadvantages in given operations are thoroughly discussed. The author prefers quinin for the great majority of cases, on account of its safety and lasting effects. The technique of all operations to which local anesthesia is adapted is minutely described, greatly enhancing the practical value of the volume. Ten pages are devoted to operations on the mouth and teeth, giving the indications and limitations of local anesthesia in this region. The numerous illustrations and general make-up of the book are to be highly commended.

R. H. I.

Review of Current Dental Literature.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, January 1913.]

CONTRIBUTIONS TO THE MICROSCOPY OF GRANULOMATA AND ROOT-CYSTS. By Dr. F. Proell, Koenigsberg.

In continuation of his researches on the microscopy of granulomata and root-cysts, which were published in the March 1911 issue of the *Deutsche Monatsschrift fuer Zahnheilkunde*, and reviewed in the Dental Cosmos, December 1911, p. 1457, Proell has come to the following conclusions:

Granulomata represent sequestral granulations, presenting the same histological pictures as albuminous periosteitis. Their chief characteristics are increase in tissue fluids, lack of fibrillar connective tissue in the central portions, and extensive accumulation of fat. The abundant fat substances found in granulomata and cysts are not due to the fatty degeneration of connective tissue cells, as Proell maintained in his first essay, but to the increase in tissue fluids caused by vascular alterations. These fatty substances are lying free in the tissue or in macrophages, which are derived from lymphocytic fibroblasts as well as plasma cells. Proof for the mucoid degeneration of the connective tissue as claimed by Partsch and Williger could not be established from stained specimens. Cysts grow by the pressure of the increased tissue fluids and the resulting irritation of the cyst epithelium, and finally by the absolute increase in size of the fat-eating cells.

ACTINOMYCOSIS FOLLOWING EXTRACTION. By F. J. Padgett.

The writer reports of a case of extraction of carious molars under nitrous oxid anesthesia. Three weeks later the patient, a farmer's wife, returned complaining of acute pain in the sockets of the extracted teeth. On examination, the gums were found to be deeply congested and inflamed, but not actually swollen. A poppy-head fomentation and purgative proving unavailing, the sockets were scraped well under nitrous oxid anesthesia, and packed with gauze dipped in a 1:40 carbolic acid solution. The patient returned two days later complaining of continuous pain and inability to sleep. The gums were then repeatedly and thoroughly lanced in the presence of the patient's physician. After several days, the writer was notified by the patient's husband that an abscess had broken out on her face, probably to result in disfigurement for life, and that the dentist must have left one or several roots behind. Suit for damages was threatened at the same time.

A week later the attending physician informed the writer that he had seen the patient, that he had noticed the discharge to be of a yellowish color, and that he suspected actinomycosis. Upon microscopic examination of the discharge, the specific ray fungus was found, and the diagnosis confirmed. Subsequently, a surgical operation was successfully performed.

The ray fungus had undoubtedly entered the wounded sockets. This case teaches a valuable lesson in regard to the post-operative treatment of extraction wounds, especially in rural districts.

[*New York Medical Journal*, New York, February 8, 1913.]

THE MOUTH FROM A DIAGNOSTIC STANDPOINT. By Dr. M. Manges, New York.

Remarking upon the curious trait of human nature that the closer at hand and the more available anything may be, the less it is resorted to, the writer scores the neglect by physicians of mouth symptoms in diagnosis. The mucous membrane, in which constitutional changes manifest themselves at a much earlier period than in other portions of the circulation, offers many diagnostic criteria which are readily detected, and are easily interpreted if one would only make the examination of the mouth part of the routine of physical examination. The proper examination of the oral cavity and all its contents should be made with a spatula or tongue depressor and a good electric light, and should include smelling of the breath—a sweet, champagne-like odor, for instance, indicating acidosis. In acute infections, the mouth manifestations often afford early diagnostic information; scarlet fever, measles, and diphtheria require only mention; but variola, varicella, and rötheln may also have their local or even early manifestations in the mouth. Herpes of the lips is a valuable diagnostic symptom, which is usually associated with a diplococcus, either of pneumonia or of cerebro-spinal meningitis. Chronic infectious diseases, like tuberculosis, syphilis, leprosy, etc., are always recognizable by unmistakable local mouth symptoms. Skin diseases, also, are often associated with lesions in the mouth, and should be divided into two classes, those in which the mouth lesions are only extensions of the process from the skin on to the mucous membrane, and those in which isolated efflorescences appear in the mouth, sometimes before they develop in the skin, and even sometimes without any cutaneous involvement at all. In the first group eczema and erythematous lupus may be mentioned; in the second, lichen ruber planus, pemphigus, multiform erythema, bullous erythema, and herpes iris.

Drug rashes may sometimes appear in the mouth and may cause great difficulty in diagnosis. These mouth lesions occur most frequently with antipyrin, quinin, phenacetin, and aspirin. Finally, angeio-neurotic edema and scleroderma should be mentioned among the skin diseases with oral symptoms.

The occurrence of pigmentation in the mouth is usually associated with Addison's disease, and pigmented plaques are not infrequently found in diabetics and patients suffering from gastro-intestinal disorders or pernicious anemia. Pigmented areas occur in the mouth following metallic poisoning by mercury, lead, silver, and bismuth, each of which are followed by characteristic lesions. In the diagnosis of anemia the pallor of the mucous membrane of the mouth is always noted. The differential diagnosis between pernicious anemia, Barlow's disease, scurvy, acute leukemia, pseudo-leukemia, lymphosarcomatosis, and chloroma, deserves special attention, and cannot be made from the oral symptoms alone. Finally, pyorrhea alveolaris must be mentioned.

In concluding, the writer makes the following remarks, which carry special weight coming from the pen of a medical man:

"We have been singularly deaf to the pleas of the dentists to pay more attention to the subject, and we should heed their statements much more than has been the habit of most physicians. A skilled dentist can tell us much about the general condition of the patient from an examination of the gums, and a good differential diagnosis can be made by them of the incipient stages of diseases like nephritis, diabetes, tuberculosis, gout, etc. Each constitutional disturbance has certain peculiarities in the pyorrheal picture which enable the skilled stomatologist to differentiate them as to their etiology. Therefore the routine examination of the gums should be included in one's inspection of the mouth, and the presence of a pyorrhea should warn us to look for the cause of it. Should we be unable to discover it, the case should be referred to a dentist who is skilled in stomatology, both for treatment and differential diagnosis."

Mouth inspection, the writer contends, is absolutely necessary in the treatment of patients, for of what avail is it to bombard the stomach with drugs and to diet patients, when the real cause of the symptoms lies in a foul mouth, missing teeth, filthy bridges and plates? A long uvula, adenoids, and enlarged tonsils may be the cause of much mischief, and in articular rheumatism, chronic or even acute nephritis, and in all cases of sepsis, the mouth should first be looked into. In the treatment of acute diseases of any kind, keeping the mouth clean is the first and a very important stage.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, December 1912.]

NOMA. By Curt Proskauer, Breslau.

Noma, cancer aquaticus, or cancrum oris is a rare form of gangrenous stomatitis involving especially the mucous membrane of the lips and cheeks, sometimes also of the genitalia. It is one of the most destructive of children's diseases, resulting fatally in from seventy to eighty per cent. of cases. It is observed chiefly in subjects whose vitality has been reduced by the disturbances in nutrition so common in children, by inclement weather, and especially by acute exanthematous diseases, such as measles, scarlet fever, smallpox, whooping-cough, pneumonia, scrofula, rhachitis, tuberculosis, and syphilis—in short, by any weakening disease. Bottle-fed children are more susceptible to the disease than breast-fed ones; there is also a preponderance of the disease in the female, probably owing to her weaker constitution. Only rarely does noma spread from the affected cheek to the other.

The symptoms of the disease consist in pronounced lassitude combined with high fever, and a painful swelling of the entire half of the face without marked discoloration. The swelling is of hard consistence, circumscribed, and exhibits at one portion a tumor, which generally develops from a blister, and is separated from the surrounding tissue by a small red line of demarcation. There is painful involvement of the submaxillary lymph glands, and increased salivation. An extremely penetrating and disagreeable fetor is present, and the oral mucosa exhibits on the affected side an ulcer of dirty brown color. The facial skin assumes a dark blue discoloration, and rapidly undergoes penetrating suppurative necrosis, the affected tissue forming a loosely connected, dirty, dark brown, fatty mass. The destructive process rapidly advances in combination with high fever, chills, and trismus; the patient grows weak very rapidly, the gingivæ and the periosteum of the alveoli become involved, exposing the bone, and the teeth become loose and fall out. In very severe case, the uvula, hard and soft palate, tonsils, tongue, pharynx, and epiglottis are also involved, causing death. In the last stages, some patients become restless, others apathetic, and perish under symptoms of exhaustion and delirium. In some cases death follows hemorrhage from the external maxillary artery.

If the disease takes a favorable turn, the necrotic portions are surrounded by a pale red zone of demarcation, which inhibits a further spread of the destructive process. The necrosed tissue is exfoliated either spontaneously or following treatment, exposing to view a portion of the oral cavity. The hole is gradually filled-in by granulating tissue, the scar generally leaving unsightly disfigurement.

As to the etiology of noma, we know nothing; even in regard to its contagious character views differ widely, although its endemic character has been frequently observed in institutions of all kinds. No specific causative agent of noma has thus far been found, nor has the experimental transplantation upon animals or man been successful beyond doubt. Bacteriologic examination reveals the typical picture of a mixed infection, containing, besides the usual bacterial flora of the mouth, diplococci, streptococci, and especially staphylococci, moreover numerous streptothrix bacilli, varying in shape from short and thick rods to long and thin threads. Of special interest are isolated semicircular bacilli, also a U-shaped micro-organism, as has been described by Perthes.

As for differential diagnosis, only certain forms of gangrenous stomatitis need be considered; but from these noma is readily differentiated by its characteristic development, duration, and symptoms.

The prognosis, as has been shown, is very unfavorable, death ensuing in from 70 to 80 per cent. of cases within from one to three weeks, although one case of seven months' duration has been reported. Recurrence of the disease is rare. The involvement of internal organs is another unfavorable factor in the prognosis, as pneumonia, pleuritis, or pericarditis, also severe diarrhea, are generally present.

The therapeutic treatment consists in raising the patient's vitality by plenty of fresh air, good nutrition, and heart tonics. The local seat of the disease can be favorably influenced only in the first stage. Caustics such as hydrochloric acid, nitric acid, caustic potash, and carbolic acid are indicated, for local applications, in combination with antiseptic mouth-washes. Partsch recommends primary excision with the scalpel and subsequent cauterization of the wound edges with 8 per cent. zinc chlorid solution. The wound is then packed with moist iodoform gauze. The Paquelin thermo-cautery is contra-indicated. Isolation of the patient is necessary.

The author adds to his comprehensive treatment of this fortunately rare affection the history of a case treated by him, illustrating his report by eight very clear and instructive photographs.

[*Oesterreichisch-ungarische Vierteljahrsschrift fuer Zahnheilkunde*, Vienna, January 1913.]

THE QUESTION OF EXTRACTION IN ORTHODONTIA. BY DR. EMIL HERBST, BREMEN.

Herbst, who wishes to assume an intermediary position between Angle and Case, and who gives both their deserved liberal share of recognition, states the following rules for extraction in orthodontia: Extraction can be resorted to—(1) In pronounced protrusion, if no results are obtainable within reasonable time by the application of intermaxillary bands. (2) In prognathism, when in the lower jaw the majority of the teeth have been lost by early extraction, and the lost space can no longer be restored, generally on account of advanced age. (3) In lateral anomalies of the bite, viz, subdivisions of Angle's classes II and III, if the patient can be saved great inconvenience by the extraction of a bicuspid, which will generally remedy the condition. (4) In cases where the teeth present are out of all proportion with the rest of the body, which has undergone defective development, and where a preservation of the teeth would continue to disfigure the patient. (5) In open bite, which can be considerably improved by extraction of the last molar. (6) In weakly, backward children who could not very well tolerate prolonged orthodontic treatment. (7) In excessive number of teeth the extraction of which will harmonize the number of teeth in either jaw. (8) In deficient number of teeth, if by extraction of teeth in the opposite jaw a harmony in the number of the teeth in either jaw and subsequently greater masticating efficiency can be produced without impairment of appearance. (9) In serious pathological conditions when the preservation of certain teeth is contra-indicated. (10) In secondary anomalies, especially in advanced age, when tooth regulation is hardly possible any longer, and the success of such regulation would be out of proportion with the time and efforts required. (11) In anomalies of the teeth themselves, such as gemination, fusion, peg-shaped and hypertrophic teeth, interfering with articulation and marring facial beauty. (12) In anomalies of the jaws when mobility of the intermaxillary bone, cleft palate, or semi-hypertrophy of the jaws justifies the extraction of teeth for hygienic or esthetic reasons.

This list, while not intended to be perfect, shows that so many reasons may oppose the ideal postulate of normal occlusion, and that this postulate can no longer be maintained. Individualization cannot be dispensed with in orthodontia.

As examples in which extraction is absolutely contra-indicated, Herbst cites the following: In case of nasal obstruction the preservation of all teeth is necessary in order to retain the normal width of the upper arch after it has been brought about by expansion. The extraction of molars in the hope of bringing about an improvement in the position of the anterior teeth by nature's own regulating forces is a fatal mistake. If anomalies have been brought about by habits in children, the defect must always be corrected by orthodontic means.

Herbst insists that the categorical demand of normal occlusion and the categorical condemnation of any extraction whatever are two extremes to which no thinking practitioner will unconditionally subscribe. While recognizing the beneficial influences of the so-called new school of orthodontia, he maintains that, after all, its doctrines have simply been borrowed from the old school and perfected and enlarged, and that no absolute distinction or contrast exists between the two schools.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, October 1912.]

THE FUTURE OF DENTISTRY IN WARFARE. BY DR. RÖSE.

[*Deutsche Militaeraerztliche Zeitung*, Berlin, October 20, 1912.]

CARE OF THE TEETH IN THE GERMAN ARMY. BY DR. TUESHANS.

In these days of practical dental hygiene in all sorts of public and private institutions, the above papers, written by members of the medical staff of the German army, are of timely interest. Röse in his paper points out the inadequate provisions for dental treatment that existed during the Franco-German war of 1870-71, and refers to the official reports of some twelve thousand injuries to the jaws, the repair of which was anything but satisfactory from the point of view of function as well as of esthetic appearance. Since then, dental technique has made wonderful progress, yet with it the tendency to injuries of the jaws has also greatly increased, owing to modern methods of warfare. Albert, for instance, estimates that of the total number of injuries to the head about twenty per cent. involve the jaws, more frequently the lower one. Dr. Hashimoto, a Japanese physician, puts the injuries to the jaws at 44 per cent., which figures are largely accounted for by the kick of the modern high-power rifle, the use of quick-firing arms, explosive projectiles and hand-grenades, and by the fact that in engagements under fire only the head is visible. Ordinary surgical procedures are by no means sufficient for the setting and immobilization of the lower jaw especially, and every army surgeon should therefore know how to apply all kinds of jaw-bandages and splints. A certain amount of familiarity with dental technique is also necessary for certain prosthetic appliances that may be indispensable in the treatment of injuries of the face, mouth, or jaws. In the Russo-Japanese war, the Japanese treated fractures of the face bones by means of fixation of the fragments by the methods employed in compound fractures; resection was resorted to only in cases of severe splintering of the lower jaw. An aluminum splint, suggested by Dr. Hashimoto, was largely used, these splints being kept in stock in several sizes, so that only comparatively minor changes had to be made for each individual case. Since the war, the German army regulations provide for two dentists for each army corps, these dentists ranking as superior officers, with the duties and privileges of such, and being attached to the military hospitals. A dentist was sent with the German expedition to the far East, and two dentally trained health officers and one dentist accompanied the German troops during the Southwest African campaign.

Dental services, however, are obviously needed by the soldier, quite apart from the exigencies of actual warfare, and although up to the year 1907 there was no regular organized military dental service, several army corps have now a regular dental station, and a propaganda is on foot for appointing a dentist to each regiment. While considering these demands excessive, Röse urges a large number of most practical reforms, such as a local anesthesia outfit as indicated by Guido Fischer. Every medical officer, he suggests, should be trained in the technique of local injection, in order to minimize the soldiers' fear of dental operations, and relieve them of pain caused by exposure to wet or cold. During actual campaigning little dental work except first aid and temporary relief can be done in the flying field hospitals, but at the base hospitals and at transport stations and forts, dentists and dental mechanics should be available. The author in this lengthy and most interesting paper goes into a number of most valuable details in regard to organization, in peace and warfare, therapeutic and prosthetic methods, instrumentarium, etc., which deserve serious consideration by all those who are intrusted with the dental welfare of soldiers, according to the classic saying of Frederick the Great: "Our warriors deserve to be taken care of, because they are staking life and health for their country."

Reviewing the present state of dentistry in the German army, Tueshans states that of a large number of soldiers whom he examined, only six per cent. were found to have perfect teeth. Before the new regulations were in effect, it was noted that of 450 recruits examined annually each man on an average had five carious and two missing teeth. All non-commissioned officers and regulars can now obtain dental treatment when ordered by a medical officer. When this treatment cannot be given by a dentally trained medical officer in the garrison hospital, it is provided under contract by fully qualified dental surgeons. At present, there are twenty-five army medical officers specially qualified in dental surgery, and dental divisions have been established in twenty-two of the large military hospitals. During the year 1910-11, there were 23,500 attendances in the dental divisions, although some of these divisions were only opened late in the year. Artificial dentures are supplied only when teeth have been lost in and by military service, and under certain conditions preventing a man from being efficient owing to the loss of teeth.

[*Le Laboratoire et Le Progrès Dentaire*, Paris, September 8, 1912.]

PROTECTION OF THE ROOT-APEX IN FILLING ROOT-CANALS OR INSERTING PIVOT TEETH. By H. Leger-Dorez.

The writer introduces into the thoroughly cleansed and sterilized root-canal a delicate point of lead reaching just a little short of the apical foramen, after having slightly heated it and passed it through sterile thymolated paraffin throughout its length, and having built up with the same paraffin compound the small portion of the lead point which it lacks in order to reach to the very apex of the tooth. After thoroughly drying the root-canal with hot air, the lead point is coated with Harvard cement mixed to a creamy consistence, the cement, however, not being allowed to cover the small point of paraffin. The root-canal point is then inserted with pliers, and the cement is allowed to set for twenty-four hours, or, if desirable for the sake of observation in doubtful cases, for several days. If a pivot tooth is to be set on the root, a hole for the pivot can be easily and safely drilled through the lead.

If no reaction has taken place in the root after correct extirpation of the pulp under aseptic precautions, a pivot tooth may be directly employed as a root-canal filling, by treating it in the same way as described for the lead point. The hot-air blast applied to the canal heats the tooth sufficiently to melt the paraffin, thus hermetically sealing the root-apex.

Periscope.

"Truing" Carborundum Stones.—The stone is mounted on the mandrel and placed in an old handpiece. Then the stone is held against a lathe-stone in lateral position so that it will rotate in the handpiece, which operation will true the stone in a half-minute. This will save time and trouble.—H. T. McCune, *Dental Digest*.

Removing Enamel from Occlusal Surfaces of Teeth in Preparation for Crowns.—Two, three, or four knife-edged carborundum disks are mounted together, and grooves are cut as deep as the thickness of enamel to be removed. By keeping the disks moist, this can be done almost entirely without pain. With a chisel placed in the grooves, the entire occlusal surface can be chipped off.—H. A. Mares, *Dental Review*.

Prevention of Irritation by the Mouth-mirror.—When operating upon second or third molars, irritation by the mouth-mirror when corners of the mouth are irritated or chapped, can be prevented by winding absorbent cotton around the handle near the glass, and moistening it with an antiseptic solution; or the mirror may be detached from the handle and a piece of thick rubber tubing slipped on.—W. I. Prime, *Dental Digest*.

Interchangeable Pin-Facing in Crown and Bridge Work.—The ordinary facing is backed in the regular way and then waxed up with inlay wax to the desired shape, or the facing can be waxed up without backing.

The porcelain facing is removed and carbon points are inserted in the pinholes left in the wax. The form is then invested and cast in the usual way. The carbon points are then removed, and the facing is cemented to place. Carbon points for this purpose may be obtained at any dental depot.—C. A. Priest, *Dental Summary*.

Insufficient Retention a Cause of Failure in Orthodontia.—One of the most frequent causes of failure in the treatment of malocclusion is inattention to the fundamental requirements of post-treatment maintenance. Progress in this phase of treatment has been quite marked, and many of our earlier difficulties have only recently been overcome. The most practical and concise statement of the problems here involved is as follows: Post-treatment maintenance must be so designed as to provide for (*a*) maintenance of tooth position, (*b*) of arch form, and (*c*) of arch relation.—B. E. Lischer, *Dental Review*.

Natural-Looking Bridge Work.—In cases where there has been much recession of the alveolar process owing to loss of teeth, the most artistic results can be obtained by shaping the porcelain substitutes in such a manner that the crowns are of the same length as the crowns of the natural teeth on each side of the space, and by cutting the balance of the porcelain to simulate the roots as they would appear in cases of recession of the gums.—O. DeF. Davis, *Dental Review.*

Extraction of Lower Bicuspids.—A good method to be pursued in the extraction of the lower bicuspids is this: After having grasped the tooth as far down below the neck as possible, the forceps should be tightly closed, then, starting with the usual out-and-in motion, traction should be applied. If this should not show results, a fresh grasp of the tooth should be made lower down, if possible, always bearing in mind the danger of injury to the vessels coming from the mental foramen, or of fracture of the bone if we go too low. Having secured a fresh grasp, the forceps are closed so as to cut through the intervening process; then, being quite sure that the process is cut, the forceps are rotated strongly, at the same time applying traction. If the force be applied carefully and persistently, the root will probably be removed.—J. F. Hasbrouck, *Items of Interest.*

Rosin Dissolved in Chloroform for Root-canal Filling.—Dr. J. R. Callahan of Cincinnati, Ohio, recommends first filling the cleansed and dehydrated root-canal with a solution of one part rosin in three parts chloroform, pumping it thoroughly into the canal. This is allowed to remain a few minutes, and then the surplus is removed with paper points, and the canal filling is completed with a rosin solution, to which sufficient pink gutta-percha has been added to make it of the consistence of chloro-percha as usually used. When using the rosin solution, in preparing the canal for filling, he uses chloroform instead of alcohol. He claims to be able by this method not only to fill the canal perfectly, but also the tubuli right up to the cementum. The rosin, he states, remains hard and insoluble in the body fluids, and makes a permanent and safe root-canal filling.—*Dental Brief.*

Inlay for a Compound Cavity Involving the Incisal Edge Without Step.—It is often desired to place a gold inlay involving the approximal side and incisal edge without sacrificing the sound structure of the tooth to make a step. This may be done by placing an iridio-platinum post near the incisal edge, after the inlay has been completed. The inlay should have a wide, deep groove carved in the approximal surface extending from near the incisal to the gingival margin. This should be done in the wax model. This groove is to pass over the iridio-platinum post, when the inlay may be set from the incisal edge without interference from an approximating tooth. An extension of this iridio-platinum post may be made for additional retention in the groove of the inlay. Since the inlay model is completed before the incisal retention post is provided, there is absolutely no interference with the removal of the model. The retention post fits loosely in the tooth and in the inlay, until cemented. Post and inlay are both set with the same mix of cement.—H. C. Dean, *Dental Summary.*

Method of Reinforcing Plaster Casts.—Many times we find that when our models are made they are very thin, too thin and weak to withstand the pressure necessary in closing the flask. We also find abutments breaking off the model in bridge work, etc. An easy, cheap, and sure method to overcome this difficulty is to get some brass wire gauze, to be found at all tin shops—this gauze is used for milk-strainers, etc. For reinforcing crowns used as abutments in bridge work, a piece about one-half inch long and one-half of the size of a lead pencil is rolled up, and after dipping it into water it is gently worked into the crown, when pouring the investment in to get the model. If a lower impression has a very thin ridge, and the operator ready to make the model, a piece of the gauze is cut, about two inches wide and long enough to go from one end of the model to the other. Then the gauze is folded in the middle and as the plaster is being poured into the impression the smooth edge of the gauze, not the cut edge, is worked into the plaster, holding it for a moment until the plaster begins to set.—J. M. Prime, *Dental Brief.*

The Use of Elevators in the Extraction of Fractured Roots.—In the case of a multi-rooted tooth, when one root is completely extracted and another root is broken off too low down to be safely grasped with the forceps, the extraction may sometimes be completed by using one of the various elevators. By so placing the elevator that the bone will act as a fulcrum, with the edge of the elevator against the root to be extracted, and by a proper manipulation of this instrument so that the force will be applied to the root along the proper line, the extraction may be accomplished. To use the elevator properly, the handle should rest in the palm of the hand with the index finger extending along the shank of the instrument, and the operation should be performed by a manipulation of the instrument in such a way that, if the elevator were not there, one would have performed the operation with the tip of the index finger. By placing the elevator in an empty root-socket, and applying force, as above stated, the broken roots adjoining will be removed, together with the septum between, which does no harm at all, and under some conditions is very much to be desired.—J. F. Hasbrouck, *Items of Interest.*

Oral Sepsis, with Special Reference to Antiseptic Properties of Tobacco.—The chewing or smoking of tobacco, the former more so than the latter, is decidedly germicidal in laboratory experiments, though the results of examinations of a small number of mouths would seem to give the use of tobacco somewhat less, though still noticeable, effects practically; by exercise of the teeth it helps their nutrition and eliminates pathologic organisms, both by destroying them *in situ* and by removing them in the expectoration. Of seventy-four males examined, twenty-three, or 31 per cent., did not use tobacco in any form; twenty-six, or 35 per cent., smoked only; nine, or 12 per cent., chewed only; sixteen, or 22 per cent., both smoked and chewed. Of this number only twenty-three, or 31 per cent., took any care of their teeth. Of those who brushed their teeth, 43 per cent. showed a marginal gingivitis as compared with 82 per cent. who took no care of their teeth. Of those who did not use tobacco, 74 per cent. showed pus under their gums, as did 69 per cent. who smoked, 77 per cent. who chewed, and 68 per cent. who smoked and chewed. Fullerton says that these results, though bearing out in the most part that tobacco is toxic to bacteria, are not nearly so striking as one might expect, and one might with considerable certainty argue that, with the same individuals and the same lack of care, the conditions might be much worse without the use of tobacco. Of twenty-two women, none of whom used tobacco, twenty, or 90 per cent., brushed their teeth, 50 per cent. showing a gingivitis.—H. D. Fullerton, *Cleveland Med. Journal*, per *Journ. of the Amer. Med. Association.*

Sulfuric Acid in Difficult Cases of Pulp Devitalization.—Everyone is aware of the difficulty of devitalizing a pulp in which nodules exist. It is here especially that the use of sulfuric acid is indicated. If an application of this acid is made, less pain is experienced, and this is always of shorter duration than when arsenic is used. At the next appointment the pulp nodule will be clearly seen, and in the majority of cases it will be found to be quite loose. The acid has not only broken up the surrounding pulp tissues, but the nodule has been slightly dissolved, which makes it readily removable.

In making the application a minim dropper is used, taking up but half a drop of the acid at a time. Care should be exercised in order that not too much acid is used at a time. When the floor and no more has been flooded, a smooth iridio-platinum, or preferably a tungsten broach, is employed to gently puncture its way into the canal. It is a good plan to have a glass of saturated soda solution always at hand in the cabinet in case of an overflow of acid from the cavity. It will be noticed that just as far as the broach penetrates the pulp is disorganized and easily taken out. This is quite different from the action of carbolic acid when used for removing the apical third. The carbolic acid coagulum is slow in losing its sensation, and is difficult to remove.

The strength of acid used for this purpose should be above 75 per cent., which will act upon cotton. When, therefore, a dressing of this strength of acid is to be left in for any length of time, asbestos wool, not being acted upon to any extent by the acid, will serve instead of cotton.

As soon as tungsten broaches can be had in suitable sizes we will have a metal almost as stiff as steel, and one which is not acted upon by sulfuric acid.

In summing up, sulfuric acid from 75 to 90 per cent. pure is indicated as a devitalizing agent when arsenic fails and is especially useful when pulp nodules are present.—L. E. Custer, *Dental Summary.*

Diseases of the Mouth and Rheumatism.—Goadby's researches have been directed to determining the special mouth organism causally associated with various arthritic symptoms; mouth diseases or oral sepsis, to use a generalized term, were so frequently complicated with chronic arthritic changes that the clinical association appeared undoubted. Typical cases were therefore selected, and the bacteria isolated from the oral secretions and tested on animals for virulence, by intravenous, subcutaneous, and intraperitoneal injections. In some cases the animals died from generalized infection; in others pus formation and local abscesses were produced, but no rheumatic symptoms appeared. Considerable difficulty was at first experienced in devising a suitable culture medium, as well as a proper standard of alkalinity for the growth of all mouth organisms. Finally this obstacle was overcome, and the majority of the bacteria obtained in pure culture. A series was then tested against the blood of the patients, and those organisms regularly showing alteration in the opsonic index were selected. Inoculations were made with these into the joints (knee), and into the periarticular tissue of rabbits. One type of organism produced chronic swelling of the synovia and membranes, while in a few instances, definite bony changes followed. The organism obtained from the majority of the mouth lesions in arthritic cases, and which produced these changes in the joints of inoculated animals, is a streptobacillus, which Goadby has provisionally termed the *streptobacillus malæ.* It resembles in its morphology, but not in its cultural characters, the streptobacillus described by Ducrey as the cause of soft chancre. In many ways the organism resembles a streptococcus, but is easily differentiated from the streptococci by its morphology and cultural characteristics. Goadby is convinced that diseases of the gums account for a certain, perhaps a very large number of cases of arthritis, namely, those of apparently bacterial origin with no obvious infective focus. Lambert states that in 172 cases of rheumatoid arthritis where special inquiry was made for an infective focus, 141 of the patients (76 per cent.) had badly decayed teeth, or the teeth had dropped out.—*London Practitioner,* per *Journ. of the Amer. Med. Association.*

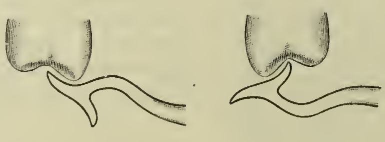
HINTS, QUERIES, AND COMMENTS.

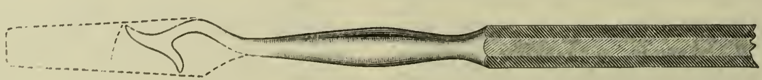
A HOME-MADE INSTRUMENT FOR CARVING WAX MODELS IN CAST INLAY WORK.

A BROKEN cement spatula can be converted into a handy instrument for carving wax models in cast inlay work.

The lower figure shows how the carver is cut out of the spatula by means of a carborundum wheel. The edges of the beaks are square, so that they will shave off the wax, while the points are rounded to make smooth indentations.

In making large contour inlays, where it is necessary to restore the cusps and fissures of the lost tooth structure, the carver can be used as shown in the upper figures. By simply turning the handle, one can carve first one cusp and then the other, at the same time also carving the fissures between them.





Plaster models can be carved in the same manner.

BERNARD FISCHLER, D.D.S.

Brooklyn, N. Y.

RECOVERING MAT GOLD FROM OLD GOLD FILLINGS.

Old gold fillings that have been saved until there is about one-half ounce of material are melted with the blowpipe, and the ingot is rolled or hammered until a large surface is obtained; then a fine platinum wire is soldered or swaged to this gold. The wire is connected with the carbon pole of a dry cell, while to the other pole a thin strip of platinum is attached. The gold and platinum are placed in a shallow dish filled with chemically pure hydrochloric acid. The acid soon turns yellow, and after it has been saturated with gold, a deposit is formed on the platinum strip. This deposit consists of very fine crystal gold, which, after having been washed thoroughly to remove all traces of the acid, dried on blotting paper, and annealed on a sheet of mica, is as serviceable for filling purposes as any other mat gold.

Obituary.

DR. D. R. STUBBLEFIELD.

Died, at his home, Nashville, Tenn., on March 12, 1913, David R. Stubblefield, B.A., A.M., M.D., D.D.S., in his fifty-seventh year.

Although he had been in ill-health for some time, Dr. D. R. Stubblefield's demise came as a shock to the host of his friends, both social and professional; for the deceased was one of the most popular and beloved men in Nashville, and his position as a teacher and his connection with many dental and literary societies had spread his reputation throughout the country.

Dr. Stubblefield was born at Jasper, Tenn., in 1856, and received his education at Emory and Henry College, Va. In 1876 he received his B.A. degree, and on account of his excellent work was honored with the A.M. degree. He was graduated from the medical department of Vanderbilt University in 1878, and from the dental department of the same institution in 1882. In 1879, when this dental department was organized, he had been called to the chair of anatomy and physiology. He practiced medicine until the spring of 1883, when he changed over to the practice of dentistry. Immediately upon his graduation he was elected president of the Tennessee Dental Association, and subsequently became president of the National Institute of Dental Pedagogics. In 1900 he was elected dean of the dental department of Vanderbilt University, which position he held until forced to retire by ill-health. He was treasurer of the dental department from the time of its organization until his call to the deanship, also treasurer and vice-president of the Athletic association of the University. The latter position he held up to the time of his death.

The deceased was an ex-president of the Vanderbilt Alumni Association, and altogether rendered to the university thirty years of indefatigable and most efficient service, in recognition whereof, following his retirement from his activities, he was honored by the conferment upon him of the title of emeritus professor and dean of the department of dentistry of Vanderbilt University.

Before his health began to fail, Dr. Stubblefield was much in demand as a lecturer and demonstrator at dental meetings throughout the South. Among many other honors that were conferred upon him was the presidency of the Old Oak Club, a prominent literary organization of Nashville.

Dr. Stubblefield was married to Miss Hettie Wilkins of Nashville, who, with three sons and one daughter, survives him.

Interment was made at Mt. Olivet Cemetery, the faculty of Vanderbilt University and many dentists serving as pallbearers.

DR. HENRY A. HULL.

Died, at his home, New Brunswick, N. J., March 5, 1913, of pneumonia, Dr. H. A. Hull, in his eighty-second year.

Henry A. Hull was born at Columbia, Pa., October 19, 1831, and was the eldest of four sons. He traced his genealogy back to George Hull, ancestor of the Hulls of Fairfield county, Conn., who sailed from Plymouth on the ship "Mary and John," and arrived May 30, 1630, at a place on Nantasket, afterward called Hull in honor of Joseph Hull, brother of George Hull. His paternal great-grandfather was Jedidiah Hull, prominent in the military record of the invasion of Canada in 1758 and during the Revolution.

At the early age of thirteen years he left school to clerk in his father's store, and at the age of eighteen, becoming interested in dentistry, placed himself under the tuition of Dr. James F. Stratton of New York City. In the early part of 1852 he engaged as an assistant to A. D. Newell, M.D., of New Brunswick, N. J., who was at that time one of the most skilful dental surgeons of the state. Two years later he opened an office in Rahway, N. J., practicing there until the outbreak of the civil war, when he was moved by the spirit of his ancestors and enlisted in the 11th Connecticut Volunteers, being mustered into service on October 3, 1861. He was soon promoted to corporal of company I, and was subsequently transferred to company D as first sergeant. Later he was clerk in the Adjutant-general's office at Richmond, Va. Before his first term of service was completed he re-enlisted for three years, and was mustered out of service on December 21, 1865.

After the war, Dr. Hull again associated himself with Dr. A. D. Newell, with whom was now associated Dr. E. W. Robbins, the offices being situated in the National Bank of New Jersey Building. After the retirement of Dr. Newell, and the death of Dr. Robbins, Dr. Jas. G. Palmer joined him, but some years afterward transferred his interest to Dr. Harvey Iredell, who then became a partner of Dr. Hull. A few years later this partner purchased the full practice, which had been in existence for forty years. Dr. Hull then formed a partnership with Dr. W. D. Rice, and carried on the practice at his dwelling until his death.

During his association with the old office, many men who have since been prominent in the dental field were connected therewith, including S. H. Guilford, now dean of the Philadelphia Dental College and the dental department of the Temple University of Philadelphia, Pa., Dr. J. D. Thomas of Philadelphia, specialist in extracting, and the late Dr. James G. Palmer of New York, a specialist in operative dentistry. He had always numbered many of the best citizens of the county among his patrons.

Dr. Hull was a stanch republican, and served New Brunswick in an official capacity for several years. He was a Scottish Rite Mason, also a Knight Templar, was a member of the Mystic Shrine, being past presiding officer in several of its bodies. He was past president of the Central Dental Association of Northern New Jersey and the New Jersey State Society, and was treasurer of the State Society until last summer, when he resigned. He was a Fellow of the American Academy of Dental Surgery of New Jersey, member of the Boggs Janeway Post G. A. R., and many other organizations, at the time of his death.

He married Catherine S. Merrill of Millstone, N. J., who died May 31, 1893. Four sons were born to them, none of whom survived. An adopted daughter brightened their home for several years, until death claimed her in his declining years, leaving him quite alone. In spite of all this, Dr. Hull's genial, sunny disposition won him many friends, to whom he very seldom unburdened his disappointed and lonely life, but made the best of his surroundings. He was a great traveler, and a fund of stories of his adventures was always at his command, he being a keen observer and capable of relating his experiences in the most fascinating manner.

A good man and a true friend has fallen, and while those of us who knew him well keenly feel his loss, we cannot but rejoice in his splendid record of achievement, covering a long and useful life.

"IN MEMORIAM" RESOLUTIONS.

Dr. Wilbur F. Litch.

Following are the preamble and resolutions passed by the American Academy of Dental Science in memory of Dr. Wilbur F. Litch, who was an associate member of the society:

Wilbur F. Litch, D.D.S., M.D., an associate member of this society, died at Philadelphia, December 25, 1912. Dr. Litch was best known to our society through his publications and his school work, for we missed to a large extent his personal contact with our members. Throughout his long and useful life he was always laboring for professional betterment. As a practitioner he was able and skilful; as a teacher, scholarly and effective, and his loss is greatly to be deplored. Be it, therefore,

Resolved, That we spread upon our records this testimonial of his worth, and record our deep sense of a great loss. And be it further

Resolved, That a copy of this resolution be sent to the dental magazines for publication, and a copy sent to his widow.

Eugene H. Smith,
William H. Potter,
Waldo E. Boardman,
Committee.

Brief Necrology.

Dr. Horace A. Davis of Boston, Mass., on March 4, 1913. Deceased was a graduate of the Harvard University Dental School.

Dr. James B. Snyder of Bryan, Ohio, on November 26, 1912, in his fifty-third year. Deceased was a graduate of the Kansas City Dental College.

Dr. Matthew H. McElroy of Newport, R. I., on December 14, 1912, of heart failure. Deceased was a graduate of the Harvard University Dental School.

Dr. William Adair Jones of Bloomington, Ill., on February 28, 1913, in his sixty-ninth year. Deceased was a graduate of the St. Louis Dental College, and for several years demonstrator at the Chicago College of Dentistry.

Dr. Samuel A. Packard of Portland, Me., on December 25, 1912, in his seventy-first year. Deceased was a member of the Maine Dental Association and the Maine Academy of Medicine and Science, also a veteran of the civil war.

Dr. David C. Whaley of Pomeroy, Ohio, on December 30, 1912, of pneumonia, in his eighty-fifth year. Deceased was a graduate of the Ohio College of Dental Surgery.

Dr. Edward Cooney of Brooklyn, N. Y., on March 11, 1913, in his forty-fifth year. Deceased was a graduate of the Dental Department of the University of Pennsylvania.

Dr. Emilio Alvarez of Granada, Nicaragua, on April 5, 1912, of malaria, in his sixty-seventh year. Deceased was a graduate of the Pennsylvania College of Dental Surgery.

Dr. James Munroe Daly of Boston, Mass., on December 27, 1912, in his eighty-third year. Deceased was a graduate of Tufts College Dental School, and a member of the Boston Dental Society.

Dr. James Richard Bell of Cleveland, Ohio, on January 31, 1913, in his fifty-ninth year. Deceased was a graduate of the Ohio College of Dental Surgery, and member of several dental societies.

Dr. Edward Lyman Washburn of New Haven, Conn., on February 10, 1913, of arterio-sclerosis, in his seventy-fourth year. Deceased was a graduate of the Yale Medical School. He was well known to Connecticut dentists as a dealer in medical and dental supplies.

Dr. Rudolph Beck of Chicago, Ill., on March 15, 1913. Deceased was a graduate of the Chicago College of Dental Surgery, professor of dental anatomy at that institution, and a member of the Illinois State and Chicago Dental Societies, and the Odontographic Society of Chicago.

Dr. Henry A. Hull of New Brunswick, N. J., on March 5, 1913, of pneumonia, in his eighty-first year. Deceased was one of the charter members and Fellow of the American Academy of Dental Surgery in 1884, and had filled the offices of examiner, president and treasurer of the New Jersey State Dental Society, president of the Central Dental Association of New Jersey, and was a member of many other dental societies.

Legal Decisions.

THE CAST GOLD INLAY CONTROVERSY.

Washington, D. C., February 25, 1913.

In the Court of Appeals of the District of Columbia:

George W. Boynton, *Appellant,*
vs.
William H. Taggart, *Appellee.*
No. 2426.

Decision.

This appeal involves a decree in the Supreme Court of the District in an infringement suit sustaining the validity of letters patent numbered 872,978, granted December 3, 1907, to William H. Taggart, the appellee, upon a divisional application filed July 12, 1907, of original application filed January 12, 1907.

According to the specification the invention relates to "a new and useful improvement in methods for making molds for dental inlays and the like." It is further stated that these molds are particularly designed for the casting of dental fillings of the type known as inlay fillings, but that "they can obviously be used for certain other types of work of a fine grade, one of their principal fields of usefulness being in the formation of other types of dental metal work, as, for instance, bridge work and the like." Searching the original specification we find that the phrase "certain other types of work of a fine grade" was intended to embrace the art of manufacturing special pieces of jewelry, for it is there written: "The process can also be used in the art of manufacturing jewelry, wherever it is desired to make a single piece of any kind, as for instance where a piece of jewelry is made to order. The manufacturer can carve up a pattern in wax with comparative ease, as the graving operation in wax requires neither the high class of tools nor high manual skill required for graving in metal. . . . . After the pattern is completed in wax the process proceeds as herein set forth and an absolutely perfect duplicate can be obtained." The claims are twelve in number, of which we reproduce the following five as representative:

1. The process of making patterns for dental inlays and the like, which consists in molding plastic material upon the tooth surface to the size and shape of the desired inlay.

3. The process which consists in making a pattern of a tooth filling within the cavity to be filled and in contact with the surface thereof, removing the pattern from the cavity, forming about the pattern a mold provided with a sprue, and melting out the pattern.

6. The process which consists in making a pattern for a cast tooth filling within the cavity to be filled and in contact with the surface thereof, from plastic material capable of being changed from its solid condition, supporting the pattern upon a sprue former, inclosing the pattern in a primary body of mold material, supporting the pattern and primary body of mold material within a flask by means of the sprue former, adding a secondary body of mold material, removing the sprue former and removing the pattern from the mold thus formed by way of the sprue.

8. The process of making molds for casting dental fillings and the like, which consists in forming a pattern of the desired size and shape, forming a mold about said pattern with a depression in the mold adapted to form a crucible, forming a sprue hole extending from the depression to the pattern, and then removing the pattern.

12. The method of forming patterns for casting dental inlays, which consists in forming moldable material to the size and shape of the desired inlay in the cavity to be filled and against its walls.

An examination of these claims discloses that they do not cover nor purport to cover a new process for filling teeth. On the contrary, they relate solely to the process of making *patterns* out of plastic material or wax, and the process of forming a mold about such pattern from which mold a duplicate of the pattern may be produced. The words "dental inlay and the like" as used in the claims of the patent, when read in connection with the specification as they may be read, clearly embrace "bridge work and the like." It is unnecessary here to determine whether they have even broader signification, although as previously stated the specification specially includes "certain other types of work of a fine grade."

To produce the pattern to which these claims relate, an impression in wax or other plastic material is obtained; that is to say, if a tooth cavity is to be filled, wax is first inserted therein, chilled and removed. When thus removed a pattern of the filling has been obtained. Substantially the same process would be followed in obtaining a pattern for a bridge between other teeth. After obtaining this pattern it is put upon a short piece of wire, technically called a sprue former, initially coated with investment material and then enclosed in a secondary layer of investment material. This is allowed to set when it is sufficiently heated to volatilize the wax. The mold is then completed and the gold or other metal may be inserted through the sprue hole.

We will here briefly review the prior art. It is not disputed that the art of producing metal castings by means of a mold formed of a wax pattern is very old. It is in evidence that this art was practiced by the ancient Greeks and Romans and was extensively used in the middle ages for producing statuary and other accurate casts. This process is known as the *Cire perdue* or "Lost wax" process. See Simpson Bolland's "Encyclopedia of Foundings," page 515. It is conceded that Cellini used this process hundreds of years ago in casting one of his most celebrated statues. It is further conceded that the burnished inlay process was also well known for many years prior to the application for this patent. See patent No. 402,352 to Robinson, dated April 30, 1889. In that process a piece of platinum or gold foil is placed in the tooth cavity and rubbed or burnished against the walls of the cavity. The foil, then called a matrix, is usually filled with wax so as to conform to the original shape of the tooth, then removed and precisely the same process followed as in the Taggart process; in other words, the only difference between the burnished inlay process and the Taggart process lies in the use of the foil, which subsequently fuses with the "solder" or lower karat gold. The patent to Hollingsworth No. 708,811, dated September 9, 1902, covers machines for casting dental bridges. The wax pattern in the Hollingsworth process is treated in substantially the same manner disclosed by the Taggart patent, and the casting process disclosed by Hollingsworth in no material way differs from that disclosed by Taggart. The patent to Reese No. 200,760, dated February 26, 1878, covers a mold for casting dental plates. It is thus seen that it was old long prior to the Taggart patent to manufacture dental castings by the Lost wax process.

It is conceded that appellant practiced the process disclosed by the claims of the patent in suit, the defense being the invalidity of these claims. In addition to the prior art as disclosed in the patents to which reference has been made, much testimony was introduced by appellant tending to show that the identical process disclosed by this patent was for more than two years prior to the date of the original application practiced by dentists throughout the country. Of course, if the testimony amounts to proof beyond a reasonable doubt of such prior use, the defense must be sustained, as the claims must fall. Sec. 4886 R. S.; Forncrook vs. Root, 127 U. S. 176; Peters vs. Active Mfg. Co., 129 U. S. 530. We shall here review that evidence.

Dr. Oscar H. Simpson, of Dodge City, Kansas, a dental practitioner since 1882, a graduate of the Ohio College of Dental Surgery, a member of the State Board of Dental Examiners, at one time president of the State Dental Association, and a member of the National Board of Dental Examiners, testified that he gave his first inlay clinic in about 1887 and had since given clinics at Topeka, Wichita, and Newton, Kansas, at the World's Congress of Dentists at St. Louis, and at other places. The witness described his process in inlay work and further described in detail the method he employed in about 1898 to form a dental tip or crown for a boy by the name of Malcolm Judd. Without going into detail it is sufficient to say that the process described by the witness was substantially the process disclosed by the patent in suit. The original apparatus by which the process was practiced was introduced in evidence. Not only this, but the original work, which had been subsequently removed after performing a useful purpose, was also introduced. While this piece of work was attacked by experts for the complainant, we nevertheless are fully convinced that the process by whch it was made was the process disclosed by the Taggart patent in suit. Dr. Simpson gave other instances of employing this process in his practice. He further testified that in the clinic at Wichita, Kansas, in about 1898 or 1899, he described the method which he employed to form the Malcolm Judd tip or crown. In this he was corroborated by Dr. B. L. Shobe, a dentist residing at Bartlesville, Oklahoma, who remembered very distinctly the clinic at Wichita, because he then thought the process adapted to a case which was troubling him. After watching the clinic he returned to his home and tried to practice the process, but failed. He then consulted Dr. Simpson at Dodge City, learned the cause of his failure and was thereafter able to practice the process. In his testimony he gave the names and addresses of different persons for whom he did that kind of work. No matrix was employed in the clinic Dr. Simpson gave at Wichita, the wax pattern coming in direct contact with the tooth. A Mr. Lyle T. Henkel, now a locomotive engineer, an entirely disinterested witness, testified in direct corroboration of Dr. Simpson. From 1893 until March 1897 he studied dentistry with Dr. Simpson, and his testimony is clear and convincing that Dr. Simpson during that time practiced the process disclosed in complainant's patent in making cast inlays for teeth.

Dr. Judson O. Ball, of Mt. Pleasant, Iowa, a dental practitioner since 1880, testified concerning inlay work. In about 1889 he prepared a tooth cavity, then ground a piece of porcelain to fit the cavity and cemented the porcelain in place. This was his first work of that kind. In 1894 a Mrs. Shaffer, living at Merrimac, Iowa, sixteen miles from Mt. Pleasant, came by appointment to have a Logan crown set. The crown had been ordered by mail but had not arrived. The Doctor desiring if possible to complete the work upon that occasion, took a wax impression and from it by practicing the process disclosed by the patent in issue produced a casting which he used successfully. He subsequently practiced the same process in the spring of 1895 in doing work for Dr. A. O. Pitcher, of Mt. Pleasant, Iowa. Sometime between 1895 and 1899 he employed the process in doing work for Mrs. William Gladden, also of Mt. Pleasant. In his testimony he described the work in detail. During September 1903, the Doctor set a large inlay for Mr. F. S. Finley, a lawyer of Mt. Pleasant. This inlay was for the right central incisor decayed on the central proximal, involving both the facial or labial and lingual surfaces of the tooth and also the lower cutting edge surface. After the cavity was prepared, wax was inserted to conform with the labial, lingual, and proximal surfaces of the tooth; in other words, a wax impression of the filling or casting was taken. A casting was then produced by a process substantially the same as that of the Taggart patent. This casting was then cemented in place and has since done service. The original apparatus by which this casting was made was introduced in evidence. The names and addresses of other parties for whom work of a similar character was done by Dr. Ball were given by the witness. Mr. Finley, formerly city solicitor of Mt. Pleasant, Iowa, his home, testified in corroboration of Dr. Ball. He remembered that sometime during the year 1903, when he and Dr. Ball were together in the city council, the Doctor had filled a front tooth for him. The witness was asked what circumstances if any impressed this particular occurrence upon his mind, and replied: "The manner of putting this filling in was impressed upon my mind from the fact that the tooth was prepared and an impression taken of the tooth and the filling cast and cemented into place, which was different from any other filling that Dr. Ball had ever put in for me, and I inquired of the Doctor at the time the filling was put in about the manner of his doing it, and he explained it to me. He told me that he had taken a wax impression of the cavity. I knew that he had done this. He then showed me the apparatus where he had set the wax filling on a point of a cone and put a cylinder over it and then used some substance something like plaster of Paris to get the form of the filling; he then removed the cylinder with the plaster cast, removed the metal cone and explained to me how he heated the plaster cast or the wax in the plaster cast, and how it would come out and leave the cavity. He then filled the cavity in some way with gold, making the cast which was cemented into my tooth. I merely have his explanation as to how he made the filling aside from the fact that I knew he took the wax impression, that the filling was put in in one piece, that he showed me the apparatus where he said he had made it and explained to me the process of making it as I have explained it above." The witness stated that the apparatus which had been introduced in evidence was exactly the same in principle and similar in fact to the one used in making the casting for his tooth. There was no cross-examination of this witness nor was an examination sought to be made of the tooth which the testimony shows had been filled in 1903. One Robinson, who had been Dr. Ball's janitor for seventeen years, also testified concerning the Doctor's use of the process here involved.

Dr. Valentine H. Hobson, of Richmond, Kentucky, testified to the circumstances surrounding the practice in 1889 of the process of the patent in issue. The Doctor subsequently practiced the process for other patients and gave their names and addresses.

Dr. William E. Harper, of Chicago, Illinois, a man of wide preliminary training, testified to casting dental bridges by the present process and to the giving of clinics in 1893 or 1894 in which he explained it. The names and addresses of people for whom he had made cast bridges were given.

Dr. Merrill W. Hollingsworth, who, as we have seen, in 1902 patented a machine for casting dental bridges, and who therefore was thoroughly familiar with the Lost wax process in the manufacture of dental castings, testified to having made bridge castings by the process in issue as early as 1893, the names and addresses of different people for whom he had made castings being given. Dr. Hollingsworth's testimony was corroborated by Dr. George A. White.

Dr. Jacob G. Schottler, of Milwaukee, Wisconsin, a practicing dentist and also a teacher of dentistry, testified to the casting of a gold inlay in 1898 by the process in issue. This casting was for a patient who refused to have the work done in the old way owing to nervousness. The name of the patient was given.

Dr. George W. Blaesser, of Cedarburg, Wisconsin; Dr. Emil M. Kapitan, of Manitowoc, Wisconsin; Dr. John M. Higgins, of Chilton, Wisconsin, all testified in corroboration of Dr. Schottler. A Mr. Thomas H. Savage, a stenographer, testified that Dr. Schottler took a wax impression of one of his teeth that had been broken off and from this produced a tip which was cemented in place. The witness was asked in cross-examination whether he had any objection to permitting an examination of his tooth by a dental expert, and replied that he had not. The record does not show that any such examination was made, however.

We come now to the testimony of Dr. George B. Martin, of Frankfort, Indiana, who has been engaged in the practice of dentistry since 1884. In 1888 Dr. Martin organized the Indianapolis Post-graduate School of Prosthetic Dentistry and was president of the school and also instructor, his subjects including crown, bridge, and inlay work. When he took up the practice of dentistry he was already familiar with the making of patterns for metal castings in other lines of work. The Doctor testified in detail to practicing the process here involved and to the disclosure of that process to his students and others. He introduced in evidence various apparatus by which his work was accomplished. His testimony covers a period from 1890 on. Dr. Blain H. Sellers, of Indianapolis, Ind., who attended the Indiana Dental College in 1891 and 1892 during the time Dr. Martin was an instructor and demonstrator of prosthetic dentistry, testified in corroboration of Dr. Martin. The witness was asked to describe the instruction he received in the casting of bridges and crowns, and replied: "Well, we first took the crown, made the crown to suit yourself—I always did, and then take a piece of wax and place that into the mouth and have the patient bite down onto that, and that would form the bite for the articulation, and then carve the wax any size and shape that we would want the cast itself to be. We would invest that in the plaster of Paris, placing into the wax an instrument to act as a sprue; after that part of the investment became hardened we added to that another on top, and after that had hardened we removed the two pieces separate and then removed the wax from the mold, and we melt our gold and pour it into what we called the die and then place the counter die on top of that, and the impression would form the cast bridge itself." Drs. Cravens and Bloor, both of Indianapolis, also testified in corroboration of Dr. Martin. Dr. Myrom E. LeGalley, of LaFayette, Indiana, who was a student at the Indiana Dental College from 1892 to 1895 inclusive, testified in detail as to the instruction which he then received from Dr. Martin in the art of making cast bridges. The testimony of Dr. LeGalley is clear and leaves no room for doubt that the process of the patent in suit as applied to dental bridges was fully explained to and understood by him during the time mentioned. It was stipulated that Dr. Clarence Williams, of Terre Haute, Ind.; Dr. W. H. Upjohn, of LaFayette, Ind.; Dr. Johnson and Minnie Howes, of Indianapolis, Ind., if called as witnesses would testify exactly the same as Dr.

LeGalley as to the instruction received by them while in attendance at the Indiana Dental College through Dr. Martin, their attendance upon said school covering a period between 1889 and 1897. In addition to these several witnesses Miss Martha Vories, who was Dr. Martin's assistant for about a year commencing in 1897, testified to seeing Dr. Martin practice the process in issue. The testimony of this witness shows that she thoroughly understood the process at the time she saw Dr. Martin practice it.

Dr. Joseph Head, of Philadelphia, Pa., whose article on inlays is incorporated in the "American Text-book of Prosthetic Dentistry," who is a graduate of the Philadelphia Dental College, a graduate in medicine of the University of Pennsylvania, and a man evidently of wide experience and attainments, testified to the casting by him in the apparatus of Dr. Ball, which had been employed in making the Finley inlay, of a cast inlay. Dr. Head says: "I find that the material and apparatus that I employed and which is stated to have been used by Dr. Ball to be capable of producing an inlay as perfect as any inlay I have ever seen." Dr. Head has produced a cast gold inlay which he had made by the use of the same investment compound and apparatus used by Dr. Simpson and to which reference has been made. There is other corroborative testimony in the record, but we do not deem it necessary to review it.

Has the defense of prior use been made out? As no two cases are exactly alike, it is apparent that the character of the invention involved, the prior art, and the particular circumstances surrounding each case must be considered, in weighing evidence of prior use. The contention in this case that Dr. Taggart's discovery was revolutionary in character is not sustained. On the contrary, as appears from the record art at the time Dr. Taggart applied for his patent, dental castings produced by the Lost wax process were well known. Having this in mind, there is nothing improbable about the testimony of appellant's witnesses. Indeed, Dr. Taggart himself according to his own testimony was in full possession of the idea involved in these claims more than ten years before he applied for his patent. The thing that most troubled him and that deferred his patent application was the production of a machine by which the gold could be quickly and easily forced into the mold after its completion; in other words, the process of producing such patterns and molds, generally speaking, was already well known. The real difficulty, therefore, was in producing a device that would quicken the practice of the process and thus induce the profession generally to make use of it. This is apparent from an examination of Dr. Taggart's bill in this case, wherein he states: "Your orator has expended large sums of money preparing for the market machines and apparatus with which the method of said patent can more readily and perfectly be practiced, and is now prepared to supply the demand for such machines and apparatus." The Doctor's testimony also shows, we think, that it was the production of these machines that consumed time, and not the evolution of the process.

The testimony which we have reviewed comes from witnesses whose standing is unchallenged in this record. Several of these witnesses are entirely disinterested. The cross-examination of nearly all of them was confined to a few questions as to the character of the investment material employed, and considerable stress is laid in the brief because one of these witnesses when recalled failed to include in the formula then given an ingredient contained in his former answer to a similar question. We attach no importance whatever to this. In the patent itself Dr. Taggart conclusively disproves the contentions of his counsel that it required any special skill to evolve a formula for investment material, for he says: "The sprue former is then used as a handle to support the pattern and the entire pattern is covered with a primary coating of investing material. *This investing material may be any one of the various dental investing materials on the market.* Moreover, the prior record art contained ample information concerning the investment feature of complainant's patent. The real question which we are called upon to determine from the evidence before us is whether the various dentists who have testified, or any of them, were in possession more than two years prior to the date of the original application for this patent of the idea attempted to be covered thereby, and whether they, or any of them, gave expression of that idea in a practical and public way. It is of no possible consequence that by the use of Dr. Taggart's machine gold inlays and the like may be produced more cheaply and rapidly than they were produced by dentists who have testified. It is enough if those dentists took a wax impression in the manner described by these claims and formed a mold around the pattern thus obtained, for the purpose of casting a dental inlay or the like. To hold that this was not done would be arbitrarily to disregard and set at naught the testimony of witnesses whose character and reputation are unimpeached and whose testimony is reasonable and in entire harmony with the circumstances of this case. We are unwilling to assume such a position. We are fully persuaded that the evidence shows beyond a reasonable doubt that for many years prior to the filing of the original application herein the process of making patterns and molds for dental inlays and the like as expressed in these claims had been publicly practiced upon many occasions. This finding avoids the patent and renders it unnecessary to determine whether the claims thereof were anticipated by the prior record art.

It follows that the decree must be reversed, with costs, and the cause remanded with directions to dismiss the bill.

Reversed and *remanded*.

[Signed] CHAS. H. ROBB,
Associate Justice.

SOCIETY NOTES AND ANNOUNCEMENTS.

DENTAL SOCIETY MEETINGS:
May, June, and July.

MAY.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA. Philadelphia. May 27th.

DENTAL SOCIETY OF THE STATE OF NEW YORK. Albany. Three days: May 8th to 10th.

ILLINOIS STATE DENTAL SOCIETY. Peoria. Four days: May 13th to 16th.

INDIANA STATE DENTAL ASSOCIATION. Indianapolis. Three days: May 20th to 22d.

IOWA STATE DENTAL SOCIETY. Davenport. Three days: May 6th to 8th.

KENTUCKY STATE DENTAL ASSOCIATION. Lexington. Three days: May 26th to 28th.

LAKE ERIE (PA.) DENTAL ASSOCIATION. Cambridge Springs. Three days: May 15th to 17th.

MASSACHUSETTS DENTAL SOCIETY. Boston. Three days: May 8th to 10th.

NATIONAL DENTAL PROTECTIVE ASSOCIATION. Washington, D. C. May 20th.

NEBRASKA STATE DENTAL SOCIETY. Omaha. Four days: May 19th to 22d.

NORTH DAKOTA DENTAL ASSOCIATION. Fargo. Two days: May 16th and 17th.

SOUTH DAKOTA DENTAL SOCIETY. Watertown. Two days: May 13th and 14th.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION. Los Angeles. Four days: May 26th to 29th.

SUSQUEHANNA (PA.) DENTAL SOCIETY. Wilkes-Barre. Three days: May 20th to 22d.

TEXAS STATE DENTAL ASSOCIATION. Temple. Three days: May 15th to 17th.

VERMONT STATE DENTAL SOCIETY. Burlington. Three days: May 21st to 23d.

JUNE.

ALABAMA DENTAL ASSOCIATION. Birmingham. Three days: June 10th to 12th.

AMERICAN SOCIETY OF ORTHODONTISTS. Chicago, Ill. Three days: June 30th to July 2d.

CALIFORNIA STATE DENTAL ASSOCIATION. Oakland. Four days: June 2d to 5th.

COLORADO STATE DENTAL ASSOCIATION. Manitou. Three days: June 19th to 21st.

DISTRICT OF COLUMBIA DENTAL SOCIETY AND MARYLAND STATE DENTAL ASSOCIATION. Washington, D. C. June 12th to 14th.

GEORGIA STATE DENTAL SOCIETY. Columbus. Three days: June 12th to 14th.

MAINE DENTAL SOCIETY. Portland Harbor. Three days: June 25th to 27th.

MINNESOTA DENTAL ASSOCIATION. Minneapolis. Two days: June 13th and 14th.

MISSISSIPPI DENTAL ASSOCIATION. Meridian. Three days: June 24th to 26th.

NATIONAL DENTAL ASSOCIATION.

THE 1913 session of the National Dental Association will be held in Kansas City, Mo., July 8 to 11, 1913. The Local Committee of Arrangements have selected the Baltimore Hotel as headquarters, and have made the other necessary arrangements for this meeting. The officers and committees are planning to present an exceptionally interesting program, the details of which, together with the other arrangements, will be presented in later journals.

FRANK O. HETRICK, *President*,
Ottawa, Kans.,
HOMER C. BROWN, *Recording Sec'y*,
185 East State st., Columbus, Ohio.

NATIONAL DENTAL ASSOCIATION—SOUTHERN BRANCH AND VIRGINIA STATE DENTAL SOCIETY.

THE fifteenth annual meeting of the Southern Branch of the National Dental Association will be held at the Chamberlin Hotel, Old Point Comfort, Va., July 22 to 25 inclusive, 1913. The Virginia State Dental Society will meet conjointly with the Southern Branch at that time.

THOS. MOORE, JR., *Cor. Sec'y, N.D.A.So.Br.*

NATIONAL DENTAL PROTECTIVE ASSOCIATION.

THE annual meeting of the National Dental Protective Association will be held at the Fredonia Hotel, Washington, D. C., May 20, 1913, at 7.30 P.M., for the election of trustees and transaction of business.

E. P. DAMERON, *President*,
M. F. FINLEY, *Sec'y*,
1928 "I" st., N. W., D. C.

NATIONAL ASSOCIATION OF DENTAL EXAMINERS.

The thirty-first annual session of the National Association of Dental Examiners will be held at the Baltimore Hotel, Kansas City, Mo., beginning July 7th, at 10 A.M. and continuing until adjournment.

Every state board holding membership in the association is earnestly requested to have at least one representative present at this session. Members of all state boards are invited. Hotel reservations should be made immediately.

John P. Stiff, *President*,
Fredericksburg, Va.,
T. A. Broadbent, *Sec'y.*,
15 E. Washington st., Chicago, Ill.

NATIONAL ASSOCIATION OF DENTAL FACULTIES.

The next annual meeting of the National Association of Dental Faculties will take place at the Hotel Baltimore, Kansas City, Mo., beginning at 10 A.M., on Friday, July 4, 1913. The Executive Committee will meet at 9 o'clock on the same morning, at the same place.

B. Holly Smith,
Chairman Exec. Com.

AMERICAN SOCIETY OF ORTHODONTISTS.

The thirteenth annual meeting of the American Society of Orthodontists will be held in Chicago, Ill., June 30, July 1 and 2, 1913.

Frederick C. Kemple, *Sec'y*,
576 Fifth ave., New York City.

OKLAHOMA STATE DENTAL ASSOCIATION.

The following officers were elected by the Oklahoma State Dental Association at its recent annual meeting: R. S. Parsons, Oklahoma City, president; N. C. Woods, Ardmore, first vice-president; A. B. Potter, Oklahoma City, second vice-president; A. B., Walker, Fairview, treasurer; C. R. Lawrence, Enid, secretary.

The society unanimously voted to continue the postgraduate feature of the meetings, which is proving to be very interesting and profitable.

C. R. Lawrence, *Sec'y.*

DENTAL SOCIETY OF THE STATE OF NEW YORK.

The forty-fifth annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May 8, 9, and 10, 1913. There will be the usual reduced railroad rates on the certificate plan from points in New York, New Jersey, and Pennsylvania.

Program.

Dr. George V. I. Brown, Milwaukee, Wis. "The Pathologies and Therapeutic Possibilities of the Upper Maxillary Contraction and Expansion as Evidenced by Experiments upon Guinea-pigs, Rabbits, and Dogs, in Confirmation of Clinical Manifestations in Human Cases."

Dr. Ellison Hillyer, Brooklyn, N. Y. "The Development of Anatomical Articulation."

Dr. T. B. Hartzell, Minneapolis, Minn. "Operative and Post-operative Treatment of Pyorrhea."

Dr. R. Ottolengui, New York, N. Y. "Can the Illegal Practice of Dentistry be Limited by Law?"

Dr. W. B. Dunning, Chairman, New York. Report of Committee on "Scientific Research."

Dr. W. D. Tracy, Chairman, New York. Report of the Committee on "Practice."

Report of the Oral Hygiene Committee.

The first session will open on Thursday at 10.30 A.M. The literary program of the meeting will be rendered in the auditorium of the Educational Building. Headquarters will be at the Hotel Ten Eyck, where the exhibits and clinics will be held.

A cordial invitation is extended to all ethical dentists in New York and sister states. Exhibitors wishing to engage space please address Dr. O. J. Gross, Schenectady, N. Y.

A. P. Burkhart, *Sec'y*,
52 Genesee st., Auburn, N. Y.

SOUTH DAKOTA STATE DENTAL SOCIETY.

The thirty-first annual meeting of the South Dakota Dental Society will be held at Watertown, S. D., on May 13 and 14, 1913.

A. O. Stutenroth, *Sec'y*,
Watertown, S. D.

KENTUCKY STATE DENTAL ASSOCIATION.

The forty-fourth annual meeting of the Kentucky State Dental Association will be held at the Phoenix Hotel, in Lexington, Ky., on May 26, 27, and 28, 1913. All ethical dentists are invited to attend.

C. R. Shacklette, *Sec'y,*

ILLINOIS STATE DENTAL SOCIETY.

The forty-ninth annual meeting of the Illinois State Dental Society will be held at Peoria, May 13, 14, 15, and 16, 1913.

Dr. Chas. M. Smith, Peoria, is chairman of the Committee on Local Arrangements.

Henry L. Whipple, *Sec'y,*
Quincy.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

The regular meeting of the Academy of Stomatology will be held on Tuesday, May 27, 1913, at the College of Physicians, Twenty-second above Chestnut sts., Philadelphia, Pa., at 8 P. M.

Dr. A. W. Sweeney of Baltimore, Md., will read a paper entitled "Prove All Things; Hold Fast That Which is Good." The subject will be discussed by Dr. M. L. Rhein and Dr. R. Ottolengui of New York, and Dr. Edwin T. Darby, Dr. F. D. Gardiner, and Dr. L. Ashley Faught of Philadelphia.

All members of the dental profession are invited to be present.

Norman L. Jameson, *Sec'y.*

TEXAS STATE DENTAL ASSOCIATION.

The thirty-third annual meeting of the Texas State Dental Association will be held at Temple, Texas, May 15, 16, and 17, 1913.

The clinics will be in charge of Dr. J. O. Hall, Waco, Texas, who will furnish any information relative to same. Exhibitors desiring space will please address Dr. J. M. Murphy, Temple, Texas. All ethical practitioners are cordially invited to attend the meeting.

Any other information will be cheerfully furnished by

J. G. Fife, *Sec'y,*
Dallas, Tex.

MASSACHUSETTS DENTAL SOCIETY.

The forty-ninth annual meeting of the Massachusetts Dental Society will be held at the Hotel Somerset, Boston, Mass., on Thursday, Friday, and Saturday, May 8, 9, and 10, 1913.

A. H. St. Clair Chase, *Sec'y,*
Everett, Mass.

NEBRASKA STATE DENTAL SOCIETY.

Change of Date of Meeting.

The thirty-seventh annual meeting of the Nebraska State Dental Society will be held in Omaha, Nebr., May 19, 20, 21, and 22, 1913, instead of May 12, 13, 14, and 15, as formerly announced.

For programs and any information address

Wm. A. McHenry, *Sec'y,*
Nelson, Nebr.

IOWA STATE DENTAL SOCIETY.

The fifty-first annual meeting of the Iowa State Dental Society will convene at Davenport, Iowa, May 6, 7, and 8, 1913, beginning Tuesday, May 6th, at 9 A.M. Elaborate clinics and lectures and a large exhibit will be presented.

Further information will be furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

Exhibitors desiring space should apply to Dr. Wm. Finn, Cedar Rapids, Iowa.

C. M. Kennedy, *Sec'y,*
Des Moines, Iowa.

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA.

The fiftieth anniversary meeting of the Susquehanna Dental Association of Pennsylvania will be held at Irem Temple, Wilkes-Barre, Pa., Tuesday, Wednesday, and Thursday, May 20, 21, and 22, 1913.

The Executive Committee is composed of the following members: A. E. Bull, W. E. Davis, T. W. Thomas, B. A. Courtwright, A. J. Heffernan of Wilkes-Barre, A. B. Miller of Kingston, and I. H. Jennings of Danville.

All ethical practitioners are invited.

E. J. Donnegan, *Recording Sec'y,*
Scranton, Pa.

NORTH DAKOTA DENTAL ASSOCIATION.

The eighth annual meeting of the North Dakota Dental Association will be held at Fargo, N. D., May 16 and 17, 1913.

E. N. Hegge, *Sec'y*,
Hatton, N. D.

VERMONT STATE DENTAL SOCIETY.

The next meeting of the Vermont State Dental Society will be held in Burlington, Vt., May 21, 22, and 23, 1913.

P. M. Williams, *Sec'y*,
Rutland, Vt.

LAKE ERIE (PA.) DENTAL ASSOCIATION.

The fiftieth annual meeting of the Lake Erie Dental Association will be held at Hotel Bartlett, Cambridge Springs, Pa., May 15, 16, and 17, 1913. This meeting celebrates the "golden anniversary" of this society, and the Program Committee have arranged for the best meeting ever held. Entertainment for the ladies; come, and bring them.

C. L. Mead, *Sec'y*,
Union City, Pa.

INDIANA STATE DENTAL ASSOCIATION.

The fifty-fifth annual session of the Indiana State Dental Association will be held at the Claypool Hotel, Indianapolis, May 20, 21, and 22, 1913.

The officers of the association recently met at Indianapolis and perfected plans for a three-day "Post-graduate Course." The very best instructors and specialists are being secured for each day. The course will be as follows: Tuesday—"Humanitarian Dentistry." Wednesday—"Preventive Dentistry." Thursday, A.M.—"Prosthodontia"; P.M., a great table clinic. The clinic will also be held in the hotel.

No tuition fee for the members of the association, or visitors from outside the state who are in good standing in their state associations, but all others desiring to take this course must arrange their tuition fees with the secretary.

Otto U. King, *Sec'y*,
Huntingdon, Ind.

SOUTHERN CALIFORNIA DENTAL ASSOCIATION.

The sixteenth annual meeting of the Southern California Dental Association will be held in Los Angeles, on May 26, 27, 28, and 29, 1913.

An excellent program of essays and clinics, as well as a large and elaborate exhibit, is being arranged. All ethical practitioners of dentistry are cordially invited to be present.

Further information will be sent upon request.

Jas. D. McCoy, *Ch'man Publicity Com.*,
708 W. P. Story Bldg., Los Angeles, Cal.

CALIFORNIA STATE DENTAL ASSOCIATION.

The next annual meeting of the California State Dental Association will be held on June 2, 3, 4, and 5, 1913, in the Hotel Oakland, at Oakland, Cal.

E. E. Evans, *Sec'y*,
Oakland, Cal.

NORTHERN OHIO DENTAL ASSOCIATION.

The fifty-sixth annual meeting of the Northern Ohio Dental Association will be held at Cleveland, Ohio, June 5, 6, and 7, 1913.

C. D. Peck, *Sec'y*,
Sandusky, Ohio.

SOUTH CAROLINA STATE DENTAL ASSOCIATION.

The forty-third annual meeting of the South Carolina State Dental Association will be held on the Isle of Palms, June 25, 26, and 27, 1913.

W. Busey Simmons, *Recording Sec'y*,
Piedmont, S. C.

MISSISSIPPI DENTAL ASSOCIATION.

The thirty-eighth annual session of the Mississippi Dental Association will be held at the Great Southern Hotel, Meridian, Miss., June 24, 25, and 26, 1913.

A determined effort is being put forth to make this meeting our best. There will be a fine clinic, excellent papers, a banquet, and a fine exhibit.

L. B. Price, *Sec'y*,
Corinth, Miss.

MONTANA STATE DENTAL SOCIETY.

The next annual meeting of the Montana State Dental Society will be held in Butte, June 13 and 14, 1913.

T. T. Rider, *Sec'y*,
Missoula, Mont.

TENNESSEE STATE DENTAL ASSOCIATION.

The Tennessee State Dental Association will hold its annual meeting in Nashville, Tenn., on June 5, 6, and 7, 1913, with the following officers in charge: F. W. Meacham, president; W. C. Gillespie, first vice-president; J. L. Manire, second vice-president; C. Osborn Rhea, recording secretary; W. G. Hutchinson, treasurer; C. E. Hines, corresponding secretary.

C. Osborn Rhea, *Sec'y*.

ALABAMA DENTAL ASSOCIATION.

The Alabama Dental Association will meet in Birmingham, Ala., June 10, 11, and 12, 1913.

We earnestly solicit every good dentist in Alabama who is not now a member to join. It will enhance your efficiency, because in the doctrines we teach we incorporate the best of professional principles and within our ranks we encompass the best of professional men.

G. F. Petrey, *Sec'y*,
Florala, Ala.

SOUTHERN WISCONSIN DENTAL ASSOCIATION.

A New Departure.

The nineteenth annual meeting of the Southern Wisconsin Dental Association will be held at Hotel Highland, Delavan Lake, June 13 and 14, 1913.

Having decided to combine business with pleasure, we will hold our sessions in the afternoons only, consisting of a few of the best papers and clinics obtainable. The morning and evening can be spent boating, fishing, bathing, or automobiling.

Hotel Highland and Delavan Lake are seldom equaled and never surpassed as a place for such a gathering. It is our purpose to take our wives with us, and together enjoy the Lake as well as the beautiful hills and valleys surrounding Hotel Highland. Bring the young folks with you; they will enjoy the outing.

All ethical dentists are cordially invited to attend.

C. W. Collver, *Sec'y*,
Clinton, Wis.

WASHINGTON STATE DENTAL SOCIETY.

The Washington State Dental Society meets June 16, 17, and 18, 1913, in Seattle, Wash.

A. D. Remington, *Sec'y*,
Seattle, Wash.

MAINE DENTAL SOCIETY.

The forty-eighth annual meeting of the Maine Dental Society will be held at the Ottawa House, Cushing's Island, Portland Harbor, Me., on June 25, 26, and 27, 1913.

I. E. Pendleton, *Sec'y*,

NEW HAMPSHIRE DENTAL SOCIETY.

The New Hampshire Dental Society will hold its annual meeting at Hotel Weirs, Weirs, N. H., June 18, 19, and 20, 1913. The profession are invited to attend.

Fred F. Fisher, *Sec'y*.

MINNESOTA STATE DENTAL ASSOCIATION.

The thirtieth birthday of the Minnesota State Dental Association will be celebrated by a large clinic and manufacturers' exhibit in Masonic Temple, Minneapolis, June 13 and 14, 1913. A rate of a fare and one-third has been granted by the railroads, and a large meeting is assured. For information address

Benjamin Sandy, *Sec'y*,
636 Syndicate Bldg., Minneapolis, Minn.

GEORGIA STATE DENTAL SOCIETY.

The forty-fifth annual meeting of the Georgia State Dental Society will convene at Columbus, Ga., June 12, 13, and 14, 1913, beginning Thursday, June 12th, at 11 A.M. Some very interesting lectures and papers will be presented; also an elaborate clinic has been secured.

Further information will be cheerfully furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

M. M. Forbes, *Sec'y*,
Atlanta, Ga.

NEW JERSEY STATE DENTAL SOCIETY.

The forty-third annual convention of the New Jersey State Dental Society will be held in the Beach Auditorium, at Asbury Park, N. J., July 16, 17, and 18, 1913, beginning on Wednesday, July 16th, at 10 A.M.

The exhibits of modern dental appliances and the latest in office and laboratory equipment will be in charge of Dr. William H. Gelston, 40 N. Thirtieth st., Camden, N. J., who will be glad to furnish information regarding rates and space still available. Early application from those desiring to exhibit with us this year will be greatly appreciated.

The clinics will be in charge of Dr. Henry Fowler, 114 N. Fourth st., Harrison, N. J., and will be comprehensive and of a very high order.

Further announcements will be made from time to time.

Edwin W. Harlan, *Sec'y*,
47 Crescent ave., Jersey City, N. J.

OKLAHOMA BOARD OF EXAMINERS.

There will be a meeting of the Oklahoma Board of Dental Examiners, May 19 to 24, 1913, at Oklahoma City.

Candidates are requested to have their application and fee of $25 deposited with the secretary at least ten days before meeting.

Theoretical examinations include the following subjects: Operative dentistry, anesthesia, oral surgery, orthodontia, prosthetic dentistry, crown and bridge work, dental anatomy, physiology and pathology, materia medica and therapeutics, chemistry and metallurgy, histology and bacteriology. Practical demonstration of skill in operative and mechanical dentistry will also be required, and candidates should come prepared with instruments and material for making fillings and crowns in the mouth. Admission by examination only. For further particulars address

E. E. Heflin, *Sec'y*,
Oklahoma City.

WASHINGTON BOARD OF EXAMINERS.

The Washington State Board of Dental Examiners will meet in Farouts Hall, Seattle, Wash., on May 22, 1913, for the purpose of holding the spring examination.

L. B. Manchester, *Sec'y*,
Wenatchee, Wash.

NORTH CAROLINA BOARD OF EXAMINERS.

The next regular meeting of the North Carolina State Board of Dental Examiners will be held in Winston-Salem, N. C., beginning promptly at 9 o'clock on Monday morning, May 26, 1913.

For further necessary information, address

F. L. Hunt, *Sec'y*,
Asheville, N. C.

ARIZONA BOARD OF EXAMINERS.

There will be a meeting of the Arizona Board of Dental Examiners on May 5, 6, 7, 8, and 9, 1913, at Phoenix, Ariz.

Candidates should have in their applications, and fee of $25 should accompany same, at least twenty days before meeting.

Theoretical examination includes the following subjects: Anatomy, physiology, chemistry, materia medica, therapeutics, metallurgy, histology, pathology, operative and mechanical dentistry, oral surgery. Practical demonstration of skill in operative and mechanical dentistry will also be required, and candidates should come prepared with instruments and material for making fillings and crowns in the mouth.

W. A. Baker, *Sec'y*,
Tucson, Ariz.

MARYLAND BOARD OF EXAMINERS.

The Maryland State Board of Dental Examiners will meet for examination of candidates for certificates, May 29 and 30, 1913, at the Dental Department of the University of Maryland, Baltimore, Md., at 9 A.M.

Candidates must pass a written examination in anatomy and physiology, chemistry and bacteriology, oral surgery, operative and prosthetic dentistry and pathology, therapeutics, and materia medica.

The practical requirements consist of the insertion of one gold and one amalgam filling in the mouth, and the submission of a metal plate or bridge of not less than four crowns —two of which shall be of porcelain—the parts being assembled and invested in advance, and soldered in the presence of the board.

Applications, accompanied by the fee of ten dollars, must be filed with the secretary prior to May 29th.

For application blanks or further information, apply to

F. F. Drew, *Sec'y*,
701 N. Howard st., Baltimore, Md.

NEW JERSEY BOARD OF REGISTRATION.

The New Jersey State Board of Registration and Examination in Dentistry will hold their semi-annual examination in the State-house, Trenton, N. J., beginning on Monday, June 30, and continuing Tuesday, July 1, and Wednesday, July 2, 1913.

Practical work Monday, June 30th, 8 a.m. sharp; theoretical examination Tuesday, July 1st, and Wednesday, July 2d, promptly at 8 a.m. The business meeting of the board will be held at 10 a.m., Tuesday, July 1st, and anyone having business with the board may have an audience. Applications must be in the hands of the secretary five days prior to the examination. For further information address

Chas. A. Meeker, *Sec'y*,
29 Fulton st., Newark, N. J.

ILLINOIS BOARD OF EXAMINERS.

The semi-annual meeting of the Illinois State Board of Dental Examiners, for the examination of applicants for a license to practice dentistry in the state of Illinois, will be held at the Chicago College of Dental Surgery, corner of S. Wood and W. Harrison sts., Chicago, beginning Wednesday, June 4, 1913, at 9 a.m.

All applications, together with the fee, twenty-six dollars, must be filed with the secretary at least five days prior to date of examination. Address all communications to

T. A. Broadbent, *Sec'y*,
705 Venetian Bldg., Chicago, Ill.

SOUTH CAROLINA BOARD OF EXAMINERS.

The next meeting for examination of applicants for license will be held Friday, June 20, 1913, at 3 p.m., at the Isle of Palms, Hotel Charleston, S. C.

J. M. Quattlebaum, *Sec'y*,

INDIANA BOARD OF EXAMINERS.

The next regular meeting of the Indiana State Board of Dental Examiners will be held in the State-house at Indianapolis, beginning Monday, June 9th, at 9 a. m., and continuing until Saturday, June 14th. All applicants for registration in this state will be examined at this time. No other meeting will be held until November; no temporary licenses are issued.
