The new law requiring annual registration will be in effect about May 15th. The first registration will take place in December of this year. For application blanks and further information apply to

F. R. Henshaw, 507-8 Pythian Bldg.,
Indianapolis, Ind.

CONNECTICUT DENTAL COMMISSIONERS.

The Dental Commissioners of the State of Connecticut hereby give notice that they will meet at Hartford, on Thursday, Friday, and Saturday, June 12th, 13th, and 14th, to examine applicants for license to practice dentistry, and for the transaction of any other business proper to come before them.

On receipt of application blank, filled in and sworn to and accompanied with fee of twenty-five dollars, each applicant will be sent a number, which number will represent the applicant during the examination.

The practical examination will take place at Putnam Phalanx Armory, corner Haynes and Pearl sts., on Thursday, June 12th. All prosthetic pieces should be tagged with the applicant's number, and handed to the Commissioners at nine o'clock Thursday morning. Applicants whose numbers range from 1 to 20 inclusive will be examined in operative dentistry at 9 a.m. Those whose numbers are above 20 will be examined in operative dentistry at 12 m. All applicants whose credentials are accepted shall be entitled to take both the practical and theoretical examinations. Credentials will be examined at the Hotel Heublein, Wednesday evening, June 11th, at 8.30, and at Putnam Phalanx Armory at 9 o'clock on Thursday morning.

On Friday, June 13th, the theoretical examination will be held from 9 to 11, 11.30 to 1.30 and 3.30 to 5.30. Theoretical examination will be held at the State Capitol.

By order of the Commission.

D. EVERETT TAYLOR, *Recorder*,
Willimantic, Conn.

CALIFORNIA BOARD OF EXAMINERS.

THE next examination by the Board of Dental Examiners of California for licenses to practice dentistry will be held in San Francisco, Cal., beginning on June 7, 1913. This will be followed by an examination in Los Angeles, beginning on June 20th. All applications, accompanied by the fee of twenty-five dollars and the necessary credentials—a diploma or license from some other state—must be filed with the secretary of the board on the morning of the date set for examination—June 7th in San Francisco and June 20th in Los Angeles. Said application must be accompanied by a recent unmounted photograph of the applicant.

C. A. HERRICK, *Sec'y*,
San Francisco, Cal.

VERMONT BOARD OF EXAMINERS.

THE next meeting of the Vermont Board of Dental Examiners for the examination of candidates to practice in Vermont will be held at the State-house, Montpelier, Vt., continuing four days, commencing at 2 P.M., June 30, 1913.

To be eligible for examination a candidate (1) must be twenty-one years of age; (2) must be a graduate of a high school of the first class; (3) must be a graduate of a reputable dental college.

Applications must be in the hands of the secretary not later than June 20th.

For further information apply to

GEO. F. CHENEY, *Sec'y*,
St. Johnsbury, Vt.

PENNSYLVANIA BOARD OF EXAMINERS.

THE next regular examination of the Pennsylvania State Board of Dental Examiners will be held in Philadelphia and Pittsburgh, on Wednesday, Thursday, Friday, and Saturday, June 11, 12, 13, and 14, 1913. Application blanks can be secured from the department of Public Instruction, Harrisburg.

Further information can be obtained from

ALEXANDER H. REYNOLDS, *Sec'y*,
4630 Chester ave., Philadelphia, Pa.

TEXAS BOARD OF EXAMINERS.

THE next regular meeting of the Texas State Board of Dental Examiners will be held in the high-school building, Houston, Texas, beginning Monday, June 23, 1913, at 9 A.M. Official application blanks and other necessary information will be furnished candidates upon application to the secretary.

All applications, accompanied by a fee of $25.00, should be in the hands of the secretary at least five days before the examination.

Address all communications to

C. M. MCCAULEY, *Sec'y*,
Abilene, Texas.

WISCONSIN BOARD OF EXAMINERS.

THE Wisconsin State Board of Dental Examiners will convene in Milwaukee, at Marquette University, on June 16, 1913, at 2 P.M., for examination of applicants to practice in Wisconsin.

High-school diploma, application, and fee of $25.00 must be filed with the secretary fifteen days prior to above date. Dental diploma to be presented in advance of examination.

F. A. TATE, *President*,
W. T. HARDY, *Sec'y*,
422 Jefferson st., Milwaukee, Wis.

MONTANA BOARD OF EXAMINERS.

THE Montana State Board of Dental Examiners will hold the annual session in Helena, Mont., July 14, 15, 16, 17, 1913. Address all communications to

G. A. CHEVIGNY, *Sec'y*,
Butte, Mont.

ARMY DENTAL SURGEONS.

MEMORANDA OF CHANGES.

For the week ending March 15, 1913:

First Lieut. F. F. Wing left Fort D. A. Russell, March 8th, *en route* to San Francisco and Philippine Islands.

J. H. Snapp, ACT.D.S., ordered to San Juan, P. R., for four months from February 1st, and to Henry Barracks for one month thereafter, and then to return to his station, Camp E. S. Otis, Panama.

For the week ending March 29th:

H. L. Rush, ACT.D.S., left Fort D. A. Russell, Wyo., for Texas City, Texas, March 20th.

First Lieuts. G. L. Mason and H. G. Voorhies, and H. L. Rush, ACT.D.S., A. R. White, ACT.D.S., and E. M. Kennedy, ACT.D.S., are ordered to report to the commanding general, 2d div., Texas City, Texas, for duty.

B. C. Warfield, ACT.D.S., left Fort Wood, N. Y., March 26th, for temporary duty at Fort Hancock, N. J.

Upon arrival in the United States the following dental surgeons, U. S. Army, will proceed to the posts set opposite their names for duty: First Lieut. R. H. Rhoades, Fort Bliss, Texas; First Lieut. J. R. Ames, Fort McPherson, Ga.; First Lieut. F. L. K. LaFlamme, Fort Hamilton, N. Y.

For the week ending April 5th:

First Lieut. J. R. Bernheim granted leave of absence for two months, about June 15th, with permission to apply for an extension of one month.

First Lieut. W. H. Chambers granted four months' leave of absence about May 1st.

First Lieut. G. H. Casaday relieved from duty in the Philippines Department, about June 15th.

For the week ending April 12th:

First Lieut. J. R. Ames granted leave of absence for three months.

First Lieut. R. E. Ingalls will leave Seattle, Wash., about April 14th, visiting posts in Alaska; returning about September 1st to his station, Vancouver Barracks, Wash.

UNITED STATES PATENTS

PERTAINING OR APPLICABLE TO DENTISTRY

ISSUED DURING MARCH 1913.

March 4.

DENTAL COSMOS.

VOL. LV. JUNE 1913. No. 6.

ORIGINAL COMMUNICATIONS.

THE *LOCUS MINORIS RESISTENTIÆ* IN PYORRHEA ALVEOLARIS.

By EDWARD C. KIRK, D.D.S., Sc.D., Philadelphia, Pa.

(Read before the Seventh and Eighth District Dental Societies of the State of New York, at Rochester, November 14, 1912.)

AT the very outset let me forestall what in simple justice I assume to be no more than a proper critical attitude in your minds, by apologizing for the title of this paper. I was told by the chairman of your Executive Committee that when he attempted to telegraph the subject of this communication to one of the gentlemen who has kindly consented to discuss it, the intelligent agent of the telegraph company said to him, "We don't take night messages in a foreign language." I anticipate no serious difficulty in clearing up whatever obscurities the title may present to your minds, but I feel beset with more or less doubt concerning my ability to elucidate the subject that it involves. I shall, therefore, confine myself to the effort to set before you some data and certain deductions therefrom which I hope will present the study of what we call pyorrhea alveolaris from an angle of view that may help us to get a little additional light on its perplexing problems.

Let it be understood that the term "Pyorrhea Alveolaris" is here used to designate that group of destructive, inflammatory disorders affecting the retentive structures of the teeth by which degeneration and necrosis of their attachment is produced and ultimate exfoliation of the teeth takes place—a series of phenomena dependent upon bacterial infection of the retentive structures for its exciting cause. I am well aware that the foregoing characterization is imperfect as a general definition applicable to all of the pathological processes that may eventuate in exfoliation of the teeth; but the same objection may be urged against the term pyorrhea alveolaris itself, or indeed against any general definition of these alveolar disorders in the present state of our knowledge concerning their etiology and pathology. Furthermore, I wish to exclude from present consideration the group of destructive gingival disorders that obviously result from the mechanical irritation due to impingement of salivary calculus upon the gingival and alveolar tissues, and to confine attention wholly to the form of pyorrhea alveolaris that is manifestly a pus-producing and therefore destructive inflammatory process.

The very fact that, by reason of the light thrown by modern scientific investigation upon the causes of pus formation and the inflammatory reactions involved, we are able to classify certain forms of pyorrhea as pus infections, at once greatly simplifies the problem of their etiology and pathology, and is fraught with suggestiveness as to their therapeutic treatment.

Viewed, then, as a destructive inflammatory process of bacterial origin, or, otherwise described, as a pus infection, the etiological problem with which we are concerned is that of susceptibility of the gingival tissues to infection by pathogenic organisms of the pus-producing type.

The history of the germ theory of disease causation is a long and interesting one, with its beginnings in the superstitions and misty obscurities of antiquity, surviving and gradually taking on more definiteness until the researches of Koch in the last quarter of the past century finally evolved the demonstration of the fact that these low organic forms were in certain instances the exciters of those reactions in the higher animal organisms which constitute the phenomena of disease. Koch's discoveries and original methods of investigation made possible the systematic study of the whole field of bacteriological activity, and bacteriology as a department of biological science may be said to have had its birth in his work.

In the evolution of the investigation of the relations of bacteria to disease causation, two distinct points of view have characterized the history of the subject. The first may be designated as that which was concerned with the modus of disease production through the agency of the bacteria, while the second involved a study of the defensive agencies of the organism against bacterial invasion. The first point of view was the necessary result of lack of knowledge of the nature and biological activities of the bacterial exciters of disease action—a lack which, through over a quarter of a century of research by a large army of skilled scientific investigators, has been eliminated by the substitution of a rich store of data covering the life-processes and disease-producing activities of a long list of pathogenic bacteria. So complete is the testimony that in general terms we may say that the principles by which pathogenic bacteria induce disease reaction are now in a broad sense clearly understood.

In the course of investigation of the modus of action of disease-producing bacteria the fact constantly obtruded itself that a given form of organism did not always produce the same disease reaction in several individuals, or at all times in the same individual; from which it was later demonstrated that there may be not only a variation in virulence of a given bacterium, but likewise a wide range of susceptibility among individuals, and in the same individuals at different times, to infection by a particular kind of organism. It is the discovery of these fundamental facts governing the reactions of the higher organisms to bacterial activity, the conditions which determine the balance of vital potential as between the higher organisms and pathogenic bacteria—in short, the question of susceptibility and immunity to bacterial invasion—that constitutes the second point of view which in an historical sense I have already referred to; and it is the vital problem of susceptibility and immunity with which medical science is at present most intensely concerned.

The study of pyorrhea, as the subject has presented itself from an historical viewpoint, seems to have evolved in much the same way that I have indicated with reference to the general attitude of investigators of the germ theory of disease. Our historical records show that in the first period attention was directed almost wholly to the objective fact that deposits of tartar, salivary calculus, were an obvious cause of destruction of the retentive tissues of the teeth, and that such teeth eventually fell out. Tartar thus became recognized as the general cause of the disease. Later it was observed that many teeth were lost, with coincident pus formation, yet without tartar deposits in such obvious quantity as to satisfactorily account for the activity of the inflammatory reaction that had characterized the destructive process; and still later, observations were reported of cases of an atrophic form of gingival destruction in which neither pus nor tartar were obviously present. Thus we have come to realize that we are dealing, not with a single disorder with well-defined and characteristic symptoms, but with a group of disorders having certain pathological features in common, but sufficiently distinct in etiology and clinical manifestations to entitle them to separate classification.

In discussing the type of gingival pyorrheal disease to which I have limited this paper, I wish to direct attention more particularly to the question of the factor of susceptibility in the retentive tissues rather than to the question of the nature of the bacterial exciter of the inflammatory process—which limitation, I may state incidentally, is the justification for the cumbersome title of this paper.

The view now held by many students of the subject that the teeth are "end-organs" as designated by Talbot, and that their retentive tissues, including the alveolar borders of the jaws, are provisional structures intended to subserve a relatively temporary purpose, is a view which has never appealed to my general conceptions of the ordinarily high standard of efficiency of nature's economics. That point of view has always seemed to me to be open to the suspicion of special pleading in the effort to find an explanation for a group of phenomena into the antecedents of which we have not as yet delved deeply enough to discover their true causes. The same kind of reasoning has been applied to the loss of teeth from caries by a learned medical writer, who asserted, even since the death of Miller, that caries of the milk teeth was nature's method of getting rid of the deciduous denture, which was intended only to subserve a temporary purpose. If we look farther for the conditions that give rise to the loss of the teeth by pyorrhea we shall probably find eventually that the inherent weakness of the alveolar structures, if it exist at all, is a relative weakness, and that there is no more reason *per se* why the teeth should be lost by pyorrhea than that they should be lost by caries, or that the patient himself should die of tuberculosis or diabetes mellitus or any other nutritional or infectious disorder.

Assuming that in the normal individual the physiological processes are balanced upon a plan sufficiently high to maintain the defensive forces of the economy at a point of efficiency that will protect the individual against bacterial invasion, then the normal individual does not have pyorrhea. We see many such mouths—free from even a suspicion of pyorrheal symptoms. On the other hand, malnutrition in any of its forms—acute illnesses, prolonged fevers, rheumatism, gout, syphilis, tuberculosis, or unhygienic local mouth conditions, a filthy buccal cavity, any of these factors being present—may develop a coincident pyorrhea, the objective features of which, its character and course, and its response to therapeutic treatment, will be in no small degree determined by and be symptomatic of the general conditions that gave rise to the attack.

In the character of the local phenomena developed during the course of the attack we frequently meet with manifestations of the factor of relativity of resistance to the progress of the disorder in the involved tissues.

In the atrophic form characterized by decalcification of the alveolar bone without noticeable pus formation or pockets, followed by shrinkage of the gum tissues with or without terminal infection and pus formation, we are dealing with the local manifestation of a general malnutritional state, accompanied if indeed it is not caused by auto-intoxication. Just what are the poisonous substances contained in the blood stream that, when carried to the alveolar tissues, set up the decalcification process, the halisteresis of the bony sockets of the teeth, is not known, nor do we know by what agency these toxic irritants effect their results. These are problems for the physiological chemist and histopathologist, but enough is known of the tissual derangements induced by toxic substances in the blood plasma from the studies of Bouchard, Lauder Brunton, and many others to warrant us in holding to a belief in the sufficiency of auto-intoxication as a cause of this form of pyorrheal disorder, and that the frequency of its association with cases of evident auto-intoxication is more than a mere coincidence. Auto-intoxication, broadly speaking, is a result primarily of faulty nutrition by which the processes of metabolism are imperfectly carried on, and poisonous substances, toxins, leucomains, etc., are taken up by the blood stream and carried to the tissues, producing a variety of reactions both functional and morphological. Incidentally the resistive forces of the organism are lowered, the defensive bodies of the blood are weakened, and susceptibility to bacterial invasion is consequently increased. Infection brings its addition of toxic substances to the blood plasma with characteristic acute disease reaction of the tissues at the field of invasion, and the tissues succumb in the order of their relative resistive powers and with clinical manifestations conditioned by their histological structure.

From the point of view of this general survey of the principles underlying the inflammatory process let us consider some of the phenomena of pyorrhea in their bearing on the question of the points of diminished resistance in the tissues in which the disorder is locally expressed.

In 1887, G. V. Black, in his work entitled "A Study of the Histological Characters of the Periosteum and Peridental Membrane," described certain structures which at that time he designated as lymphatic glands of the peridental membrane, a study which he has further elaborated in a later publication, "The Fibers and Glands of the Peridental Membrane" (DENTAL COSMOS, 1899, vol. xli, p. 101), in which he has somewhat modified his earlier statement as to the lymphatic glandular character of these bodies. The previous studies of Magitot and Malassez and the exhaustive investigation of Von Brunn, published the same year as Black's original communication, point very strongly to the conclusion that these structures described by Black are epithelial "rests," débris or remnants of the epithelial sheath of Hertwig, the embryonal tissue of the enamel organ. The origin and histological character of these bodies found embedded in various parts of the peridental membrane is of considerable importance in connection with their susceptibility to infection by pathogenic organisms. Black reports a direct microscopic observation made upon a section of an extracted tooth with a portion of the alveolar wall and peridental membrane adhering, in which he found these so-called glands filled with micro-organisms, and in his later paper on the subject (*loc. cit.*) he says: "It seems to me very certain that the disease which I have described as phagedenic pericementitis has its seat in these glands. The location of the initial lesion and its progress to the formation of deep pockets indicates that the beginning is in these glands, and that in its progress they are followed into the depths of the alveolus, the fibers and adjacent tissue suffering by reason of their proximity."

My own observations from a clinical standpoint are wholly in accord with the view of Black here quoted, with the understanding that it applies only to that type of pyorrhea which is a true pus infection of the deep-seated and pocket-forming variety.

If these so-called glands of the peridental membrane are epithelial rests, remnants of an embryonal tissue that has subserved its purpose, they are degenerative in character, and like all other degenerative tissues are lacking in vital resistance. They therefore are readily infected by pathogenic bacteria when the general resistive forces of the organism become lowered to a degree that permits bacterial invasion at any point. Or, otherwise stated, a degenerative tissue being relatively weakest is the first in order to succumb to bacterial invasion when invasion through any generally acting cause becomes possible. Black's observation of the fact that these gland-like structures of the peridental membrane were the nidus of bacterial infection in the specimen examined and reported upon by him, I regard as extremely important and suggestive. It is quite true that a single observation is wholly insufficient as a basis upon which to establish a generalization, nevertheless it constitutes a scientific datum that must be given its due weight of consideration; and even should it serve only as a point of departure for further investigation, a single positive observation of this character viewed in its proper relationships is often of the utmost importance.

Granting that the embryonal origin and character of these gland-like bodies of the peridental membrane stamp their cellular elements as degenerative in type, and therefore of inferior resistive power toward bacterial invasion, then we have accounted for a *locus minoris resistentiæ* in the peridental membrane, and in the light of the histological distribution of this degenerative tissue in the membrane itself, as described by Black, we are able to account rationally not only for the major features of the etiology of the disorder, but for many of its characteristic clinical phenomena. I am not able to find from a fairly close study of the literature that any observer other than Black has reported upon the infection of the gland-like bodies of the peridental membrane.

A. Hopewell-Smith, in the report of his studies of sections of mandibles with teeth *in situ* affected with pyorrhea (Cosmos 1911, vol. liii, p. 404) in describing the "apical space," says: "The gland-like bodies, which may be of the nature and perform the functions of a lymphatic system, are increased in numbers and very prominent in the sections. The latter frequently branch and are filled with small cells."

In the article quoted the author reports the presence of bacteria in large masses or clumps visible in his sections when examined by a one-inch objective, but makes no report of specific findings of pathogenic bacteria in the gland-like structures of the peridental membrane as described by Black.

In the only other report of a direct microscopical study of the retentive structures of the teeth affected by pyorrheal inflammation, of which I have any knowledge, that of Professor Znamensky of Moscow University (see *Jour. Brit. Dental Association,* vol. xxiii, October 1902, page 585, the examinations of tissues made by him, in connection with Professor Nikiforoff, of the same university, were all made under magnifications ranging from 80 to 360 diameters, a magnification quite insufficient to determine the question of the infection of the glandular structures under consideration, and while we are left to make the necessary and logical deduction that the inflammatory process is the result of infection by pyogenic organisms, we are still in the dark regarding the modus of infection, and especially with regard to the particular tissue constituting the avenue through which infection takes place—in other words, the tissue of greatest vulnerability in the dento-alveolar structures. It seems to me to be of the utmost importance that more light should be thrown upon this fundamental question, for, given the fact of bacterial invasion of the tissue and the causes leading to it, then the balance of the inflammatory process, its nature and results, will become reasonably clear.

Black's studies point to the conclusion that these gland-like bodies of the peridental membrane surround the tooth-root as a sort of reticulum ramifying throughout the peridental membrane; and if, as he believes, they are the seat of that form of pyorrhea which he designates as phagedenic pericementitis, a belief with which for the reasons already stated I am in sympathetic accord, then we can understand not only the pocket-forming tendency of the disorder, but its pathological identity with the condition designated by D. D. Smith as pericemental abscess, known otherwise and frequently reported as "abscess upon teeth with vital pulps." Invasion of these glands by pyogenic bacteria sets up suppurative inflammation the clinical phenomena of which are determined by the depth and rapidity of the infection. Thus the disorder may be ulcerative in type where the invasion is superficial, or it may take on an abscess character when the invasion is deeper; and whether the discharge of the purulent exudate takes place, on the one hand, between the cementum of the tooth and its investing membrane, or, on the other hand, through the gum tissue forming a free fistulous outlet upon the gum surface away from the gingival margin, has thus far determined whether we designate the resulting lesion as a pus pocket or a pericemental abscess respectively.

In presenting for your consideration the foregoing aspect of the pyorrhea problem you will recognize that I regard the disorder as a local lesion symptomatic of a constitutional aberration from normality, a nutritional vice having a local expression. I am quite well aware that the data which I have presented to you concerning the probability of a *locus minoris resistentiæ* in the tissues which are the seat of the local lesion are meager and unsatisfactory in the sense that they fall short of being conclusive. I have, however, been emboldened to set this view of the subject before you in the hope that it may lead to more exhaustive investigation of the histo-pathological side of the question, to the end that the truth concerning it may be brought to light. My long and careful study of the clinical phenomena involved encourages me to believe that further investigation will demonstrate the correctness of Black's single observation, and that we shall find that the gland-like bodies of the peridental membrane are the weak points, the tissue of greatest susceptibility to pyorrheal infection.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

SCIENTIFIC AND PRACTICAL PHASES OF THE AMALGAM ALLOY QUESTION.

By **WM. W. ATKINSON, Philadelphia, Pa.**

(Read before the Monmouth County Dental Society of New Jersey, at Asbury Park, N. J., April 4, 1913, and the North Philadelphia Association of Dental Surgeons, Philadelphia, April 9, 1913.)

FOR many years after the introduction of amalgam alloy for the filling of teeth, dentistry had looked forward to the time when an ideal material of this kind should be found—one which would possess the qualities of plasticity, pleasing color, resistance to the stress of mastication, durability, and preservation of the teeth without staining them. Troublous years were these, for the science of metallurgy had seemed to be a side issue with those who had the business of alloy-making in hand, and who, despite the observations of distinguished scientists, gave scant heed to the chemical constitution of alloys, and in many instances had shown only a commercial interest in the subject. Thus, those upon whom dentistry most depended for its supply of amalgam alloy knew least about it.

DR. J. FOSTER FLAGG'S EARLY SCIENTIFIC STUDIES ON AMALGAM ALLOYS.

Small wonder then, that in these early days amalgam alloy should so often have been condemned as untrustworthy, and that there were sorrowful tales of "bulging," "shrinkage," and "tooth-staining." At that time, when amalgam alloy was most fiercely assailed because of such aberrations, there emerged the sturdy figure of Dr. J. Foster Flagg, patient, resourceful, and courageous, who made what was probably the first attempt to investigate systematically the subject of amalgam alloys and arrange the facts in orderly fashion. Out of his work grew formulæ that are basic, each with its leading property clearly accented, and each a guidepost for future investigators. He definitely established the functions of gold, zinc, and copper as modifying agents in the customary mixtures of silver-tin. Gold contributes plasticity, hence his "Contour" alloy contained a percentage of that metal. Zinc he showed to be a whitening agent, hence his "Facing" alloy contained zinc in addition to a small percentage of gold, introduced to add plasticity. Copper contributes strength, is by the germicidal action of its salts a tooth preservative, and has the quality of setting under saliva, which, needless to say, was exemplified in his "Submarine" alloy.

He made many original observations on the preparation and clinical manipulation of alloys, and proved that alloys undergo a change through what he termed "aging," and demonstrated how this may be artificially produced. The work of Dr. Flagg was based, however, largely upon empirical experiment rather than upon scientific considerations. The result was that no one of his alloys combined within itself those qualities imperatively required, nor were any of his alloys properly balanced, using the term in its broader sense.

Dentistry is deeply indebted to Dr. Flagg; his results have been eclipsed through the more exact knowledge of the present day, yet his painstaking labors stand as his enduring monument.

DR. G. V. BLACK'S STUDIES.

The formulæ of Dr. Flagg dominated the amalgam alloy situation until Dr. G. V. Black took up the question. Equipped with a well-trained, analytical mind, he was in these respects well fitted for the work of investigation, which he approached from the standpoint of the conditions existing in the mouth itself, which he first studied, and from this factor resolved the problem into its ultimate form, viz, the requirements for a satisfactory amalgam filling. These investigations were, I am informed, suggested by another line of investigation in which he was engaged, namely that of ascertaining the significance of the term "soft teeth." He first established the average force exerted by the jaws in masticating, thereby determining the resistance which a filling of any kind must offer to this force. He determined the space necessary for the invasion of micro-organisms between the walls of a tooth cavity and a contained filling which has shrunk; he made improvements in certain testing machines, one a dilatometer which reads down to 1/20,000 in., the other a device for determining crushing strength and percentage of compressibility, the ideas for which were, however, not original with him, as similar machines had long been used in this and other scientific fields. He termed these devices "amalgam micrometer and dynamometer," and with them made many tests. He developed the fact that "contouring" quality due to gold content in an amalgam usually meant too high a percentage of change of form under compression, which he termed "flow," and therefore that gold as a modifier is undesirable. He proved that the Flagg formula, 60 per cent. Ag, 35 per cent. Sn, 5 per cent. Cu, undergoes condensation (shrinkage) when amalgamated. This he showed to be due to an excess of tin and a deficiency of silver.

He demonstrated that in order to preserve a tooth, an amalgam filling should undergo an increase corresponding to an advance of at least 1/20,000 in. in the altitude of a column 0.38 in. high by 0.33 in. diameter; this he termed ½ point expansion, thus a "point" on his micrometer index equals 0.0001 in. He proved that a filling, to meet any crushing stress that might be placed upon it in masticating, should, on a cube of 0.085 in., withstand a pressure of 350 lb., which is said to mean about 38,000 lb. to the square inch, or 19 tons, and compressibility not exceeding 0.002 inch.

Dr. Black believed, nor has his belief been seriously questioned, that silver, tin, and copper are the only metals now known which should be combined in an amalgam alloy, and that the usual percentages of other metals, such as platinum, gold, or zinc are either without beneficial effect or are detrimental. He thus established several of the requirements for a satisfactory amalgam alloy, and upon these and the scientific research and experiment which preceded their enunciation, as well as his improvements in testing apparatus, rests the fame of Dr. Black as an amalgam investigator. For this service the dental profession must accord him its grateful appreciation.

THE G. V. BLACK METHOD OF ALLOY-MAKING AND ITS DEFECTS.

Had Dr. Black left the utilization of his work to others, the luster of his achievement would now be undimmed; but unfortunately he followed his researches into a strange realm, that of metallurgy, and as a result threw the question of alloy-making into confusion. He developed an elaborate system of "balancing" which is entirely empirical, and the system itself is condemned by the facts. Summarized, it is as follows:

First: As, in his opinion, all metals procured commercially for use in amalgam alloy-making are impure, and as impurities aggregating from 4/10 to ½ of 1 per cent. are fatal to the attainment of certain requirements in an amalgam made from their alloys; therefore test batches must be made from each new lot of metals, and, upon the basis of the results obtained on the micrometer and dynamometer a perfect "test" formula must be evolved from which the regular batches intended for use are to be made.

Second: Alloys are not chemical compounds but mere physical solutions of two or more metals within each other, the percentages of which may be varied at will.

Third: No "formula" is needed when the manufacturer follows the G. V. Black method of "balancing."

Let us take up the first of these assumptions. Upon the authority of Mr. Jacob P. Eckfeldt, chief assayer, U. S. Mint, Philadelphia, bar silver of a fineness of 999.5 and from that point upward to 999.75, is commercially available at the U. S. Assay-office, New York City, N. Y., at current market rates. This silver the writer is able to purchase, regularly, from a Philadelphia broker of precious metals, who does not seem to regard its fineness as being especially remarkable. Purified shot copper, electrolytic, has a guaranteed fineness of 999 plus, and analyses have shown that the odd one-thousandth of impurity is oxgyen, due to dissolved oxids, an easily corrected deficiency. "Straits" tin, purified, has an average fineness of 999.5, often it is finer, and a recent analysis of commercial tin made for me by Booth, Garrett & Blair, showed a fineness of 999.61. Thus a "G. V. Black" alloy made from a formula approximating 68 per cent. Ag, 27 per cent. Sn, 5 per cent. Cu, made from metals of the purity noted, should be within 0.036 of 1 per cent. of 1000 fine, a negligible difference.

It might be argued that such metals were not to be secured at the time of Dr. Black's investigation, but that would not be correct, for pure metals were certainly then obtainable at an added retail cost to dental alloys not exceeding 20 per cent. With such metals available, a formula once established could be continuously reproduced, provided the work were done by a metallurgist having the knowledge and exercising the care needed in such operations.

Pursuing this, then, to its logical conclusion, it must have been assumed that the dental fraternity was unwilling to pay a price commensurate with an alloy of pure metals, which assumption seems untenable.

The second assumption, that the metals of an alloy may be varied in their percentages, which means that their chemical affinities may be disregarded, shows that Dr. Black either did not avail himself of the copious literature on the subject or entirely ignored it, and therefore merited to some extent the caustic criticism of Dr. Ad. Fenchel,* who denominated Dr. Black's measurements as superficial and his metallurgical investigations as barren of a true comprehension of the internal structure and chemical constitution of alloys.

The first published observations upon this important theory of alloying (quantivalence and chemism), by an American investigator, are, so far as I have been able to learn, those of Dr. Edward C. Kirk, in the section of Dental Metallurgy, chapter on Alloys, page 796, Litch's "American System of Dentistry, 1887," from which I quote the following:

> There is little doubt that in many, if not the greater number of alloys, the laws of quantivalence and chemism are factors of their formation, giving rise to the production of metallic compounds, the component parts of which are united in equivalent atomic ratios. This is indicated by the energy which attends their union in some instances, and the definite crystalline form of many of the alloys, notably those of copper with tin. The tendency of metals to unite in definite proportions may be verified by cooling a melted mixture slowly, and when partly solidified pouring off the liquid remnant (as in the familiar experiment of making sulfur crystals), when crystals are left which are always combinations in the proportions of the atomic weights of the component metals.

There has been no lack of convincing confirmation of this statement, as many American and foreign scientists have sustained it; in fact, there can be no doubt that Dr. Black's achievement would have been enhanced had he given serious consideration to this factor, for alloys made according to his system of physical balancing are, of their nature, out of chemical balance—an error which seems unexplainable when his opportunities are considered.

DR. C. M. MC CAULEY'S TEST OF ALLOYS.

Dr. C. M. McCauley's report to the National Dental Association of his tests of amalgam alloys, which report was published in the DENTAL COSMOS for January 1913, may be cited to show the weak points of Dr. Black's system of "balancing." The results of Dr. McCauley's tests have not only caused a great change in the attitude of dentists toward purely commercial alloys, but have shown that there are marked aberrations in alloys made by Dr. Black's method. Some of these alloys showed a wide range of shrinkage and expansion, a phenomenon easily understood by those who accept the chemical theory of alloying. It may be remarked that the alloys of silver, tin, and copper stood the best, while those containing zinc showed greater aberrations; but as zinc must be used in alloys of the Black or other percentage types, if light color be required, it may be easily seen that "percentage" alloys without a zinc content are likely to undergo chemical solution in the oral fluids as a result of their not being in chemical balance, and so, despite their "physical balance," discolor the teeth in which, as amalgam fillings, they are placed. The alloys with a zinc content should, from the observations of many investigators and from the electro-chemical relation of this metal to the copper content, exhibit volume movements in both directions—in fact, set up a battery in the mouth which should prevent their amalgams from ever attaining equilibrium. There are other factors which militate against the use of zinc, one of which is its property of determining to the top of a cooling mass of alloy, which causes the ingot to be uneven and therefore out of physical balance, and the other is its property of oxidizing during

* See Ad. Fenchel, "Is Dentistry a Science? —An Open Letter to Dr. G. V. Black," DENTAL COSMOS, February 1910, p. 196.

the pouring of the melt, its oxids penetrating and dissolving in the alloy mass before it has cooled, with the effect of reducing the strength of the amalgam which contains it.

The third assumption, that no formula is needed for the making of an amalgam alloy when the manufacturer follows the G. V. Black system of "balancing," might at first thought be dismissed as the extravagant utterance of an overzealous enthusiast, were it not for the commercial advantage which may be taken of it, to the consequent detriment of efforts to secure uniformity in this most important material. It has given rise to a multiplicity of formulæ, afforded opportunities for advertising claims of wonderful and mysterious properties secured through the medium of awe-inspiring "tests" with micrometers and dynamometers—all with the glory of Dr. Black's prestige skilfully interwoven —and, through the relatively enormous expense which attaches to frequent analyses of such alloys, has blocked attempts to ascertain their constituents or to secure other details of importance excepting those of strength and volume change. This leaves the behavior of amalgam fillings made from these "tested alloys" to the "test of time," the very thing that Dr. Black most strongly and most justly condemns. The assumption that no formula is needed, however, falls of itself, for it is a well-known fact that, under the Black method of "balancing," a formula must be worked out before a melt is made, and this formula must be based upon a previously attained "tested" formula which has met the physical requirements noted.

THE CHEMICAL THEORY OF ALLOYS.

Opposed to all this empiricism comes the science of chemistry, illuminating a pathway that has been dark, and with invincible fact leading to truth. Its charts map out the behavior of the metals and their alloys, its microscopes search into their structure and reveal their internal physical characteristics, its delicate apparatus weighs and dissects and classifies them, marks their freezing-point, cooling-curve, miscibility, electrical and thermal conductivity, volume changes, specific and atomic weights—in fact, nothing escapes its searching scrutiny. Chemistry has shown that certain alloys of metals undergo condensation in freezing, and that others undergo expansion, that the affinities of certain metals for each other must be considered before they can be perfectly combined into an alloy, and that the atomic law is the important factor in such combinations. Herein lies the significance of the failure of percentage alloys; they are not combined with respect to their atomic relationship, and therefore, within them, atomic compounds are formed which are surrounded by an unappropriated surplus, a eutectic perhaps, which makes physical balance impossible.

Therefore, bearing in mind the precision of its data, and the fact that such data afford the means whereby the physical behavior of alloys of metals may be accurately forecast, I place supreme confidence in the chemical theory of alloys, and know that it offers the only solution to the amalgam alloy problem.

THE PRACTICAL PHASE.

In connection with the chemical theory of alloying, the writer has repeatedly been asked the question, "Is this chemical theory, which to many of the dental fraternity is unfamiliar, of merely academic interest, or has it a practical significance? Has is been, and is it now, of use?" This, it must be conceded, is an entirely fair question, for truly the dentist busy with everyday problems should not be asked to assume the burden of the consideration of a theory which does not attain results that will be useful to humanity and to dentistry.

The answer to this question is that this theory is the foundation upon which all practical metallurgical work must be based. Without it the metallurgist can well be likened to a navigator afloat upon an uncharted sea, without compass or sextant to guide him. He may grope his way into port and be thankful for his good fortune, but the way has been strewn with wrecks, for which he and others of his kind have been responsible. In the laboratory the study of the chemistry of the metals will enable him to work with them understandingly, to do with them that which in empirical work would seem impossible. The information gleaned from the scientific study of metallurgy will dispel a host of untoward and confusing phenomena, it will be a revelation of the possibilities of applied chemistry, and will, in addition to its practical and useful side, prove a delightful and beneficial study to the dentist having the welfare of his profession in mind.

CAVITY PREPARATION FOR THE GOLD INLAY.

By J. V. CONZETT, D.D.S., Dubuque, Iowa.

(Read before the Seventh and Eighth District Dental Societies of the State of New York, at their annual meeting, Rochester, November 14, 1912.)

THE science of cavity preparation has become a science within the past twenty years. Before the monumental work of Dr. G. V. Black, who demonstrated the fact that all teeth were of the same density and that the carious condition of certain teeth was not the result of their softness, cavity preparation was in a most uncertain and chaotic state. There were good operators before that day, to be sure, operators whose names stand out with the most resplendent glory to this day, and we do not wish to detract one iota from the honor which they so fully deserve; in fact, the greater credit is due them for being what they were in a time when science had not reached its present point. The splendid operations that these men made were made under conditions to cope with which would have been well-nigh impossible for the great operators of today. But great as these men were, they evolved no scientific system that could be handed down to posterity for the guidance of other men not so gifted as they were; each man was a law unto himself, and each operation was made as the exigencies of the case demanded. Today we have a method of cavity preparation that is founded upon scientific and well-demonstrated principles, a system that is fundamental to the preparation of all cavities and all classes of cavities, regardless of whether the cavities are prepared for the reception of a gold filling, an inlay, or a plastic. This system is the work of Dr. Black, and in presenting this paper I do not wish to arrogate any of the credit for the principles that I present. All that I have done in the way of evolving a method of cavity preparation for the reception of the gold inlay has been based upon the system that Dr. Black has given us.

INLAY FAILURES VS. FILLING FAILURES.

The gold inlay has now been before the profession sufficiently long to enable us to determine something of the permanence of operations made by that method, and I think that we can rest assured that the method is all that we hoped for. There have been failures, indeed many of them, and we see them multiplying before our eyes day by day. The poorly made inlays are beginning to assert themselves, for now the cement, which has heretofore saved the teeth in spite of the poorly made inlay, is dissolving out and leaving a space for the ingress of the organisms of caries, and as a consequence there is a recurrence of caries around the inlay, and a recorded failure. Most faulty inlays, however, do not require so long a time to manifest their shortcomings, for the greater part of faulty inlays simply drop out. This is the desirable way of their failure, for a failure of that kind does not disastrously affect the tooth, as the cement usually clings to it and the dentin is protected from caries even though the inlay has fallen out. The loss of the inlay at the same time is an immediate warning to the patient, and as the result the dentist is visited in order to have it replaced, or a new one made, as the case may demand. How different is the failure of a filling! Here the cavity is so made that the filling is mechanically retained, and, if there is a failure, it consists in a leaking of the filling, or a recurrence of caries around the margins; in either case, before the filling is entirely lost, the caries progresses until a sufficient amount of the tooth is gone to render the mechanical retention of no avail, and when such is the result, so much of the tooth structure is lost that there is grave danger for the future safety of the organ. We need no amplification of that truth; it has impressed itself upon all of us so often that no comment is needed.

THE IMPORTANCE OF CAVITY PREPARATION.

There *are* failures of the inlay, however, and it is our duty to observe them, and, if possible, try to find the cause and the remedy.

In all of the failures that have come to my notice there has been one great cause, and that has been an unscientific cavity preparation.

If this observation be correct, then it is our duty to point out the defects and show how to prevent them in the future. It will be impossible to go over the entire field of operative dentistry in the time allotted to this paper, neither will it be possible for me to take up all the classifications of cavity preparation, but certain fundamental principles should be stated and their application to a few selected cases studied, in an effort to establish our argument from the few cases at our disposal.

THE OUTLINE FORM.

The first object that we must attempt to obtain in the preparation of any cavity is the outline form. This form comprises the doctrine of extension for prevention and the esthetic form. It would hardly seem to be necessary to emphasize the necessity of obtaining sufficient extension of the margins of the cavity to bring them into the areas of comparative immunity to caries, but an extended observation of operations made by various practitioners in all parts of this country convinces me that it is still necessary to preach extension for prevention.

EXTENSION FOR PREVENTION.

What is extension for prevention? Does it mean cutting a tooth all to pieces, as has been frequently charged by those who have opposed this principle? Or is it a safe and sane method of so preparing a cavity that the organisms of caries will have the greatest difficulty in obtaining a foothold for a further invasion of the tissues of the repaired tooth? We contend it is the latter, and that no cavity is scientifically filled if this principle has been ignored. We claim that it is scientific because it takes into account the universally recognized etiology of caries, and represents the most rational method of combating a recurrence of that disease.

We know that caries of the teeth is caused by a micro-organic invasion of the dental tissues, and that the inherent strength or weakness of the tooth has nothing to do with this invasion. In other words, there is no such thing as a hard or a soft tooth; all teeth are of the same density. That being the case, and knowing further that the organisms of caries, in order to begin their work of devastation, must protect themselves with an osmotic membrane called the bacterial plaque of Williams, and further knowing that this plaque cannot be deposited upon a surface of the tooth that is subjected to the friction of the food or the movement of the tongue and lips, we believe that, by carrying the lines of a cavity that we are to fill out far enough to have the margins of the finished filling lie in such territory, we are safeguarding the tooth with the greatest factor of safety against the recurrence of the process of caries around the filling.

This doctrine has been thoroughly tested for over twenty-one years by men who have won for themselves a place in the forefront of the ranks of operative dentistry, and has in no case been found wanting. It means, in cavity preparation, the carrying of all the lines of the cavity margins so far out of the embrasures buccally and lingually that the food in its excursions over the teeth during the process of mastication will keep the margins of the filling clean. All fissures and pits are followed out to their farthest ends. The margins of the fillings in such territory will lie in smooth surfaces, and the gingival surface will lie under the free margin of the gum, for again it has been observed that caries never occurs under healthy gum tissue. The argument has been raised that it is not possible or advisable to extend a cavity so that the filling will be under the gum in those cases in which the gum has so receded by reason of pyorrheal process that the cementum is exposed. All this is true, but in such cases and those of a similar character in which the gum tissue has been crowded out by reason of the food crowding into open interproximal spaces, the extension should be sufficient to carry the margin far enough to have it lie in the territory that would normally have been under the gum, and if the tooth is then properly contoured, and the contact point is properly reproduced, the gum will in many cases come back into the interproximal space, and a healthy condition of the septal tissues will be reproduced.

There is no ironclad rule to determine just how far each tooth must be cut in order to carry the margins into safe territory; this is determined by a study of the conditions involved in each case. In teeth with well-developed bell-shaped crowns there is no necessity for as great an amount of cutting buccolingually as in teeth that have flat, broad contact points. In those cases, if it is possible to obtain sufficient separation and the contour of the tooth can be so shaped that there is a well-defined contact point, it will not be necessary to cut as far as it would otherwise be. In all cases, however, the cavity should be cut far enough to bring the margins to lie in territory that can be automatically kept clean.

ESTHETIC CONSIDERATIONS IN CAVITY PREPARATION.

The esthetic form is that form given to the filling which most perfectly conserves the beauty of the tooth. A curve is always more beautiful than an angle, therefore it should be our endeavor always to avoid sharp angles in any part of the filling that is visible. The filling should always be so shaped that the tooth is as nearly as possible restored to its original shape. A tooth that is not so restored loses its symmetry and disturbs the harmony of the entire denture, and is, to that extent, lost. A restoration made with gold is in most cases more esthetic if the metal itself is brought into the line of vision, rather than if it is hidden to the extent of appearing as a dark line between the teeth, consequently making the tooth surface appear unclean. It is far better to show the clean gold than to expose the patient to the suspicion of having neglected the toilet of the mouth. Therefore, for esthetic reasons, the cavity is extended until the metal comes into the line of vision.

THE RESISTANCE FORM.

The resistance form is the next step that demands our attention, and must be determined by a study of the condition that we are called upon to correct. All fillings do not have the same amount of stress to resist, consequently it would be foolish to cut as broadly and as deeply in one case as in another. If we were not to cut sufficiently deeply and broadly for the filling that is to bear a great amount of stress, the filling would fail by being forced out of the cavity, or by the walls of the tooth breaking under the force. All individuals do not exert the same amount of force upon their teeth. The dynamometer tests will vary from 75 pounds in one individual to 300 pounds in another, and it would obviously be foolhardy to use the same cavity form for two fillings which are to resist different stress. We should in all cases observe the strength of the occlusal force, the strength of the masticatory muscles, and the facets that have been worn upon the teeth by reason of occlusal stress, and then, with the knowledge so gained, lay out a proportionately resistant cavity form. Neither do all surfaces of the teeth in the same mouth receive the same amount of stress. For instance, a filling placed in the mesio-occlusal surface of an upper molar or bicuspid will have to resist many times more stress than a filling placed in the opposite surfaces of the same teeth; likewise a filling placed in a cavity in the disto-occlusal surface of the lower molars or bicuspids will have to bear a much greater stress than fillings placed in cavities in the mesial surfaces of the same teeth. This by reason of the fact that the mandible closes upon the maxilla with a combined upward and forward motion; thus the thrust is directed against the distal surfaces of the upper teeth and the mesial surfaces of the lower teeth, and fillings placed within these surfaces are thrust into the cavities, while fillings in the mesial surfaces of the upper and in the distal surfaces of the lower teeth receive the stress in such a way that the filling has a tendency to be forced out of the cavity. Therefore it is necessary to make the resistance form broader and deeper in the mesial surfaces of the upper and in the distal surfaces of the lower teeth than in the opposite surfaces of the same teeth.

FLAT SEATS AND OTHER IMPORTANT FEATURES IN THE PREPARATION OF CAVITIES FOR INLAYS.

The form best adapted to resist the forces that are brought to bear upon a filling is that of the flat seat and parallel walls. The box form is the ideal, and the nearer we approach that in our cavity formation, the nearer we will be to the perfect cavity. The flat seat is the logical form to give to any foundation that is to carry any stress, for in that form the stress and weight are equally distributed over the entire surface of the seat, while if the seat were made round, there would be a tendency for the filling to rock away from the point of greatest stress, and as a consequence some other point of the seat would have to bear more than its equal share of the burden; and if the walls were not of sufficient strength to withstand the additional stress placed upon them by reason of the tendency to rocking, they would break; in fact they frequently do so in this form of cavity seating. Not only is the tendency to rock a menace to the stability of the walls of the tooth, but, if there is the slightest motion of the filling within the cavity, a fissure is opened for the ingress of the fluids of the mouth, followed by leakage and failure. Both the gingival and the occlusal seat should be made as flat as it is possible to make them. This can be readily accomplished with an inverted-cone bur of the proper size, which should be sufficiently large to make the seat in one sweep of the bur—usually a number 37 or 39. If the filling is to be an inlay, there may be some danger of making an undercut with an inverted-cone bur, but it is my practice to use this form of bur, and I have no trouble in that respect, but, if it is desired, the same effect can be produced with a square-end fissure bur of the proper size, or with an end-cutting bur, which is really ideal for this form of work. The walls of the cavity should then be paralleled as nearly as possible, and while all undercuts must be avoided in the making of an inlay, we should not err in the other direction, and make the cavity cone-shaped, for that form of cavity offers the minimum of frictional resistance and is the cause of frequent failures, owing to the falling out of the inlay. The walls can be paralleled with a fissure bur held at the proper angle and by sweeping back and forth. At the same time the pulpal wall is prepared in proper relationship to the gingival seat and axial line angles. The occlusal seat should be sufficiently deep to resist all forces that may be brought to bear upon the inlay, whether these forces be those of thrust or pull, and it is just at this point that the majority of failures occur. I have seen many cavities prepared in which the occlusal step was made so shallow that it scarcely penetrated the enamel, so that I was not surprised at the failure of the inlay. It is upon the occlusal step that the safety of the filling chiefly depends. If the step is made deep and broad enough and has its axial walls properly paralleled, there will be no danger of the inlay coming out, but if it is not so prepared, failure may be confidently expected after a shorter or longer period, according to the stress that is exerted upon the inlay. I purposely emphasized the broadness of the cavity in its occlusal aspect, for there must be width of cavity sufficient to allow for enough gold to give strength to the inlay.

SUFFICIENT BULK OF GOLD REQUIRED FOR AN INLAY.

If the inlay is a little narrow piece of gold in its occlusal aspect, it will not have sufficient strength to resist the forces of mastication without the gold stretching or flowing, and if this occurs to ever so slight a degree, the gold moves away from the cavity margin, leaving a vulnerable point which the organisms of caries will readily invade. Gold, and particularly cast gold, flows and stretches under stress, and he is a wise man who, understanding this physical characteristic of the metal, will so protect it from the flowing and stretching forces of mastication that his inlay will not receive a dangerous amount thereof. When the gold must bear a great amount of stress it must be so reinforced that the stress will not be too great for it to bear.

Time forbids to take up in this paper the subject of casting in any of its many aspects, but by way of digression it should be said that in all cases where any stress will be exerted upon the inlay, regardless of whether that stress is occlusal or approximal, pure gold is decidedly contra-indicated. Cast gold is too soft to bear any appreciable degree of stress without flowing or stretching, and the result of its use in many cases will be calamitous.

THE RETENTIVE FORM.

The retentive form is very largely comprehended in the resistance form in the cavity preparation for the gold inlay. A cavity with a flat gingival and occlusal seat and parallel walls answers the purpose of retention in all but special cases which cannot be considered at this time. The resistance form is that form which tends to resist the thrust forces that are brought to bear upon the finished inlay, and the retentive form is more particularly that which has to do with the resistance to the forces that would pull the inlay out of the cavity. In the case of an inlay, the preparation that will best serve the one purpose will best serve the other, so we will only attempt to emphasize that in a cavity which is to receive an inlay there should be no converging gingival lines necessitating a conically formed inlay, for such a form offers practically no frictional resistance, and must therefore depend almost entirely upon the cement for its retention. While the modern cement-makers have given us a cement that is splendid in its place, it never was intended to glue an inlay into the cavity without the assistance of any mechanical retention.

THE CONVENIENCE FORM.

In the formation of a cavity for an inlay there is very little need for a convenience form, and yet a cavity must always be so cut that the wax model and the finished inlay as well can be properly introduced and removed, and if there is a necessity for more extensive cutting of the tooth in order to accomplish this than would be necessary for the sake of extension for prevention, I should never hesitate to do so. It is not possible or advisable for us to make any rules for this purpose, for a cavity that can be easily filled by one operator of greater skill often presents insurmountable difficulties to another. All these factors must be decided by the operator according to his ability. It would be foolish for a dentist, simply because some other operator is able to do so, to attempt to prepare and fill a cavity when he knows it to be an impossibility for him; neither would I admit for a minute that there is any operation that I could not do, when I know that I have been doing it time and time again, simply because some other man says that it could not be done. The only rule, then, that I would make in regard to the convenience form would be always to cut the cavity broad enough to make it perfectly accessible so that the operator is able to make and trim his model perfectly in it. For unless a perfect model of the cavity is obtained, it will make no difference how well the cavity has been prepared, the inlay will fail at some time by reason of the faulty adaptation of the inlay that has been made from a poor model.

PREPARATION OF THE CAVO-SURFACE ANGLE.

The preparation of the cavo-surface angle really belongs to the outline form, but, as it is the last thing that we do in a cavity preparation, and as it is one of the most important, and one of the most abused factors in the preparation of the cavity, I have purposely reserved its discussion for the last. The enamel is the protective coat of mail of the tooth; as long as its integrity is unbroken, the tooth is safe. It is the hardest tissue in the body, and the most resistant to the forces that make for dissolution. In structure it is composed of rods or prisms resting upon the dentin, and held together by a cementing substance. It contains extremely little organic material, and some histologists claim that it contains none at all. Those who think that there is some organic matter in its chemical makeup, admit that it is but a trace. The organ that called it into existence disappears with the eruption of the tooth, consequently the finished enamel is finished for all time. There is no possibility of repair, for the organ of amelification has gone out of existence. While it is exceedingly resistant to chemical and physical forces in its perfect state, once its continuity is broken, by reason of its morphology—viz, a succession of rods resting upon the dentin—when some of the rods have been broken out, the neighboring rods are very easily displaced, and fall into the ditch made by the loss of the approximating rods. Consequently, the repair of a tooth that has been attacked by caries must be made in such a way that the enamel will be properly protected; for if it is not so protected, and if there is left a place where the enamel rods are not supported, they will in turn fall out, and the destructive process will continue as long as there are any unsupported rods next to the carious process. In the preparation of the cavo-surface angle it is the purpose of the operator to prepare this angle so that the filling will protect and seal-in the rods next to the cavity, and, if this is done, the rods farther on will find their accustomed support continued and all will be well; if it is not done, and the rods next to the cavity continue their disintegration, the process will continue indefinitely, no matter whether the tooth has been filled or not. The enamel must be protected, and in the best way.

THE BUTT JOINT CONDEMNED.

There has been advocated the butt joint in the making of an inlay, and I cannot too severely condemn it. In the first place, the butt joint affords no protection to the enamel rods in many places upon the surface of the tooth. In the second place, there is nearly always a slight discrepancy between the inlay and the tooth in the butt joint by reason of shrinkage of the metal. In the third place, there is no flange upon the finished inlay that can be burnished down upon the tooth; and in the fourth place, the butt joint inlay leaves a thin flat piece of cement between it and the tooth which, under the continued pounding during the process of mastication, is liable to fall out and leave a large opening for the entrance of food débris and bacteria. All enameled surfaces should be beveled, and the bevel should be a generous one, but should not be so long that it will leave a thin flange of gold which will curl up under stress, and make a ditch for the harboring of all kinds of filth.

The gingival angle is perhaps the most important, as it is the most frequently neglected, and most frequently the seat of recurrent caries. This angle should be beveled very carefully, because at this portion of the tooth the enamel rods incline apically and, if the margin is not sufficiently beveled, the margin of the cavity would contain a multitude of cut-off rods, leaving unprotected short rods to fall out, subsequently leaving a gap between the inlay and the tooth. This angle can be beautifully made with the gingival margin trimmers designed by Dr. Black, but in some cases I prefer an instrument that I make myself by beveling two Wedelstaedt chisels No. 39 right and left, thus making an ideal trimmer to reach the gingival margins in most of the upper teeth.

IMPORTANCE OF A CORRECT CONTACT POINT.

While the title of this paper does not include making or finishing of the inlay, I cannot but emphasize the necessity of properly shaping the inlay so that the contour of the tooth is properly restored and the contact point properly placed and made. The making of the contact point is a fine art and one of the achievements that distinguish the operative dentist from the bungler, for a filling made so that the contact will allow the food to crowd in between the teeth is worse than a failure—and many a filling I have removed for no other reason. A filling so made is a constant source of discomfort to the patient and a menace to the life of the tooth. The contact point should be placed near the occlusal surface, but not upon that surface, for there should be a rounding of the filling toward the contact point in all directions, or, as Dr. Black puts it, the contact point should be as though two marbles were placed together. If this is done, the embrasures will be so accentuated that the food will encounter no difficulty in traveling over them and keeping them polished, neither will there be any difficulty because of the food crowding in between the teeth, for the bolus will strike the contact and slide off over the rounded margins over the marginal embrasures and into safety.

IMPORTANCE OF SMOOTHLY FINISHED GINGIVAL MARGINS.

Again I must point out the necessity of obtaining a smoothly finished gingival margin. The gingivæ will not tolerate a rough surface, and, if there are overhanging portions and rough surfaces on the filling in this region, a gingivitis will be set up. Dr. Arthur Black has pointed out the fact that the large majority of cases of gingivitis are caused by faulty dental operations in this region.

[See also *Discussion,* as reported under "Proceedings of Societies," this issue.]

TUMORS OF THE MOUTH.

By ROBERT P. BAY, M.D., Baltimore, Md.,
LECTURER ON ORAL SURGERY, DENTAL DEP'T, UNIVERSITY OF MARYLAND.

(Read before the Maryland State Dental Association, Baltimore, June 14, 1912.)

IN considering the very important subject of tumors of the mouth, I shall mention the benign tumors, but shall lay special stress on the early diagnosis of the malignant ones, namely, the sarcoma and the carcinoma groups.

We hear daily of the dreadful scourge of tuberculosis, and the profession and the laity are instructed in its symptoms, prevention, and treatment, but little do we hear of the ever-present and much-dreaded malady cancer.

CANCER.

In my opinion, this malady is more amenable to treatment than is tuberculosis, but we are not trained to be on our guard, to recognize it, and advise its removal. Why should a young girl be ashamed to mention the fact that she has a breast tumor, and why do men carry a carcinoma of the lip under a long mustache to hide it, rather than have it cured? Simply because they are not educated to the fact of the danger of this disease and the possibilities of its cure. And we cannot blame this entirely on the laymen, for we are seeing daily cases in which the different patent medicines have been and are being applied until the disease has spread beyond hope.

This worldwide disease is not confined to any certain people, but occurs among all races of mankind and is found throughout the animal kingdom, being especially prevalent in fish, birds, and rats. It is estimated that twenty-five thousand deaths occur in Japan each year from this disease, and in this country we have constantly eighty thousand cases, and forty thousand deaths each year.

It is undoubtedly true that the public is at present looking for a specific or cure for cancer rather than for a means of preventing it, but we must remember that the profession has done more to prevent disease than it has ever done toward specific cures as we have stamped out smallpox and yellow fever, and recently have gotten typhoid fever under our control by prevention.

ETIOLOGY OF CANCER.

What is cancer? I will quote Dr. L. S. Pilcher, who describes the condition as follows: "It is in the lawless proliferation of pre-existing epithelial cells—in luxuriant, irregularly arranged masses that invade underlying and surrounding tissues, permeating and destroying them, and finally themselves attaining a mass which can no longer be adequately nourished by an accessible blood supply, and which itself then falls into central decay while at the periphery the process goes on—that cancer consists."

From all information which has been presented on this subject, it is evident that there often exists a precancerous condition. Bashford shows that, while no race of mankind is exempt from cancer, the predilection for the disease in certain countries is more due to local irritation than to the peculiarity of climate, soil, or diet. I shall mention only a few well-known sources of irritation as the cause of special cancer. For instance, cancer of the mouth is rare in

European women, but common in men, yet in Ceylon and India women suffer greatly from this form of cancer, because of the chewing of betel-nut and holding the plug in the mouth. In this country, we usually find a history of using a rough pipe-stem, or of a jagged tooth with constant chewing. This process, a chronic irritation, is the causative factor in the production of cancer.

CLASSIFICATION OF TUMORS.

Irritation cannot be classed as the responsible factor in the other form of malignant tumor, namely, sarcoma, as it is largely a growth of young life, and there may be no history of irritation. In this class, the pinched-off embryonic tissue seems to be the more plausible theory. But although many theories have been advanced, we are absolutely ignorant as to facts concerning the production and growth of this form of tumor.

Clinically, a tumor may be defined as an abnormal swelling. The diagnosis of tumors naturally falls under two heads, clinical and microscopic. Clinically, we distinguish two groups of tumors, the benign and the malignant. Microscopically, tumors are classified according to the character of the tissues composing them, namely, epithelial, connective tissue, and mixed tumors.

A benign tumor is one which has no unfavorable influence upon the general health of an individual. It may, however, produce disagreeable and even fatal symptoms on account of its size or situation, by pressure on the surrounding vital structures.

The malignant tumors, on the other hand, possess what may be called an infectious character; that is to say, they not only increase in size, but sooner or later infect the entire organism. Their growth takes place not only by an increase in volume, but by growing into, infiltrating, as it is called, and destroying the surrounding tissues, without regard to their character. They may also spread through the lymphatics and bloodvessels; another marked tendency of malignant tumors is to return after they have been removed.

DIFFERENTIAL DIAGNOSIS OF SYPHILIS.

In the diagnosis of tumors, it is necessary to exclude certain inflammatory processes, notably syphilis, either as a primary lesion of the lips, tongue, gums, or the inside of the cheeks, or the tertiary stage of gummata of jaw, tonsil, etc.

We should no longer be content to wait for the secondary symptoms of syphilis to occur, or to try the administration of mercury or the iodids; rather should we make a section of the tumor and have it examined by a competent pathologist, to whom the section may be mailed, and from whom a diagnosis may be received in from forty-eight to seventy-two hours. We also have two positive diagnostic means, namely, Wassermann's reaction and, if a chancre be present, the examination for spirochæta pallida. By these methods we can exclude the most common disease resembling a beginning oral tumor.

AIDS IN THE DIAGNOSIS OF TUMORS.

The history of a tumor furnishes our most important aid. A tumor which has existed for a long time and has grown slowly is probably benign; if such a tumor takes on a rapid growth, it has probably become malignant.

Age has a certain characteristic attraction for tumors. For example, the benign tumor may be considered a growth of young life. The sarcoma, or malignant connective tissue tumor, also occurs most frequently in the young adult; while a cancer or malignant epithelial tumor practically always occurs in middle life, or the cancerous age, from forty to sixty. It may be stated here that the younger the patient, the more rapid the growth of the malignant tumor, and the more advanced the patient is in years, the more favorable the prognosis. The average duration of sarcoma, untreated, is from eighteen months to two years; of carcinoma, from three to four years. This includes the pain and suffering known only to those bearing the burden, and the foul ulcerating tumors are disagreeable not only to the bearer, but to his friends, making him an outcast during the remaining days of his life.

SYMPTOMS OF SARCOMA.

I shall discuss briefly the local appearance of the most common tumors of the mouth and their most prevalent position. Sarcoma involves the jaw in the form of an osteosarcoma. It may start in the interior, from the cells of fetal marrow, or from the surface of the bone and the periosteum. This tumor usually occurs in the young, it grows rapidly, is of a soft consistence, and gradually absorbs the bone, with no enlargement of the neighboring lymph glands. It is of a brownish-purple color, and there is no limit to its extent. It may invade the antrum and orbit, or form a large mass of the size of a child's head in the lower jaw. Concomitant with this, there is the anemia and cachexia so characteristic of malignant disease. To recapitulate, sarcoma has its origin in connective tissue; it is a tumor of rapid growth; it may early be incapsulated, but later infiltrate; it practically always occurs in the young.

SYMPTOMS OF CARCINOMA.

Carcinoma or epithelioma has its favorite site in the lip and is generally due to chronic irritation. It always occurs after middle age, and is caused by the irritation of a tobacco pipe or a prominent jagged tooth. The first symptom will be a slight thickness of the mucous membrane, which will peel off and practically disappear only to recur again. There will be noticed a slight discharge and, at this early period, no enlargement of the lymphatic glands, but it requires only a short time for the disease to become embedded in the tissues and to extend to the neighboring glands, often involving a dangerous risk, and a serious prognosis, if surgical treatment is finally resorted to.

NECESSITY OF EARLY CORRECT DIAGNOSIS AND TREATMENT.

These conditions are frequently overlooked by the busy dental surgeon or are passed by in the early stages as mere ulcerations, and temporized with until the critical time has passed, and what would have been a preventable disease stands out defying every known means of treatment. This is not mere hearsay, but almost daily we see neglected cases coming to the surgeon too late, which while not wholly the fault of the profession, is largely due to our failure to teach the layman not to trifle with conditions with such grave possibilities.

At present we recognize no cure of cancer other than that obtained by its removal from the body by means of the knife, the cautery, or destructive rays. We ourselves must learn and we must teach our patients that the risk lies not in surgery, but in delayed surgery. We can, however, say this—that we know nearly or quite as much concerning cancer as we do of other medical and surgical diseases. Our present knowledge of the prophylaxis of cancer indicates that all tumors of the mouth should be subjected to a careful examination, and excision should be advised in order that we may reduce the mortality by early and careful diagnosis.

SUGGESTIONS IN THE TECHNIQUE OF RETENTION.

By ALFRED M. DESNOES, D.D.S., Brooklyn, N. Y.

(Clinic given before the Eastern Association of Graduates of the Angle School of Orthodontia, New York, N. Y., April 26, 1913.)

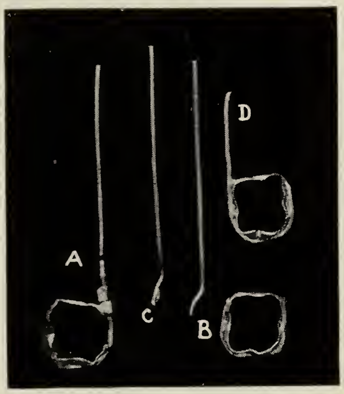
ACCURACY in the alignment of their component parts is essential in the construction of all retaining devices.

The method most commonly in use for making retaining appliances, by first fitting the bands, placing them on the teeth, then taking an impression with the bands in position, replacing the bands in the impression, and then filling this up with some suitable material, and building up the device on the model thus obtained, insures accuracy in alignment, but occupies a considerable portion of time, allowance having to be made for the pouring of the impression, the hardening of the plaster, and the separating of the model.

The suggestion that I am about to make is one that insures absolute accuracy in adjustment with a great saving of time and obviates the necessity of pouring the impression and separating the model.

Previous to the patient's arrival, in order to save time, bands are fitted for the anchor teeth, using some old model for this purpose. If an old model is not obtainable, a modeling-compound impression is taken of the teeth to be banded, from the original model, and the bands are fitted upon this. If a screw band is selected, the end of the screw portion is filed to the same gage as the lingual wire that is to be used, and this wire is soldered to the end of the screw. (Fig. 1, A.) I will later explain the purpose of this procedure. If plain bands are used, they are placed on the teeth, and a scratch is made at the spot where the lingual wire is to be soldered. The end of this wire is bent to the contour of the band, and a flat surface filed so that it will rest firmly on the band. (Fig. 1, B.) A little solder is then flowed on this surface (Fig. 1, C), the band is held with a pair of tweezers over the seam, the wire dipped in flux, placed in position and soldered;

FIG. 1.

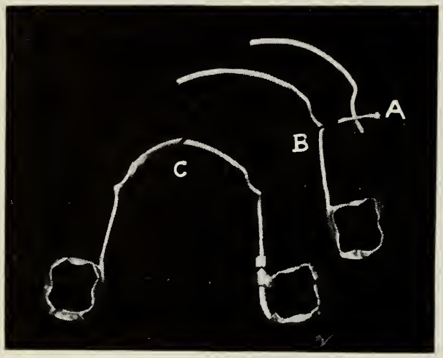


the flat surface on the wire forms a seat, and keeps it in position while soldering. This wire is then cut off to a length that will reach either distally or mesially to the canine, depending upon where the next attachment is to be soldered (Fig. 1, D), and adjusted in the mouth.

A piece of wire is then selected to be made into the front segment; this is bent at a sharp angle and then conformed to the contour of the canine (Fig. 2, A), allowing, of course, for a band if one is to be placed on that tooth, leaving it sufficiently long so that it can be cut off distally to bend—it is much easier to cut this wire off distally than to change the sharp bend in the wire. It is then soldered to the extension wire coming from the molar band. (Fig. 2, B).

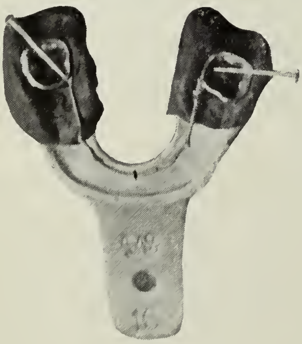
At this point I would say that joints of this character are often weakened in

Fig. 2.



soldering by the slight jarring of the hand in the removal of the piece from the flame, while the solder is in the process of congealing. I prefer, therefore, to keep the hands in the same position and blow the flame out of the way,

Fig. 3.

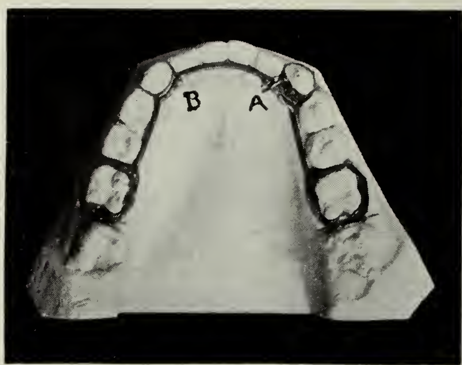


thereby cooling the piece quickly and preventing the jarring of the congealing solder.

The band with the attached wire is then placed in the mouth and bent to conform accurately to the lingual surface of the incisors, allowing the end to just barely come in contact with the end of the extension wire coming from the opposite band (Fig. 2, C). In my experience the easiest place to make this joint is at the central incisors, although it can be made at any convenient spot.

At this stage the attachments are added to the bar, regardless of whether it be a spur to maintain a space, or whatever other attachment the case demands. On this particular piece an attachment has been placed for a stop—and this is done by soldering a piece of wire lengthwise on the spot where the stop is to be made, and then cutting off the surplus. After the attachments have been soldered in position, the appliance is polished in order to avoid the

Fig. 4.



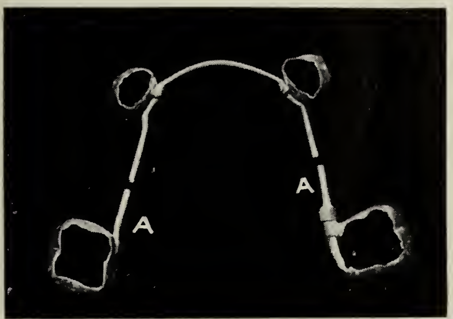
possibility of its bending when finally assembled.

The two parts are now placed in position on the teeth, and a suitable impression tray—from which the front and back flanges have been cut away (Fig. 3) is selected, and the inside surface roughened so that the impression material will adhere to the cup. A small amount of plaster or modeling compound, depending upon the location of the joint to be soldered, is placed in the ends of this tray, and an impression taken over the bands. By having the flanges of the cup removed, it can be observed that the ends of the two wires do not move out of position while the impression is being taken. When the impression material is hard, the whole is taken from the mouth; the bands are then removed from the teeth and replaced in the impression. If a screw band is used, the number of turns required to loosen the band is counted, and the screw is turned back again before replacing the band in the impression. The bands can be held firmly in position by means of a few pins. The two ends of the wire are thus held in perfect alignment, and with a delicate flame can be easily soldered together. (Fig 3.)

The joint can be soldered quite near the compound, if the imprints of the teeth are filled with cold water while soldering, and a small flame is used. In this way a rigid retainer is provided as far as the molar bands are concerned.

In this case, I am going to put on an extra attachment to hold the canine

Fig. 5.

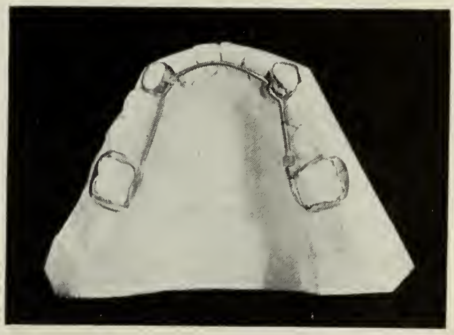


region; it was for this purpose that the stops were placed on the wire. Bands are made in the usual way for the canine teeth, and, with the appliance in place, a scratch is made on the band to mark the position for the soldering of a small wire hook. The band with the hook soldered to it is then replaced on the canine, and a mark made on the lingual wire alongside this hook. (Fig. 4, A.) The appliance is then taken off, and a groove filed on the lingual wire following the mark (Fig. 4, B), into which the hook coming from the canine band will fit when adjusted.

The lingual wire is now cut apart at any suitable place—usually about one-eighth of an inch from the anchor bands—and a tube is slipped over each short end and soldered to it. (Fig. 5, A.) The lingual wire will fit accurately into these tubes when assembled.

The object of filing the screw portion of the screw band will now be fully comprehended; by cutting it apart at the

Fig. 6.



joint where it was soldered to the lingual wire, the tube can be slipped over the end of the filed portion of the screw and soldered.

It is much easier to make the appliance first rigid and then cut it apart and solder tubes to the end of the wires coming from the bands, than to solder the tubes first to the bands and attempt to fit the lingual wire into these tubes.

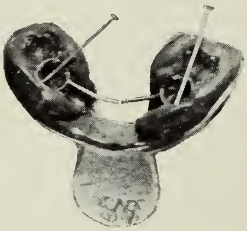
Fig. 7.

After the appliance is cemented in place, the little hook attached to the canine bands is bent over the lingual wire into the groove filed in it and the canine region is thus securely held by the stop on either side of the hook, and yet free movement is allowed for the roots of the teeth. (Fig. 6.)

Occasionally a great deal of the retaining appliance can be made on a model before the arrival of the patient, and the final adjustment made in the mouth and the appliance held together while soldering in the manner shown. Fig. 7 shows one of a pair of right and left pliers for the bending of the lingual wire.

The same plan can be utilized for making an independent retainer between the canines, and I have here a cup trimmed for the purpose, and holding an appliance in position. (Fig. 8.)

Fig. 8.

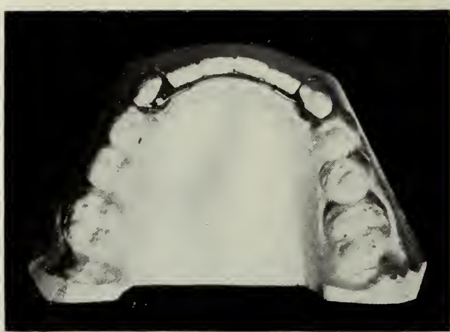


After the halves have been soldered together they are cut apart, and tubes are soldered to the short ends of the wire attached to the bands. The lingual wire will fit accurately in the tubes and allow the movement of the canines during the period of retention. (Fig. 9.)

This method of holding the parts of the appliance in alignment while soldering—by means of the impression instead of the models—can be utilized in other ways, and will save a considerable amount of time when it is necessary to complete the retention at one sitting.

One word should be said as to the cementation of this appliance. I usually cement one molar band at a time, keeping, however, the two bands in position, but with the cement in only one of the bands. In this way the appliance is still kept in alignment, but one's attention is concentrated on the band that is being cemented. After the cement is hardened, the uncemented band is slipped off, dried, and cleaned, the cement is placed in the band, which is slipped over the end of the lingual wire and cemented in place. In this way a firmer cementation of the band is insured than if the operator's attention were occupied by the manipulation of two bands at the same time.

Fig. 9.



BLOOD PRESSURE.

By P. H. MARKLEY, M.D.,
VISITING PHYSICIAN TO COOPER HOSPITAL, CAMDEN, N. J.

(Read before the Southern Dental Society of New Jersey, at its monthly meeting, held at Camden, N. J., March 19, 1913.)

THOUGH the phenomenon of blood pressure was pointed out nearly two centuries ago, it attracted but little attention until comparatively recent years, and even at the present day but few practitioners have any definite conception either of the elements controlling its variations—so far as they are known—or of their significance.

THE PHYSIOLOGY OF BLOOD PRESSURE.

Blood pressure may be said to be a mechanical problem of physiology, an evolution of the laboratory, depending upon four separate factors: (1) The energy of the heart; (2) the peripheral resistance; (3) the elasticity of the arterial walls, and (4) the volume of the circulating blood. A disturbance of the equilibrium normally existing between these factors, even though it be but of functional origin, will be shown by a variation in the normal blood pressure scale.

HISTORY OF BLOOD-PRESSURE MEASURING APPARATUS.

As far back as 1733, Hales demonstrated the importance of some of these factors, though it is to the kymograph of Ludwig, perfected in 1847, that we owe nearly all of our knowledge of the circulation.

His method consisted in obtaining a blood-pressure tracing by a recording manometer, connected directly with an opened artery, and writing upon a rotary cylinder. As this method involved the opening of a vessel, it was not adapted for clinical purposes, and it was left to Marie, in 1858, and later to Kries, in 1878, to perfect the working models, of which the instruments now in use are modifications.

These instruments, it should be borne in mind, do not register the mean pressure, but simply the highest, the systolic, and the lowest, the diastolic, though by certain mathematical calculations the mean pressure may be accurately obtained.

THE VALUE OF BLOOD-PRESSURE RECORDS.

To attempt other than a brief reference to these various methods would involve a multitude of details far exceeding the limitations of the present paper, which simply consists of an attempt to call attention to a few practical points.

So customary has the recording of blood pressure become that no examination of a patient is considered complete without a chart attached to the usual history, showing the findings and variations. In the light of our present knowledge, is this not largely mere fashion? For the mere reading of 150 or 200 does not mean anything definite nor conclusive, and becomes significant only when studied in connection with the concomitant symptoms.

Within the past year, at the bedside of a patient whom he had been called to see, one of the most prominent surgeons of the East made this statement in my presence regarding the value of blood-pressure recording: "I can tell all that it is necessary to know by compressing the radial artery with my finger." This was perhaps true, and entails a condemnation, not of the taking of measurements of the blood pressure, but of our inability to interpret properly the variations of the dial; thus, now, from these variations, we simply know that there is something pathological somewhere in the system, though as the physiologist and the pathologist further enlighten us regarding the significance of such variations we shall no doubt find the study of blood pressure filling an important field of practical usefulness. Its present status may be aptly compared to the position of a young mother using a clinical thermometer. She finds her child to have a high fever, but is entirely unable to interpret it properly, having but little idea as to whether a slight stomach attack, which will subside in a few hours, or the beginning of a profound infection is indicated by the reading of the thermometer, though these phenomena can usually be easily differentiated by the physician.

Life insurance companies have almost universally adopted the measuring of blood pressure as a part of their routine examination, and for this purpose it would, even in its present state of uncertainty, seem to be of the greatest value, for when the physician has carefully examined the applicant, and fails to find anything abnormal, the blood pressure reading affords an additional safeguard, for a reading not conforming to the average table indicates that there exists somewhere in the economy some pathological condition, though its nature and seat may be, for the time being at least, but a mere conjecture.

EFFECTS OF NITROUS OXID ANESTHESIA ON BLOOD PRESSURE.

With the exception of nitrous oxid, I presume, the blood-pressure phenomena observed during the administration of general anesthetics do not interest the average dental practitioner. Observers agree that, in all cases, before the administration of an anesthetic the blood pressure was found to be above normal, and the pulse-rate increasing. This is accounted for by excitement stimulating the cardio-motor and vaso-motor centers.

When nitrous oxid is administered, hypertension and consequent rise of blood pressure quickly follows, presumably owing to the partial asphyxia which it induces. This rise of pressure may be reduced to a minimum by the simultaneous administration of oxygen.

BLOOD PRESSURE IN PNEUMONIA.

Personally, I have found the most reliable and practical use of blood-pressure phenomena in pneumonia, a disease in which death is now believed to be due to vaso-motor paralysis, the patient, as has been suggested, actually bleeding into his own vessels. To use Gibson's words:

> A pressure appreciably below normal in pneumonia is invariably of evil omen, and any considerable fall bodes disaster. When the arterial pressure, expressed in millimeters, does not fall below the pulse-rate expressed in beats per minute, the fact may be taken as an excellent augury, while the converse is equally true.

My personal results are entirely in accord with those of Gibson.

AN INTRODUCTORY STUDY OF HABIT.

By A. LE ROY JOHNSON, D.M.D., Springfield, Mass.

(Read before the Eastern Association of Graduates of the Angle School of Orthodontia, at its annual meeting at New York City, April 26, 1913.)

IN orthodontia we have heard a great deal about the influence of pernicious habits upon maxillary development, a little about the treatment of these habits, and practically nothing about the normal manifestation of *habit* in the life-history of the organism. When we remember the generally accepted fact that an intelligent understanding of pathological processes depends upon a knowledge of normal conditions, we cannot fail to realize our position. If we are to solve the problems presented by this phase of our work, we must get down to a study of the normal expression of it; then we shall have a basis to work upon, and from such a foundation will evolve scientific methods of treating its abnormal expressions. It is in the appreciation of these facts, together with a belief in the vital influence that habit has upon our work, that I have essayed to present an introductory study of it. A paper of this nature must of necessity be elementary and didactic. It is a preliminary study, first pointing out the source of the material, and then introducing the subject itself.

SCOPE OF INVESTIGATION.

When investigating any phase of human experience, recourse is first had to the mass of accumulated knowledge. As the facts of life are observed they are classified, systematized, and formulated with reference to the discovery of general laws or truths. These classifications are called sciences, but, though designated by different names, they are not essentially distinct. How can it be otherwise? —since the units of an organism, though functioning more or less separately, are equally essential to the life of the whole, and therefore the ultimate analysis of the phenomena pertaining to the life-history of the organism must result in but one great classification of knowledge.

Despite our logic, since the present-day schemes of analysis cannot explain away the facts of life, we classify our observations, and from comparative study of these classifications a conception of the whole is evolved. So it must be from a study of many sciences, or at least of the more fundamental laws upon which they are built, that we arrive at anything like a just appreciation of the value of our own.

The study of Habit involves a consideration of both physical and psychical phenomena, as expressed in the general sciences of biology and psychology.

Biology, in its broadest sense, is the science of the physical life of organisms, and at the present time implies a knowledge of molecular physics and chemistry.

PSYCHOLOGY AND ITS DOMAIN.

Psychology is the science of mental life or consciousness, and bears the same relation to the mind as biology to the body. It attempts to treat the mind analytically, to resolve it into its ultimate factors, and to observe the transition from the simple to the complex. Mental life is individual. As expressed by Royce, "Physical facts are public property, while psychical facts are private property. All may observe the same outward physical facts, while but one can be informed of his own mental state." If it were possible to interpret psychical processes as modes of motion or of physical energy, all would fall within the domain of biology. But such is not the case. How, then, since mental life is individual, and since its processes are subjective, can there be a science of it? It is a science owing to the fact that all mental activities have physical expressions, that all psychical processes are accompanied by an interchange of physical forces, and that much of our mental life depends upon more or less definable physical conditions. The science of psychology, then, is the result of study of the physical concomitants to mental activity. It is "symbolic verity." How else can a mind know itself?

In psychology there are two methods of study, one subjective or introspective, the other scientific, observing what exists in nature as contrasted with that which exists merely in the thought of the individual. The first applies more especially to the older general psychology. It consists in the psychologist's determining general laws of the mind by comparing his own mental states with those of other adult human beings. The scientific method is purely objective, and is, in consequence, undoubtedly of greater value. It is the method of experimental and genetic psychology. The former is the most recent branch of psychological investigation, and is carried on in laboratories by means of instruments which seek to determine the physical conditions of mental processes. The latter begins with a study of structure and behavior as a basis for inference regarding possible mental states. However, it is to physiological psychology, which combines both methods of study, that one turns most frequently in the investigation of habit. It is "the science of the human mind investigated by means of its relations to the physical organism." In consequence of its purpose, the subject-matter of this science furnishes a most valuable source of information. In fact, to gain such a conception of the sciences of biology and psychology in general that the material of each pertaining to orthodontia may be systematized and formulated with the ultimate aim of practical utility, they must be studied with the final purpose of ascertaining laws of development, not for the physical side alone, nor for the psychical side, but for the living unity. This, physiological psychology aims to do: "It attempts to ascertain and combine under definite laws the facts of the human nervous system and the facts of consciousness;" to unite in one classification the phenomena of the nervous system and of the mind.

DEFINITION OF HABIT.

Habit is the tendency of matter to yield more readily to subsequent influences of external force, and is manifest by increased facility of adjustment or by decreased resistance. It is the tendency to repetition, and depends upon the plasticity of matter, the physical attribute of yielding to external influences without disgregation of substance. In drawing illustrations of this characteristic from the inorganic world, Dumont says:

> Everyone knows how a garment, after having been worn a certain length of time, clings to the shape of the body better than when it was new. It costs less trouble to fold a paper when it has been folded already. The sounds of a violin improve by use in the hands of an able artist, because the fibers of the wood contract habits of vibration conformed to harmonious relations.

In the organic world the "law of habit" forms a part of the groundwork of life. Every phase shows signs of its influence—the moral rules, the intellectual acquisitions, and the physical activities both of the individual and the race. It is agreed to be the cornerstone of the various theories of development, since with contractility it is fundamental in organic adaptation. It "simplifies movements, makes them more accurate, and lessens fatigue." It reduces action to the realm of the subconscious, and makes possible the highly complex adjustments and activities of our daily lives.

Of protoplasmic substance, nervous tissue is by far the most highly endowed with this property of plasticity; in fact, it owes its very existence to its expression of this characteristic. Here, however, the principle applies to inner structure rather than to outer form. The nature of the effect of stimuli upon the inner structure of nerve tissue has been a source of much speculation, yet at present there is very little definite information to be obtained. In the higher animals the nervous system links the life processes of the organism together in accordance with the external and internal conditions acting upon it, so it is quite evident that a study of the movements of an organism must be founded upon a knowledge of the nervous system, its structure and function.

HABIT-FORMING INFLUENCES.

Now, since habit is a tendency, its study is, in the main, the study of the influences to which it is subject. These influences are the causes of all action, and philosophers see fit to divide them into two great classes, the *external* and the *internal*. As will be seen later, this division is in recognition of the limits of our methods of investigation.

The External Influences include all stimuli from the world outside the organism; stimuli from within the organism itself other than nerve tissue, as the kinesthetic sensation or consciousness of our own movements; and also stimuli from within the brain through its association centers.

The Internal Influences include the type known as mental initiative, free-will, or spontaneous variation, and the idea is clearly conveyed that these are not distinct influences independent of the external class. Some of the activities of animals cannot be explained by either their present sensory disturbances, past experiences, or habits, but seem to possess a certain spontaneity of action, which stubbornly resists reduction to the great external class of influences. At times, what have seemed to be spontaneous activities have been explained, but leading writers think it wise to retain, at least provisionally, the separate class. It is quite obvious that phenomena cannot influence our ideas until they have first impressed our brain through our senses. It is of interest here to note how the view of James that "A particular emotional condition is due to a particular physiological state of some peripheral tissue" received a qualifying jolt by Prof. Sherrington's observation that "A dog was capable of exhibiting much emotion even after all neural connection between a very large portion of the periphery and its brain had been severed some months previously."

Rather than discuss in detail these great divisions of influences as possible causes of habit formation, I think it more advisable, at this time, to suggest three important factors in the development of a specific habit movement. But let it be clearly understood that the division which I make is solely for the purpose of study, and is not to be thought of as distinct in effect; also, that the potency of these factors is due largely to the inherent tendency of neural tissue to repeat adjustments, and of impulses to pass more readily along channels through which others have just passed. These divisions are, first, the nature and order of stimulation; second, the result of action; third, inherited instinctive tendencies. I name them in order of scientific value, although it seems better to consider them in inverse order, beginning with instinctive tendencies.

INSTINCTIVE TENDENCIES.

The conceptions of instinct conveyed by different authorities vary to quite an extent. Some express it as being of a general reflex type, called forth by a particular sensation, perception, or image. They consider instinct and reflex as synonymous, definable as "innate reactions to stimuli." Instinct they apply to the more complex reflex which may be attended by consciousness and desire. Other writers of equal authority say that a concrete explanation of instinct must be looked for, at present, in other fields than science, perhaps metaphysics, or wherever we can explain sympathy. They say that our feeling is what happens in the consciousness of animals acting upon instinct.

Professor Loeb has made a careful study of what he calls tropism—"the innate tendency of an organism to react in a definite manner to external stimuli." His investigations were made upon the simple organisms of low life, and, from his point of view, a nervous system is not essential to these tropisms; organisms without a nervous system exhibited these tendencies, and also those normally possessed of such a system retained for quite a period the power of discriminating sensitiveness, after the system itself had been deprived of its functioning power. He says in conclusion: "I consider a complete knowledge and control of these agencies the biological solution of the metaphysical problem of instinct and will."

But notwithstanding this variation in opinion, it seems agreed that the human organism is born with an extremely large number of tendencies to certain sorts of action, and that the first reaction in a given situation is strongly influenced by these tendencies, whether they are structural determinants or natural dispositions. The influence of the instinct is upon the primary reaction.

Many instincts ripen at a certain age, then pass away. Sucking is one which at birth is strong in all mammals. But it is difficult to realize its existence unless furnished appropriate stimuli during the first few days of life. It would almost seem that instincts appear at different periods as accompaniments of adaptation. Now, as we recognize the influence of instinct upon action, so shall we appreciate the restricting influence of the phenomenon of habit upon the realization of these innate tendencies. And further, the repetition of a reaction which has vitalized an instinct to the profit of the individual, if continued under conditions of abnormal nervous equilibrium and forces productive of the same, will persist and induce disproportion and deformity. May not the normal tendency for old habits to assimilate new ones, and for new impressions to revive old habits, predispose this abnormal expression under such conditions?

THE RESULT OF ACTION.

As yet our conception of habit does not take into account a factor which might select the movements it is desirable the organism should repeat. No provision has been made for the exercise and development of movements upon which life processes depend as contrasted with all other movements. And yet we know that some forms of reaction are more liable to be repeated than others; that painful movements are inhibited is a fact verified in the lowest living creatures. So it is that a consideration of the result of action as a determining influence upon its repetition will extend our knowledge of the significance of the law of habit as expressed in the living organism.

If a movement or action result advantageously, if it elicit a feeling of pleasure, satisfaction, relief, or desire, the chance of its being repeated is greatly enhanced. The apparatus concerned in its exercise is strengthened. It is upon this conception that Baldwin, in his "Mental Development of the Child and Race," builds his circular reactions as a basis for imitation. He says that "Accommodation is the outcome of habit. The result of every attainment of a beneficent experience is to discharge an excessive pleasure wave of movement from which new adjustments are selected." In contradistinction to Baldwin's idea of pleasure as the determining factor in the repetition and extension of activity, Royce suggests restlessness. He says that an unsatisfactory result will lead to the repetition of movements when few sources for variation are available, and, under reverse conditions, to efforts at movement in new directions. It is quite evident that both recognize the determining influence of the result of action upon its repetition.

Professor Freud, in his "Three Contributions to the Sexual Theory," discusses certain habit movements in children as a manifestation of infantile sexuality. Thumb-sucking he takes as an illustration, showing how, as a result of a rhythmic sucking or rubbing contact, a portion of the skin or mucous membrane may behave like an erogenous zone, and the child find gratification in the simplest way. Notwithstanding the wide difference of opinion among his critics regarding the merits of his work, it is pregnant with many suggestions. And one cannot fail to appreciate his viewpoint that every child is born with instincts which furnish desires and cravings of a primitive nature, and that these are molded into energies of value under the influence of a healthful environment acting through a normal nervous irritability. If the reverse is true, then under the pressure of conventional civilization and an unhealthy environment, a hypersensitive nervous system will develop unlimited variation. Habit movements in children are, to an unknown extent, expressive of the conditions of nervous equilibrium in the growing organism.

NATURE AND ORDER OF STIMULATION.

The first factor in habit formation which I mentioned was the nature and order of stimulation. That it is the most prolific source of study can hardly be questioned in the light of the nature of our subject. We know that a habit movement is primarily the result of a reflex or impulse. Consequently a study of the nature and order of stimulation as a factor in the development of a specific habit is a study of the cause and character of the primary reaction from which the habit movement has evolved, and of the increased susceptibility to different expressions of this primary cause, as a result of organic modification from exercise. Such a study, as intimated, must be founded upon a knowledge of the structure and functions of the nervous system.

THE NERVOUS SYSTEM.

So far as the nervous system will admit of scientific explanation, it must be considered as a molecular mechanism. Such parts of it as can be controlled for experimental purposes demand a physical and mechanical interpretation. The inadequacy of a mechanical theory, however, is obvious when we realize that, to explain the acts of the nervous system is to explain what it is—since, when the nerve dies, the physiological functions depart. Nevertheless, the nervous system is a mechanism; but it is a biological one, and distinctly so. Its plan shows the marks of growth and adaptation, of modification from exercise. The structural units are arranged in a systematic whole; they are dependent upon each other for the part each plays in the system. For this reason it is not possible to isolate perfectly the elements, such as a nerve fiber or cell, to study its normal functions. Just so far as they are separated from the other parts, they are in abnormal conditions and show abnormal results. Notwithstanding this fact, many important discoveries in the general physiology of nervous tissue have been made by experimental methods upon detached parts. But the results of such experiments assume their real value through an appreciation of the fact that the mutual condition and reciprocal action of the units are essential to the normal nervous mechanism. A scientific study of human action is inseparably linked with general nervous physiology.

PURPORT OF THE RECENT INVESTIGATION TO ORTHODONTIA.

The purpose of orthodontia is to assist in establishing and maintaining normal occlusion of the teeth of the human individual. This end we have endeavored to realize through the direct application of artificial force. The limitations of this method are evidenced by clinical experience and scientific data. Both call for the utilization in treatment of those natural forces to which all cases are in the end referred. The teeth are units of the human organism, and so bear a definite relation to the whole life-history of it; consequently, an intelligent conception of the influences to which they are subject can be formed only from a thorough study of the fundamental expressions of life activity. I have endeavored to emphasize one—the Law of Habit.

CORRESPONDENCE.

THE DENTIST'S RIGHT TO ADMINISTER ANESTHETICS.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—The Legislative Committee of the Ohio State Dental Society takes a pride (a pardonable pride, we believe) in telling the dental profession through the COSMOS that the dentist's authority has been widened here in the State of Ohio by the passage of the Senate bill No. 220. Said bill gives legal authority to the dentist to practice the administration of anesthetics for any purpose.

Hitherto a construction of the medical practice law limited the dentist's right to give general anesthetics to their administration for dental operations alone. Under the new law a dentist has the right to administer anesthetics for a physician or surgeon for all sorts of major or minor operations.

This extended power was asked for by the organized physicians of this state, as well as by the dentists, and the work that has been done this winter by the dentists of the state through the Legislative Committee has only cemented more firmly the bonds of fraternal friendship that already existed between the professions of medicine and dentistry.

W. I. JONES,

Ch'man Legislative Committee.

COLUMBUS, OHIO, April 26, 1913.

Proceedings of Societies.

NATIONAL DENTAL ASSOCIATION.

Sixteenth Annual Meeting, held at Washington, D. C., September 10 to 13, 1912.

THE CLINICS.

(Continued.)

CAST INLAYS.

Dr. Joseph Head, Philadelphia, Pa. "Compound Approximal Contour Gold Inlay, with a Gold Matrix, Moss Fibre Gold, and 22-Karat Solder."

The method demonstrated by the clinician is as follows: An accurate impression is made of the cavity with pure gold plate, 1/300 of an inch in thickness. A mass of moss fibre or any sponge gold is then molded in the fingers until it has the form of a wedge that will approximately fill the cavity when condensed. This wedge is pushed into the gold form while it is resting in the tooth cavity, great care being taken to burnish the moss fibre gold toward the wall of the adjacent tooth, so as to make a dense plate of gold that will serve as an approximal contact point. The filling being thus formed, more gold being added to obtain the desired contour, the gold matrix with the molded moss fibre gold is removed from the cavity and is filled with 22-karat solder, great care being taken that no solder flows on the outside of the contact point. When this is finished, the filling can be trimmed and polished in the usual way.

Dr. L. L. Zarbaugh, Toledo, Ohio. "Removing Impressions, Attaching and Chilling Sprue Wire in the Mouth."

The sprue wire is attached to the end of a nozzle on a water-syringe by means of a set-screw. The wire is heated and inserted in the wax, and a jet of cold water chills and firmly attaches the wax to the wire. The wax model is then removed and invested.

Dr. H. H. Street, Baltimore, Md. "Facing Inlays with Silicate Cement."

The cavity is prepared in the same manner as for a gold inlay, and the wax model is made; then the labial surface of the wax is carved away, and the model invested and cast. The gold is cemented into place, and the labial surface filled with any silicate cement. It is best to make undercuts in the gold before using the silicate cement.

By using this method we have all the advantages of a gold inlay without any gold showing.

Dr. C. O. Simpson, St. Louis, Mo. "Details in Inlay and Treatment Work."

The clinician demonstrated the following methods of practice: A staple of gold is incorporated in mesio-disto-occlusal wax inlay models to prevent their distortion. Hollow inlays are made by investing the external surface and the margins of the wax models, with the cavity surface exposed, so that the interior may be removed as desired without danger of distortion or injury to the margins. The desired contour on the approximal surface of inlay models is built up by additional wax before investing.

The clinician also showed some technique cases which illustrated the accuracy of fit to be obtained with Welden's Casting Porcelain. The clinician also demonstrated the ease with which cotton dressings may be carried to place in root-canals by the use of Dr. Funk's Apex-treating Broach. This broach has a small notch in the end to carry the dressing forward, but offers no resistance on its removal.

Dr. H. Herbert Johnson, Macon, Ga. "Other Methods of Making Gold Inlays, and Ideas in Crown Work."

The clinician demonstrated that in many cases the making of inlays by the Alexander Plastic Gold method is simplified by using a matrix in the cavity of No. 60 gold foil, or No. 20 rolled gold. The use of plastic gold was also shown in mounting crowns, backing teeth, etc. The clinician also showed how fillings of a high karat can be made for exposed surfaces by burnishing moss fibre or Corona gold into a matrix of No. 60 gold foil in the cavity, and can afterward be further solidified with a limited amount of 22-karat solder flowed into its surface.

Cases, represented by models, of broken lower jaws set with an original burnished gold splint to be cemented on the teeth, were also shown and explained. The use of Price's artificial stone was shown in the making of Alexander's hood abutments. This method was recommended because of the hardness of the stone, which renders it possible to do burnishing on its surface. This artificial stone will withstand a high heat, and annealing and soldering can be done directly on a model made of this material.

Dr. W. C. Gowan, Peterboro, Ont., Can. "New Cavity Forms for Gold Inlays, Shown by Preparations upon Extracted Teeth. Impressions, Models, Wax Patterns, and Castings."

The clinician demonstrated a departure from hitherto established cavity forms, which is rendered possible by Price's artificial stone and a new technique.

A cast inlay of complex form differs from a corresponding foil filling, in tensile strength, retention, manner of insertion, and form necessary for resisting stress.

Gold alloyed with 5 per cent. of platinum or coin silver, or reinforced with iridio-platinum wire and cast under high pressure is stronger in all ways than is a foil filling of like size and form.

Certain interior dimensions and a certain form of the cavity are necessary for the insertion of foil which are not necessary for the insertion of an inlay.

To withstand masticatory stress an approximo-occlusal foil filling requires a broad, flat gingival wall at right angles with the axis of the tooth, as a foundation, and a dovetailed step on the occlusal aspect as a brace. An inlay, on the other hand, being a single rigid piece, is supported by the whole transverse area covered by it. Its hoodlike hold in the occlusal portion of the cavity is much stronger than that of a foil filling, so that in order to resist occlusal stress, a relatively smaller gingival wall, and sometimes none at all, is needed.

When the dentin underlying a marginal ridge is not destroyed by caries, broad rectangular preparation of the proximal portion of the cavity only transfers a part of the stress-resisting area from the step to the gingival wall, without increasing this area at all. Such preparation for a gold inlay, while perhaps necessary for making a wax pattern in the mouth, is obviously unnecessary for the purpose of retention or resistance against occlusal stress. It is, moreover, a cruelty when practiced in vital teeth, and a waste of tissue in any tooth. Thin edges of a gold inlay can be extended to any desired distance beyond the necessarily deep parts of a cavity; therefore the extension of the cavity outlines to immune areas does not require a like extension of deep parts designed for retention or resistance, as in foil fillings.

By use of an impression and stone model, the complex cavity preparation for gold inlays can and should be made simpler and less wasteful than that for any other filling.

A thickness of gold sufficient to withstand the impact of opposing teeth without changing form, and a depth and distribution of parts effectual for resistance and retention when cemented, are always necessary; but no advantage is gained by adding to the mass of gold in excess of these requirements—the remainder of the cavity space, if any, would be better if filled with cement.

With our present facilities, cast inlays do not exactly fit cavities; they fit approximately. The joints are closed by burnishing. Speaking from experience, the greater the mass of gold in a cast inlay, the greater will be the errors in fit due to small though unavoidable inaccuracies such as arise from expansion or contraction in the wax, investment, or gold. Besides, the massive casting is more stubborn to manipulate in case of a small error in fit than is a thinner one.

Ordinary approximo-occlusal preparation. After excavating the débris to ascertain the extent of caries, the cavity is filled with a temporary cement. With a safety disk moistened with water the approximal surface, cement and enamel together, is cut flat, until a satisfactory cavity outline is established by the margins of the facet so prepared. It is not necessary that this facet be exactly flat, but it will be found that a flat preparation of either approximal surface of a molar or bicuspid will terminate in an outline closely measuring up to the ideal extension for prevention. The plane of this facet may be inclined slightly to the long axis of the tooth occlusally, to allow of withdrawal of the impression, or to terminate the facet gingivally without a step.

The occlusal step is prepared with a square-edged wheel, so as to terminate in a pit or groove to be deepened for the reception of a hook on the inlay. The margins upon the occlusal surface are beveled with stone points.

With a tapered fissure bur a groove is cut parallel to the long axis in the cement, as deep axially as the tooth is decayed, and reaching from the step to the dentin at the gingival termination of the carious area. This groove may vary in form or depth axially, according to the space for retention or resistance required in each case, but it always marks with certainty the gingival termination of the cavity, beyond which only the beveled enamel extends.

If the impression of the gingival outline should be mutilated in withdrawal, the end of this groove marks the place so well that no error need be made in building the wax or finishing the gold. The rib upon the casting produced by this groove serves to strengthen the casting, to guide it to place in setting, and to afford the cement a firm grip.

For mesio-occluso-distal cavities, the preparation is very simple. The mesial and distal portions are united by a square groove with beveled margins.

Chisels are not used in this method of preparing cavities. Before setting the inlay, the temporary cement filling and all carious tissue are removed.

The advantages of this new method of preparation are:

(1) Conservation of tooth tissue and consequent economy of time and labor. Conservation of the strength of the cavity walls and avoidance of painful cutting and needless removal of tissue in the region of the marginal ridge.

(2) An abrasive disk moistened with an excess of water cuts sensitive tissue with less pain than other instruments cause. Enamel cut with wet abrasive is in better condition to resist an attack of any kind than if cut with steel instruments.

(3) The impression and stone model technique, for which this form of preparation is intended, lessens the work done in the mouth, to the comfort of patient and operator.

(4) The form of the casting determined by this mode of preparation, especially of a mesio-occluso-distal cavity, makes the control of shrinkage in the solidification of the gold upon the stone model effectual, so that the inside di-

mensions of the casting are maintained, resulting in a more accurate fit.

(5) The relatively thin inlay, with consequently larger quantity of cement or tissue between the gold and the pulp, better protects the pulp against thermal irritation. The greater overlap of the joints protects the cement in case of inaccuracy of fit, and by their thinness the margins of the casting yield to the burnisher, allowing of perfect closure of the joints. An inlay that does not touch the interior surface of the cavity at all points is not so difficult of management in case of misfit, as a massive casting always is when designed to fill the whole interior of a complex cavity.

(6) The gold being outside the tooth tissue rather than inside—*i.e.* the tough material inclosing the brittle—the latter is better protected against stress and abrasion. This permits the conservation of walls too thin or weak to be allowed to remain in any other form of cavity preparation or design of inlay.

(7) The principles, if not the details, of the preparation described are applicable to any complex cavity where a gold inlay is indicated, no matter whether in a molar, bicuspid, or incisor.

ORAL SURGERY.

Dr. Don M. Graham, Detroit, Mich.

This clinic consisted of radiographs showing various dental lesions, and illustrating the method of treating fractures of the jaw by means of wire anchorages and fracture bands.

The wire anchorage and immobilization of the mandible is the method most frequently used. Fracture bands can be made to do good service also, but the wire anchorage would appear to give a wider range of usefulness and does not require the same close attention for safe retention, as do the fracture bands. Wires can be adjusted for anchorages about the teeth with almost absolute assurance that they will remain where placed. Copper or its alloy is the best material, and a 22-gage annealed copper wire will be found of sufficient strength for most cases. A German copper alloy of from 24 to 26-gage, as used by orthodontists, is employed by the clinician.

There appears to be no universally satisfactory method of fixation, but binding the jaws together seems to promise the best results. The comparative comfort and the results obtained are sufficient justification for such a procedure, and it is very seldom that objections are made to this method by the patient. The difficulty of obtaining nourishment has been greatly over-estimated, and the average patient, after such a fixation, can go about his usual duties with comparative comfort. Patients should return at frequent intervals for inspection and adjustment of the apparatus. The wires will sometimes demand tightening, and the prevention of oral sepsis will necessitate careful oversight of the case until treatment is concluded.

Dr. John B. West, Elmira, N. Y. "Hyperemia in Dentistry."

The clinician demonstrated the technique of the application of Dr. August Bier's method of producing obstructive hyperemia to dentistry.

The oldest and most favored means of producing obstructive hyperemia is the elastic bandage. Soft rubber is generally used, but for dental purposes garter elastic is preferable. The elastic should be about one inch wide and about eighteen or more inches in length, with a hook at one end and a number of eyes at the other.

The bandage is placed around the neck for the purpose of producing passive hyperemia of the superficial veins of the head. By passive hyperemia we mean a condition in which a part of the body has its vascular net more full on account of a diminished venous outflow.

The bandage is placed about the neck below the larnyx. It should feel somewhat like a tightly fitting collar, but only the superficial veins should be partially obstructed, and there must never be an increase of pain. Its action may be intensified by placing upon the jugular vein a pledget of soft cloth. Soon after the bandage is adjusted, the focus of acute inflammation will show an increase in the cardinal symptoms, viz, marked redness, heat, and swelling, but a slow definite diminution of pain. If the bandage is placed about the neck for combating acute inflammation, it should remain in place from twenty to twenty-two hours, then be removed to allow the slight edemic condition to pass away. For chronic affections a shorter time will suffice—from two to four hours per day is generally sufficient.

The suction cups used for producing passive hyperemia are made of glass. The larger cups are intended for use on the outside of the jaw, while the smaller ones are for use on the gums. By means of a short piece of stout rubber tubing the suction cups are connected with the saliva ejector, and by regulation of water-pressure, suction of any desired degree is readily obtained. The suction for the ordinary cases of pericemental trouble is applied but once a day for about three-quarters of an hour, five minutes at a time, with three minutes' intermission, repeating the suction five to six times at the same sitting.

In certain stages of pyorrhea, congested hyperemia is of marked benefit. A special suction cup has to be constructed for each individual case. For the lower anterior teeth, the clinician uses an Angle impression tray from which the handle and heels have been cut off and a hole drilled in the center of the tray, to which brass tubing is soldered. The tray is filled with modeling compound, and an impression of the lower anterior teeth is taken. After the tray has been removed from the mouth, the modeling compound is cut away from the inner surface of the cup, leaving a thick continuous roll of compound covering the rim of the tray. By means of the rubber tubing, the tray is connected to the saliva ejector. The suction must be of mild degree, and is applied but once per day.

Bier's method of producing hyperemia is indicated in the treatment of all painful disturbances of the periosteum of the teeth and jaws. Some of the advantages of hyperemia treatment over the therapeutic procedures are suppression of infection and avoidance of suppuration, diminution of pain, and culmination of pathologic processes. Large incisions into abscess cavities may be entirely dispensed with, simple punctures, which naturally heal quicker, leaving very small or no scars, are usually sufficient for drainage with the suction cup. In the very early stages an artificially increased inflammation may successfully abort an incipient infection, and in already existing suppuration the processes of demarcation and final resolution are materially hastened.

Dr. H. L. Oliver, Dayton, O. "Restoration of Lower Mandible."

The cause for removing a section of the mandible in the case presented by the clinician was sarcoma originating in the region of the second bicuspid. The entire portion of the lower mandible was removed from the canine posterior to the glenoid fossa, including the coronoid process. No matrix was left.

The technique employed in the restoration of the mandible was as follows: In the remaining portion of the mandible eight teeth were left. Shell crowns were made to fit the two centrals, the left lateral, and the second molar, the first molar having been extracted. After the crowns had been fitted, an impression of the lower mandible was taken. The mandible should be drawn to the left in order to get the muscles at their highest point. An impression of the upper arch was taken, and models were made of both jaws. The case was articulated with the crowns in position. Before pouring the model, a thin film of wax may be spread on the inside of the crowns. After the model is made the crowns may be easily removed by warming. The three anterior crowns were soldered together on the incisal edge in order to insure strength. A 14-gage wire of clasp metal is used. The angle-bar is then adjusted, and soldered at the cervical portion of the crowns. The latter can now be placed on the model in its original position. In order to obliterate the undercut, arising from the wire being round, a little plaster is spread along the sides of the bar before packing, otherwise the rubber would so engage the wire as to make separation after vulcanizing difficult. A clasp standardized, adjustable for tension and made to engage exactly a 14-gage wire of clasp metal, is used.

A lingual bar is used on the lower arch, with lugs fastened for the attachment of rubber where a portion of bone has been removed. Facial expression is restored by building up with rubber and articulating to the upper arch. The case is finished in the usual way. If occlusion, etc., is satisfactory, the abutments are tapped in position on the respective teeth, and the whole appliance is cemented in position at once.

CROWN AND BRIDGE WORK.

Dr. F. E. Buck, Jacksonville, Fla. "Soldering in Bridge Work."

The object of this clinic was to show the advantage of using solder in long strips and being able to change the position of the work instantly without being obliged to lower the temperature.

The solder flows by gravity to the spots where it is wanted. Less solder is used, and bubbles are entirely eliminated.

The solder in this work is made up into strips, eight inches in length, and one-fourth of an inch in breadth. The invested bridge is held in an adjustable soldering tray which can be moved instantly to any desired position.

Dr. R. F. Rowdybush, Decatur, Ill. "(I) The Injurious Effects of Poorly Constructed Crowns and Bridges. (II) Proper Construction for the Conservation of Hygienic Conditions of the Mouth."

I. The clinician showed poorly constructed pieces of crowns and bridge work and their injurious effects upon the surrounding tissues, also the systemic effect produced by wearing an unsanitary crown or bridge.

II. Sanitary bridges were shown.

Dr. P. B. Laskey, Marblehead, Mass. (I) "Refinement of Impression. (II) Repairing Inferior Bridges in the Mouth. (III) Compound Hypodermic Syringe. (IV) Stiffening Logan Crown Posts."

I. The clinician's method consists in eliminating all superfluous material. This is done through the form of the cup employed.

II. A tooth is fitted to take the place of the broken artificial one, and is placed in position; the pins should extend well through the backing, which has been countersunk. With a piece of firm metal charged with compound plaster or other impression material, an impression of the labial surface is taken and allowed to harden in place. With a pair of strong pliers the ends of the pins are riveted down to the backing.

III. The instrument demonstrated is controlled by a lever which increases the power fourfold. The labor is divided, one hand controlling the needle and the tissue, the other applying the power.

IV. Strong, short-beak pliers were shown adapted for compressing the post.

Dr. J. L. Kelly, Chicago, Ill. "Removable Bridge Work."

Dr. Kelly demonstrated removable bridge work in which the principle of retention is a dovetail obtained by converging or diverging the attachments toward or from each other, or placing them in such relation to a tuberosity or other projection of the mouth that a dovetail or undercut is produced.

The attachment consists of three parts, viz, holding post, adjusting tube, and bridge tube. The holding post is made of round iridio-platinum wire, generally 14 gage, and one-eighth of an inch long. The adjusting tube and bridge tube are made of iridio-platinum in steel dies. The adjusting tube telescopes the holding post, and is telescoped in turn by the bridge tube.

After the attachments are made, the holding post is soldered to the cope, which is constructed as for a Richmond crown; then the adjusting tube is cemented to the holding post to center the bridge tube, which is made to telescope it. The bridge tubes are connected by a bar, completing the framework for the bridge, the remainder of which may be constructed as in the making of a plate.

When this denture is completed, the adjusting tubes which have been cemented on the holding posts are removed, so as to give play between the bridge tube and the holding post. This play is necessary to put the bridge in harmony with the flexibility of the tissue, thus preventing any strain on the roots.

If the play becomes so great as to loosen the bridge in time, a very thin adjusting tube may be cemented on one or as many of the holding posts as is necessary, until the desired retention is obtained. This makes it possible for the dentist to control the retention at will, without weakening or changing the attachment.

Dr. D. C. Clark, Blacksville, W. Va. "Restoration of Broken-down Roots for the Insertion of Porcelain Crowns."

The clinician demonstrated two methods of restoration, as follows:

(1) If the operator desires to place a porcelain crown on the root or roots of any tooth that is broken down on one side below the free margin of the gum, a small groove is drilled around and in the end of the root at the portion where it is broken down. A slot is drilled into the canal and around for a short distance on the inside. The canal is filled with amalgam, and the crown is placed in position while the amalgam is yet soft, to secure a perfect joint between the crown and the amalgam. The crown is then removed and placed back in position with cement. This method causes much less pain than the placing of a gold band in cases where the gum adheres closely to the root.

(2) The broken-down side is restored by placing around the end of the root a gold band wide enough at the broken side to extend above and fill out the broken place. The band is to be very narrow for the balance of the distance around the root, so that it covers the joint between the root and the crown, and also strengthens the union.

If the band fits the end of the root, and also the tooth, the broken-down part will be filled with cement when the crown is in position. This cement will not dissolve any more than if employed according to the ordinary method of setting a crown.

Dr. Edward C. Hoffman, Plainfield, Ill. "Bandless Crowns."

A method of substituting metal or porcelain for enamel on teeth that have been worn down by mechanical abrasion was demonstrated by the clinician.

First the tooth is devitalized, the root-canals are treated and filled in the usual manner, and about one-eighth of an inch of the tooth is cut off; next an opening is cut in the center of the crown of the tooth about one-eighth of an inch in depth, and from one-eighth to one-fourth of an inch square, according to the size of the tooth. This opening is filled with inlay wax. The patient is requested to bite, and the cusps are carved in wax. The wax model is removed and cast in any metal desired, but, if porcelain is used, the space should not be less than three-sixteenths of an inch. The inlay is cemented to place, and the margins are finished in inlay wax.

Dr. J. G. Reid, Marion, N. C. "Suggestions for Crown and Bridge Work and Operative Dentistry."

This clinic showed a method of making a post for a cast crown, casting the post and crown together. A little piece of ordinary iron wire is cut and on it sufficient casting wax is built up to fill the canal. The wire is placed in position, allowing it to extend far enough in the root-canal to hold the facing when placed in position; then the crown is waxed up and carved ready for investing. The sprue is attached to the waxed post and the crown is invested. When the wax melts out, the little iron wire drops out, and when the cast is made, the post and crown are in one piece.

The clinician also demonstrated his method of casting into diatoric teeth. He also demonstrated a method of repairing broken facings in bridge work as follows: The old pins are ground off and the backing is slit up to the pins. The backing is ground off and a facing selected and set in position. A piece of 36-gage pure gold is then burnished over the back of the facing to extend over the tip, and the pins of the backing are pushed through the gold. The facing is held in position with sticky-wax, removed with the impression, invested, and soldered.

Dr. Reid also showed two cavities, one prepared and one filled, in the lingual surfaces of lateral and central incisors, the feature of the filling being that it was started with cement.

Dr. J. W. O'Bryon, Lawrence, Kans. "A Bandless Crown Which Reinforces the Root."

The crown described by the clinician is especially indicated in cases where the root is subject to fracture or splitting, as in lateral incisors, but it is applicable to any of the six anterior upper teeth. The root is prepared labially as for any bandless crown, being ground just below the free margin of the gum, to make sure that the joint between the root and crown is hidden by the gum.

Lingually, however, the root is ground only to within one millimeter of the gum line. A lingual step is then made by cutting away with a small knife-edged stone the lingual side of the root to a depth of about one millimeter, this step to extend toward the root just below the free margin of the gum. The root can be more perfectly squared by preparing it, following the stone, with a sharp square-end fissure bur. The root-canal is then enlarged until a No. 4 round bur can easily be passed into it. A round 16-gage clasp-metal post is to be adapted to the canal with the end projecting sufficiently to reach the bottom of the hole in the base of a detachable-post crown —such as the Davis or S. S. White. The next step consists in grinding the crown labially to fit the labial surface of the root—which usually requires very little grinding. The lingual two-thirds of the base of the crown should, however, be ground considerably more in order to produce a V-shaped space which will insure sufficient bulk to impart adequate strength to the cast base with its lingual projection.

Having the crown thus prepared and fitted to the labial portion of the root, and the post adjusted to the opening in the base of the crown and reaching its bottom, a plate of pure gold of 34-gage is adapted to the lingual two-thirds of the base of the crown and perforated at the opening into the crown so as to receive the crown end of the post. The object of this plate of gold is to reinforce the thin portion of the wax pattern for the cast base and to prevent its becoming loosened from the post during manipulation. This plate of gold having been adapted, the crown end of the post is inserted through it into its place in the crown, and then carefully removed together with this plate, and the two are tacked with a bit of 18-karat solder. The little plate with the post attached is then placed in position on the base of the crown, and a small portion of Taggart inlay wax is softened and adapted to the lingual two-thirds of the base of the crown, the wax being shaped to approximate the form of the cast base to be, and without very much excess of material.

The crown and the adapted wax are then warmed together and placed in position on the root and pressed home, and with a warm, flat-sided burnisher the wax is pressed lingually closely to the root. It is then carefully carved to conform with the perimeter of the root. The crown is then removed, leaving the post and wax base pattern *in situ*. The wax may be further carved if necessary, and then removed and cast to the post in 22-karat gold. The remainder of the operation is the same as for any cast-base crown.

The finished crown has a 22-karat gold lingual extension, engaging with the step in the prepared root, which affords more strength than the ordinary band, absolutely prevents rotation of the crown, and being flush with the outline of the root, causes no irritation of the lingual margin of the gum.

Dr. S. D. Ruggles, Portsmouth, Ohio. "Crown-Setting Pliers."

The purpose of this clinic was to demonstrate a new instrument for setting crowns and regulating bands.

When a crown is to be set, the mouth is usually packed with cotton rolls, bibulous paper or napkins, and when into

this already obscured field the crown is introduced, being held between two fingers, it is seldom that a clear view is at all possible.

The nervous strain at this point of the operation often results in a mishap, or in placing the crown in an incorrect position, resulting in failure.

The pliers illustrated have been used for two consecutive years, and have proved beyond a doubt their adaptability to holding and accurately placing any crown in its proper position on a bicuspid or molar without at the same time obstructing the full view of the root. A four-tooth bridge can be manipulated with the same ease as a regulating band by means of these pliers.

Dr. C. B. Reed, Topeka, Kans. "Steele's Facings in Plate Work."

Dr. Reed demonstrated the utility of Steele's facings as applied to "short-bite" dentures, the special feature being that of soldering gold plate extensions to the backings with dovetail terminals to engage in the vulcanite, resulting in the greatest possible strength, and at the same time reducing the bulk and thickness to an absolute minimum. Such a denture is indicated in those exceedingly troublesome cases where the mechanical stress is such as to force the teeth continually from the plate when attached in the conventional manner.

Dr. Reed also exhibited various partial plates, both of gold and rubber, showing the peculiar adaptability of Steele's facings in cases of extreme absorption. These facings being replaceable render possible the substitution of longer teeth as resorption progresses.

Dr. C. E. Peters, Pittsburgh, Pa. "A Banded Porcelain Crown Combining All Necessary Requirements with a Time-saving Technique in Its Construction."

The preliminary preparation of the root demonstrated by the clinician is the same as for a Richmond crown. A gold ferrule is fitted to the root, and to this a floor of 36-gage pure gold is soldered, allowing the solder to attach only the lingual half of the circumference. A 14-gage tapered iridio-platinum or platinized gold wire is then fitted to the root-canal, allowing it to project about three-sixteenths of an inch. The cap is then placed upon the root, and the pin forced through it to place. This is attached to the cap with sticky-wax, removed, and placed into a soft asbestos block, which holds the parts in their proper relation until soldered. The labial portion of the band is then cut away. Before being placed upon the root for final adaptation, the labial portion of the root end is trimmed beneath the gum sufficiently to hide the joint, using a large bur or small stone. The cap is then placed, and the labial portion burnished to the root. A detached-post crown of the proper size is ground to fit, using thin carbon paper to secure the joint. The crown is then cemented to the cap, removed, and ground flush with the side of the cap, polished, and cemented to the root. This method combines pleasing results and interchangeability with strength, simplicity, and economy of time.

Dr. J. E. WATERBURY, Los Angeles, Cal. "A Quick and Accurate Seamless Gold Crown."

The clinician demonstrated a method of reshaping the ordinary, conventionalized cusp of the die-plate-made crown, by softening the gold in alcohol at white heat, replacing it on the tooth in the mouth, and allowing the patient to bite it into perfect occlusion. The points of the cusps are extended and shaped with special pliers in such a manner as to provide the best possible masticating surface for the finished crown. The pliers are also used to form the correct contact points with the adjoining teeth.

The clinician also showed a method of coaxing the solder which reinforces the cusp back to the center and away from the sides of a crown, by dropping a small bit of plate gold, fluxed on the lower side, into the invested crown and reheating. The solder will flow to this piece in the center and distribute itself evenly over the whole floor of the cusp.

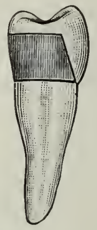
Dr. W. A. CAPON, Philadelphia, Pa. "Porcelain Bicuspid Jacket Crown."

The preparation of the crown or remainder of crown—more often the latter—is very similar to that for a gold cap, with the exception that the buccal surface must be ground to allow for the veneer, as shown in Fig. 1.

The circumference is measured with wire, and the band cut from platinum plate, gage 31, allowing for the lap-joint always used in this crown as in other porcelain jacket crowns. The joint is soldered with a small quantity of pure gold, then the edge is cut to conform to the gum margin, and the root is fitted as shown in Fig. 1. The joint of the platinum band is placed on the lingual side. If found to be a little large, the edge is compressed with bent-nose pliers; but in any case, the fitting must be corrected before adding porcelain. The band is then marked to be cut almost even with the tooth-crown, or at

FIG. 1.

FIG. 2.



least closely enough to be free of the opposing tooth.

The band is removed and platinum foil is burnished over the end of the root or the portion of the tooth to be crowned, and the band replaced. Porcelain body is then packed over the whole surface even with the edges of the band. A veneer is put into position, or the face may be carved, and the whole crown is drawn and placed in the furnace ready for fusing. After the first baking, it is placed on the root and the bite noted, and the crown is then finished by making cusps of porcelain and fusing a second time. When completed, the outward appearance of this crown is as represented in Fig. 2. The platinum foil is allowed to remain.

Dr. W. W. FLORA, Colorado Springs, Colo. "Casting Gold Against Porcelain Without Fracturing the Porcelain."

Some metallurgists claim that the contraction of porcelain under heat renders it impossible to cast gold against it without cracking the porcelain, yet the clinician's demonstration proved conclusively that it may be done if just a few principles are observed.

If a large pin is embedded in the porcelain, as in a Logan crown, it is necessary to place the crown in the investment in such a position that the pin will be farther from the metal ring than the porcelain; the heat should be applied very slowly, but carried to almost incandescence. The sprue should be so placed that the molten metal will first come in contact with the investment, backing up on porcelain. If these simple rules are observed, no difficulty will be experienced in casting against porcelain successfully.

ORTHODONTIA.

Dr. E. S. BUTLER, New Rochelle, N. Y. "Orthodontia."

This clinic consisted in the demonstration of Angle's new appliances for moving the teeth bodily by gentle stimulation of bone-growth, and their adaptation and technique. Some of the advantages claimed for these appliances are the practical abolition of pain, more perfect control over the distribution of the force, elimination of all danger of displacement of the appliance, lesser frequency of appointments, and elimination of the necessity of prolonged retention.

Dr. C. G. BELL, Ashland, Ky. "Shortening and Rotating Teeth by Excising."

The tooth to be shortened is devitalized. A small portion is resected at the gingival portion of the tooth and a platinum post is used in the same way as if an artificial crown were to be used, bringing the incisal edge to the normal incisal line.

In rotating a tooth, the same procedure is used in regard to the post and devitalization, but no tooth is resected unless the tooth to be rotated is also elongated.

Dr. SINCLAIR TOUSEY, New York, N. Y. "Radiographic Measurement of the Permanent Teeth Before the Loss of the Deciduous Teeth, to Provide for Preliminary Regulation of the Arch, If Required."

Imperfect development of the teeth is not only a disfigurement, but renders proper mastication impossible and the proper action of the saliva unlikely. The immediate effects are starchy indigestion and irritation from unmasticated meat, with auto-intoxication from both.

In the young child, as Dr. Strang remarks—"The nasal passages are lined below, in front, and on both sides by the germs of the teeth," and imperfect development of the teeth and of the maxillary bones supporting them occasions maldevelopment in the bony walls of the nasal passages and the accessory pneumatic sinuses of the face; and the effect of underdevelopment may even extend to the cranial cavity and the brain.

Deviations of the septum and mouth-breathing unrelieved by the removal of adenoids and tonsils are among the results of maldevelopment of the teeth with a too narrow and too highly arched hard palate.

The object of the clinician's most recent work has been to determine beforehand the presence and position, and especially the size, of the permanent teeth before the loss of the deciduous ones. The latter may be quickly and easily trained to a curve of the proper radius, and will then guide the permanent teeth into proper position.

Actual measurements of the deciduous teeth bear no fixed ratio to actual measurements of the permanent teeth. In a series of seven cases shown in table *A*, the ratio varied thirty per cent. In the same cases untreated, the curve of the deciduous arch, whether suitable for the permanent teeth or not, was reproduced in the permanent arch. X-ray measurements of the width of the unerupted permanent upper and lower central incisors at the age of five or six years correspond within one-hundredth of an inch with the actual measurements of the same teeth five years later, after eruption (see table *B*).

The clinician's technique is as follows: The deciduous centrals are measured

(*A*)

PERMANENT CENTRAL INCISORS:

Measured radiographically before eruption, and actually, some years later, after eruption.

with a sharp-pointed caliper square with a screw adjustment, and graduated in one-hundredths of an inch. A wax impression of the curve of the deciduous upper and lower arches is made. Radiographs or X-ray pictures (Figs. 1, 2, and 3) are made of the unerupted upper and lower central incisors, and the width of the images of these teeth is measured (see Fig. 4). A curve suitable for permanent teeth of this size is calculated by a modification of Hawley's and Bonwill's tables. The deciduous bite is photographed with the actual curve formed by the cutting edges of the incisors, the cusps of the canines, and the buccal cusps of the bicuspids and molars, and upon the same photograph is drawn the correct curve (Fig. 5) to accommodate permanent teeth of the size determined by the X ray. The orthodontist may regulate the deciduous teeth to this curve, and so guide the permanent teeth into proper position as they erupt. Fig. 6 shows the same case as Fig. 5, in which the deciduous curve was too small for permanent teeth of the size shown by the X ray. The case was untreated, and five years later the curve formed by the erupted permanent teeth was a contracted one of the same radius as that originally formed by the deciduous teeth.

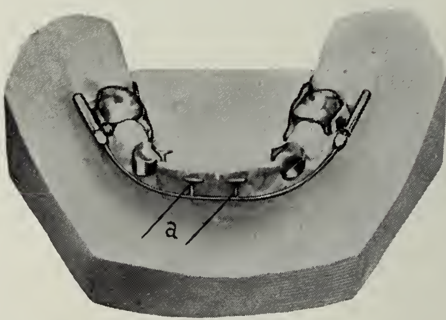
of the curve required to accommodate them.

Dr. HORACE L. HOWE, Boston, Mass. "(I.) An Appliance for Making Badly Inclined Teeth Perpendicular. (II.) An Appliance for Retaining Class II Cases. (III.) Band with Inclined Plane for Retention."

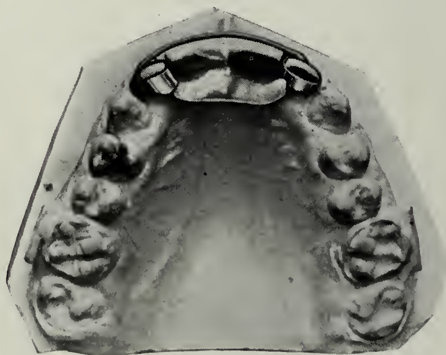
I. Fig. 1 illustrates the arch wire and appliance in position. In class II cases the lower incisors are usually badly inclined. To overcome this, T's are soldered to the arch wire so that the horizontal parts of the T's rest against the upper part of the labial surface of the teeth with the arch wire away from the necks of the teeth. Ligatures are applied to the teeth and arch as usual, with the result that the crowns are forced lingually, and the roots of the teeth carried labially. If desirable to force the crowns considerably lingually, the nuts may be turned away from the tubes on the anchor teeth. If rotation of a tooth is desired, the horizontal part of the T

FIG. 1.



may be bent with pliers so as to bear harder on the part of the tooth to be turned. These T's are most effective, and are designed to take the place of the double arch in front, which the clinician used for the same purpose and brought out in 1904. (See DENTAL COSMOS,

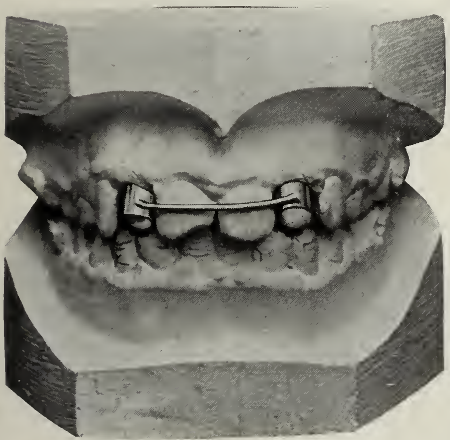
FIG. 2.



December 1904.) The T's may also be used upon the upper arch. I find them very useful in aligning the upper laterals that have been carried considerably forward. With the T, the tooth may be made more perpendicular, and the mesial corner may be forced inward, which is so often desirable. It is sometimes desirable to band the tooth to be moved, to prevent the ligature from slipping.

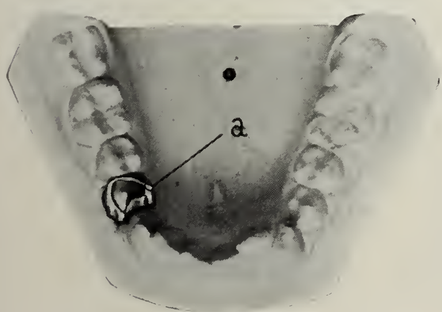
II. An appliance for retention in class II cases (Fig. 2) illustrates an inclined

Fig. 3.



plane adjusted to the laterals to receive the lower incisors. A retaining wire must be adjusted to the lower incisors to prevent any labial movement. Fig. 3 shows the labial aspect of the appliance in position. This appliance is a modifi-

Fig. 4.



cation of the Ainsworth principle, which is so useful in retention.

III. Fig. 4 shows an inclined plane soldered to a band on the lower first bicuspid. This is designed to maintain normal occlusion in unilateral distal occlusion cases. A sharp incline, a, is built up to strike mesially to the palatal cusp of the upper first bicuspid.

Dr. T. P. Sullivan, Fall River, Mass. "Casts Showing Supernumerary and Supplemental Teeth and Peculiar Positions of the Same."

Dr. Sullivan exhibited thirteen models, five showing supplemental laterals and eight showing supernumerary teeth; in three of the latter cases there were two supernumerary teeth in each case.

Dr. M. F. Finley, Washington, D. C. "Orthodontia."

Dr. Finley demonstrated the use of the Jackson system in rotating centrals, bands being cemented to central teeth, using the double U or staple, which is removable; also the moving of a single tooth by means of finger springs. The clinician also showed again the case presented at the Denver meeting, in which there was absence of all the bicuspids, and in which there were no germs for the second and third molars, leaving the patient with a permanent denture of sixteen teeth and four deciduous molars.

Dr. C. W. B. Wheeler, New York, N. Y. "Technique of Making the Jackson Appliance of Precious Metals."

Dr. Wheeler's clinic consisted in showing how the Jackson appliance could be made of precious metals, thus forming a cleaner, stronger, and more springy appliance in the parts where the spring is most essential.

The clinician also demonstrated the ease and rapidity with which a repair can be made, or an extra wire added.

The metal recommended is pure gold containing a trifle of platinum, the same metal being used in making gold and platinum arches.

The technique follows closely that of making a Jackson appliance with base metal, with the exception that 22-karat solder is used, and the parts are tacked together by means of an orthodontic blowpipe on a green model. After this is done, the appliance can be removed, its body waxed up, then invested, and in a few minutes soldered, letting the solder flow into the parts that are essential to give strength.

These appliances can be made much lighter and also more compact than those of base metal, owing to the strength of the gold alloy.

Dr. ARTHUR ZENTLER, New York, N. Y. "Inherited Malalignment."

FIG. 1.

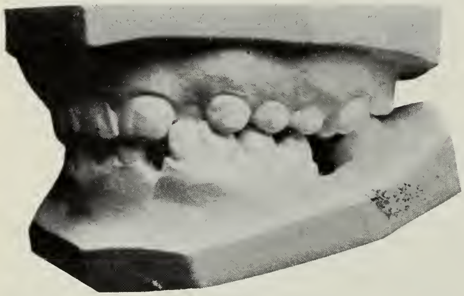


FIG. 2.

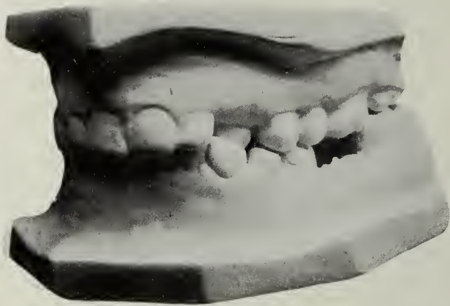

FIG. 3.

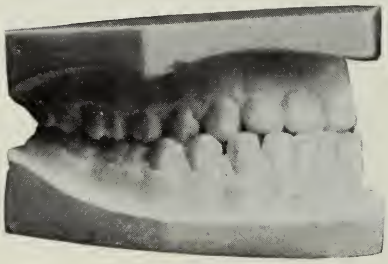

FIG. 4.

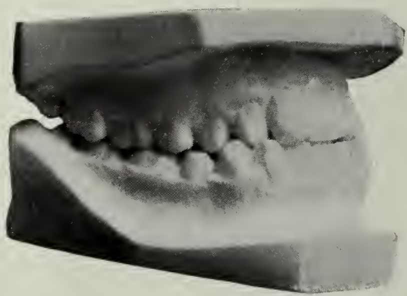


The clinician's object in exhibiting casts (Figs. 1, 2, 3, and 4) was to substantiate the belief that the etiological factors with which orthodontia is concerned are not postnatal only, but often prenatal. It would otherwise be difficult to explain the influences bringing about similar faulty alignment of teeth in children of the same parents.

Figs. 1 and 2 represent casts of the mouths of two sisters, one of seventeen years, the other twenty-five, both showing, on the left side of the mouth, one upper front tooth, in one the lateral and in the other the canine inlocked by the lower teeth, interfering with proper occlusion.

Figs. 3 and 4 represent casts of the mouths of two sisters, one twenty-six years of age, the other sixteen, showing each the same faulty tooth alignment, producing pronounced malocclusion.

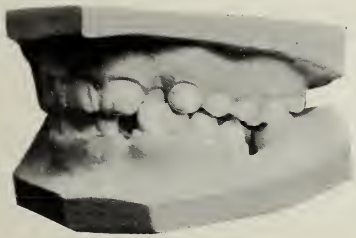
The family histories in both these and in several other cases under the clinician's observation point to similar malalignment of teeth in one or the other parent.

Dr. ARTHUR ZENTLER, New York, N. Y. "Improving Occlusion of Posterior Teeth Through Correcting One Malaligned Front Tooth."

The upper left lateral in the cast shown (Fig. 5) having been brought into proper alignment, the improved occlusion of the posterior teeth is seen in Fig. 6, showing the left side of the mouth, as well as in Fig. 7, showing the right side of the corrected case in contrast with Fig. 8, showing the same side before correction.

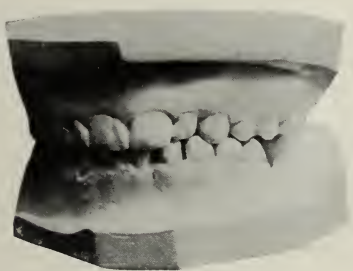
Fig. 9 shows the appliance *in situ* in a different case, similar to the one used in case Fig. 5, and its construction is plainly visible.

Fig. 5.



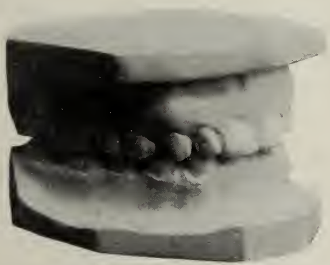
For the purpose of bringing the tooth into proper alignment, the free end of the retracting spring wire is bent out

Fig. 6.



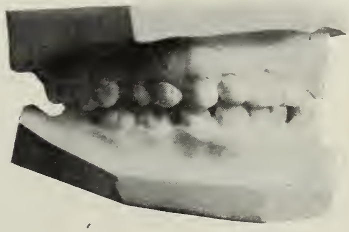
of the line of the dental arch to a point representing twice the distance between where the malaligned tooth stands and

Fig. 7.



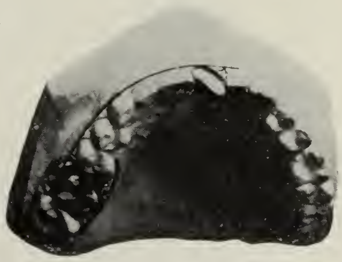
where it is desired to move it to. Then the retracting spring wire is sprung close to the dental arch and tied to the tooth by passing a wire ligature through a tube soldered vertically in the center of the labial side of the band cemented on the tooth to be aligned, and engaging the retracting spring wire. This manner of ligating promotes a complete carrying out into alignment of the entire tooth, avoiding a mere tipping of the crown.

Fig. 8.



When the malaligned tooth needs not only to be retracted, as in case Fig. 5, but also rotated, as in case Fig. 9, the attachment is made lingually, and according to the direction in which the tooth must be rotated the tube is soldered nearer to

Fig. 9.



the linguo-distal or linguo-mesial part of the band.

CROWN AND BRIDGE WORK—PORCELAIN WORK—CASTING.

Dr. J. C. Reed, Harrisburg, Pa. "Special Dentures made with the Aid of the Casting Process."

This clinic consisted in the demonstration of the clinician's method of retaining difficult lower dentures, also his method of making bridges with inlay abutments. The clinician also showed a large gold inlay with removable core, insuring ease of access in root-treatment.

Dr. Emerson R. Sausser, Philadelphia, Pa. "The Insertion of Two Porcelain Inlays."

The patient presented two cervical cavities, one in the upper left lateral incisor, the other in the upper left canine. These cavities had been prepared painlessly under novocain local anesthesia by the operator in his morning clinic. In preparing the cavities, the operator secured depth, shaping the walls almost perpendicular with the floor and with no bevel on the margins. The matrix was filled with porcelain while it was still in position in the tooth, which procedure eliminates the necessity of reburnishing the matrix after the first bake. The clinician emphasized that there is little or no doubt in his mind that distortion of the matrix is due to the handling, and not to the baking.

Dr. C. B. Brownell, Sandwich, Ill. "Cast Retaining Appliance Carrying Missing Teeth."

Cavities were prepared by the clinician with gem stones and cross-cut fissure burs, in the lingual surface of teeth involving the mesio-lingual and disto-lingual embrasures, extending the cavity across the incisal edge by removing the lingual plate of enamel. On the gingival margin the enamel is cut away to make a shoulder or base, while the enamel over the pulp is not disturbed. Retention is secured by slightly undercutting the central portion of the enamel over the pulp. The wax model is to be drawn toward the incisal edge. Inlays are then cast separately and replaced in the mouth. An impression is taken, and the appliance is invested and soldered in the usual way. Any style of tooth can be used for replacing the ones lost. When completed the appliance is set with cement as in the case of any inlay.

Dr. E. E. Cruzen, Baltimore, Md. "Exposing the Margins of Inlays Used as Abutments in Bridge Work."

The object of this clinic was to demonstrate a method of assembling bridge and inlay abutments in such a manner that the margins of the inlay are as free and accessible for cleansing as though they were individual fillings.

Proper cavity preparation for the inlay in regard to outline and walls is presupposed.

The technique consists in inserting a post of 14-gage iridio-platinum or clasp gold wire into the canal, and bending it at a right angle at a point corresponding to the natural contact point of the approximal surface. Inlay impression wax is shaped about the bend of the pin, and the pin is inserted in the canal, the wax pressed into the cavity, the occlusion obtained, and the wax carved to the form desired. The angle of the pin should protrude 1/16 of an inch or more through the wax on the approximal surface. The impression is removed by grasping the angle of the pin, or by a sprue wire, and a casting is obtained. The inlay is to be polished, but the pin projecting through is not to be disturbed. The inlays are then placed in the cavities, the bite is taken, and an impression obtained in plaster. This is done by using a cup that is smooth and free from scars, so it will come away easily from the plaster. After the plaster has hardened so that it will break with a clean and sharp fracture, it is removed in sections. The sections are brought together, and the inlays placed in position and tacked with a small bit of wax.

The model obtained from the impression is to be made of the same investing material as is used for soldering.

In this way a model is obtained with the inlays in position, and the projecting points. A piece of 24-karat gold plate of from 30 to 35 gage, such as is used for backings, is cut to the size of the approximal surface of the filling or tooth, and a hole punched through it corresponding to the size and position of the projecting pin, over which it is placed and tacked with a little sticky-wax, but no wax is to be allowed to flow between the filling and the gold plate.

This little gold plate should be contoured as desired before it is waxed to place, as it is to represent the approximal surface of the bridge tooth, and should be spaced at the gingival margin as desired, so as to represent the interproximal space.

The dummy is then adjusted in any manner that judgment may dictate, whether it be a saddle, so-called self-cleansing space, or a compromise. In any case, the margins of the inlay abutments, when the piece is completed, will be as fully exposed for cleansing as though they were individual fillings.

The model is invested with the appliance waxed in place, care being taken to insure that the investing material fills the space between the inlay and the little plate of gold, in order to avoid any possibility of solder flowing on the face of the inlay and defeating the object.

Dr. C. P. Grosby, St. Louis, Mo. "Inlay Attachments and Root Preparation; Illustrating (*a*) Cavity Preparation for Inlay Abutments with Dowel Attachment. (*b*) Saving Badly Broken-down Roots."

(*a*) The clinician demonstrated the advantage of a bridge having inlay abutments with dowel attachments, by showing various models and a bridge mounted on an articulated form. The success of the inlay abutments depends largely upon the careful preparation of the cavities, consisting of a flat base from which the axial margins should be trimmed at right angles or very slightly diverging toward the periphery. Care should be taken in the preparation with the view of creating a self-cleansing area, and the attachments should be well supported by threaded iridio-platinum dowels, No. 14 gage.

Fig. 1 shows the preparation of the abutments.

Fig. 2 shows the occlusal surface of the inlay, with the bridge in position.

Fig. 3 shows the side view of an inlay bridge in position.

Fig. 4 shows the buccal view of an inlay bridge in position.

(*b*) Dr. Grosby also showed several badly broken-down roots, many of which are being daily sacrificed by extraction. He demonstrated that by using careful judgment, these roots may be saved and rendered useful for several years. The procedure adopted by him is as follows: After being properly treated, the tissues

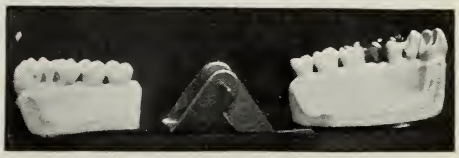
Fig. 1.

Preparation of abutments.

Fig. 2.

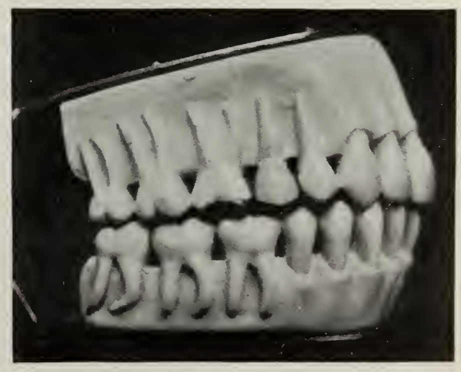
Occlusal surface of inlay bridge in position.

Fig. 3.



Lingual view of bridge in position.

Fig. 4.



Buccal view of bridge in position.

are gently pressed back, and the carious portion is carefully excavated, shaping the cavity as nearly to a step formation as possible. An inlay cast in some metal and attached to a 16-gage iridio-platinum dowel, the post extending well into the canal when cemented to place, forms a strong abutment for either a crown or a bridge.

Dr. Geo. S. Tignor, Atlanta, Ga. "Steele's Facings in Bridge Work; Illustrating Construction of a Bridge."

The clinician showed one upper four-tooth bridge with gold inlay abutments in the first bicuspid and in the second molar, with iridio-platinum pins in the root-canals; also one lower four-tooth bridge with iridio-platinum pins in the bicuspid root-canals, and a saddle under the end of the extension.

SEVENTH AND EIGHTH DISTRICT DENTAL SOCIETIES OF THE STATE OF NEW YORK.

Forty-fourth Annual Union Convention.

The forty-fourth annual union meeting of the Seventh and Eighth District Dental Societies of the State of New York was held in the Seneca Hotel, Rochester, N. Y., November 14, 15, and 16, 1912.

The meeting was called to order on Thursday afternoon, November 14th, at 2.30 P.M., by Dr. C. L. Brininstool, Rochester, president of the Seventh District Society.

Dr. Brininstool introduced Rev. Dr. Henry H. Stebbins, Rochester, who invoked divine blessings on the deliberations of the meeting.

Mr. Roland B. Woodward, secretary of the Rochester Chamber of Commerce, then welcomed the two societies to the city of Rochester.

Dr. C. F. Baylis, Oneonta, president of the Dental Society of the State of New York, next addressed the societies on behalf of the State Society.

Dr. Walter H. Ellis, Buffalo, president of the Eighth District Society, addressed the union meeting on behalf of the Eighth District Society.

Dr. H. J. Burkhart, Batavia, was called to the chair, and introduced to the audience Dr. Edward C. Kirk, Philadelphia, Pa., who read a paper entitled "The *Locus Minoris Resistentiæ* in Pyorrhea Alveolaris."

[This paper is printed in full at page 577 of the present issue of the Cosmos.]

Discussion.

Dr. Egbert T. Loeffler, Ann Arbor, Mich. It is, indeed, a great privilege to listen to a paper that comes from the pen of such a distinguished essayist. The logical and comprehensive manner in which the subject has been treated leaves but little room for additions except by way of emphasis. Very much has been written upon the treatment of pyorrhea alveolaris, while the question of etiology has been left almost untouched.

I have always been a great admirer of Dr. Black and all his valuable contributions to dental literature. I am very much in sympathy with the theory advanced by the essayist that these glands or remnants of embryonic tissue cells are weak points in the structure of the peridental membrane, but whether they should be designated as *the* weak points requires further investigation. These glands of Serres, so called by some, are very generally found in all peridental membranes, but their function or purpose is still an unsettled question. As Dr. Noyes says: "Sufficient work has not been done upon this subject to know whether this is a constant arrangement, or whether it is found only in certain animals, or even whether it may not be pathologic."

Some have made the statement that the peridental membrane is one of the most vulnerable tissues in the human body, and it has always seemed reasonable to me to suppose that there must be some specially weak points that are more liable to break down under unfavorable conditions.

May I call your attention at this time to a very important communication by the essayist entitled "The Dental Relationships of Arthritism," published in the DENTAL COSMOS for July 1909, an article that every broadminded practitioner should read; also to a paragraph on page 504 of the "American Text-book of Operative Dentistry," in which the author says that "The close relationship of arthritic malnutrition to pyorrheal involvement of the retentive tissues of the teeth is now clearly recognized, and the constitutional predisposition induced by arthritism to bacterial invasion is found to be dependent upon a diminished tissue resistance, with lowering of the opsonic index, which in many cases is amenable to autogenous vaccine therapy, under which treatment the opsonic index has been raised to normal, with cure of the local lesion."

I have always been a firm believer in the statement that, in the treatment of pyorrhea alveolaris, the question of malnutrition or faulty metabolism must be considered as a very important etiological factor.

Dr. Kirk states at the close of his paper that in his judgment the data presented are meager, to a certain extent unsatisfactory, and fall short of being conclusive. This is simply another illustration of the charitableness of our distinguished essayist in all his original communications.

To my mind, the most important point brought out in this paper is that in the treatment of the various diseases of the oral cavity, the question of the susceptibility of the tissues involved, or of their resistive forces under unfavorable conditions is not at present sufficiently emphasized.

In closing, I wish to join the essayist in the hope that this paper may be a means of stimulating greater enthusiasm for further research in this most interesting subject.

Dr. R. H. HOFHEINZ, Rochester. The unfortunate feature of the essay is that it cannot well be discussed, nor can even the great point around which the paper focuses. The subject of pyorrhea in dentistry corresponds very vividly with those of theology and of politics in our daily life—there is no end to its discussion. It seems rather lamentable for both the suffering patient and dental science that so much discrepancy still exists regarding the etiology and cure of this unfortunate disease.

We still have with us the men who cure every pyorrhetic condition with the scaler, pumice, and the orange-wood stick. There are but a few left who attempt to cure exclusively by air, water, and cathartics. The *locus minoris resistentiæ* of pyorrhea remains the delicate fibrous connective tissues, known as the peridental membrane.

What has puzzled us poor daily practitioners has been the question: *Ubi est causa?* We know that salivary and sanguinal secretions form a great part of the disturbance. Are they the primary or secondary causes?

Bell tells us in his "Diseases of the Teeth," as early as 1837: "In cases of great irritability of constitution and want of tone in the system, the irritation which is caused by salivary calculus frequently leads to more serious conditions. Although the gradual loss of substance in the gum and alveolar processes occasionally takes place without any obvious local or constitutional morbid action, it is much more frequently produced by derangement of the digestive organs, or some other constitutional cause, either immediate or remote." Chapin A. Harris, in his "Dental Surgery" of 1839, says: "I am led to believe that no matter how great soever may be the constitutional tendency to the disease, it would never manifest itself were it not for some cause of local irritation." Nathaniel Chapman, in his "Dental Surgery" of 1829, says: "Similar causes, *ceteris pari-*

bus, in general, produce similar effects, and as the organization of the human frame is the same everywhere, so, if exposed to similar causes of disease, similar diseases will follow, especially if those diseases have a specific character, and this explains the reason why inhabitants of opposite countries have similar diseases, because exposed to similar causes of disease." We see that the old writers, with few exceptions, recognize both the local and constitutional factors in the disease known as pyorrhea alveolaris.

Dr. Kirk, at the very beginning of his paper, lays special stress upon bacterial infection as the principal cause of the disease. The question arises, Does pyorrhea not manifest itself until pathogenic bacteria have ingress into the peridental membrane and the *locus minoris resistentiæ.* Does not pyorrhea already exist when the peridental membrane is in an incipient stage of inflammation—though inflammation is only too much blood in a part with motion of that blood partially increased or partially diminished, as an old pathologist expresses it. The essayist alludes to the action of the phagocytes in the peridental membrane. It would be interesting to know to what extent the phagocytes do their work in cases of peridental disease, compared with their relative action in other infected tissues of the body. It seems to me that their field must be restricted by the vascular supply of the pericemental tissue, which, though rich, is not so much so as other parts of the body. The fibrous structure of the peridental membrane and its increase with age makes it less vascular, and thus shuts off more and more the vascular supply, and diminishes the freedom of action of the phagocytes.

The point of relative susceptibility has been well emphasized. It is equally well illustrated in cases of syphilis, typhoid, etc. The remarkable part is that a man in health and of good tonicity may be one of the most generous distributers, in fact a reservoir of the disease, though himself immune and utterly unconscious of the fact that he carries the typhoid bacteria. You may all remember the case of "Typhoid Mary," who distributed the germs to numerous families by whom she was employed as cook.

The end-organ theory of Dr. Talbot always had some fascination for me. Though we do not all lose our teeth nor all lose our hair, every peridental membrane becomes more fibrous, all hair grows gray, both a sign of senile change and destruction. Senility is not necessarily a question of years; some are old at thirty, and the so-called end-organs are the first ones to suffer.

The reasoning of the medical man that caries of the deciduous teeth was nature's method of getting rid of these teeth is certainly not based on any scientific facts, and does not fit into this argument. Nature certainly takes advantage of congenital defects, but the lodgment of micro-organisms in the fissures of deciduous teeth is simply incidental.

Dr. Kirk gives auto-intoxication a most prominent place in his paper. Though we do not know what the bloodstream carries to those parts, we do know that the expressions of auto-intoxication continually change. I have seen some of the most remarkable results after a Carlsbad cure, change of diet, mode of chewing, or change from sedentary habits to outdoor life. Automobiling has cured many sufferers from auto-intoxication—though many feel intoxicated when the monthly bills are presented. This is not only demonstrated and proved in man; it characterizes the life of the dog with equal force and truth. The more highly civilized he becomes, the nearer he reaches the ladies' lap and heart, the more certain he is to gain admission into the aristocracy of pyorrhetics.

We now have reached the pivotal point of Dr. Kirk's paper. Dr. Black, who has left an immortal imprint on everything pertaining to dentistry, tells us that what he termed "phagedenic pericementitis"—the Western Union would have doubled its rates on transmitting this title if telegraphed as a night message—has its principal seat in the lymphatic glands of the peridental membrane. Von Brunn and others who have made a special study of the peridental membrane do not, as Dr. Kirk tells us, recognize these bodies as being glandular. They call them epithelial rests, débris of the epithelial sheath of Hertwig, the embryonal tissue of the enamel organ. In hurriedly looking over Dr. Black's article and the splendid illustrations of Dr. Noyes which accompany it, I find that Dr. Black himself was not quite sure as to the glandular character of these organs. He tells us that when he first discovered these glands, he naturally expected to find ducts leading to the gingivæ. Later on he found occasional cell groups, indicating the possible presence of ducts. He was unable, however, to so connect them as to make them out as ducts. This led him to the opinion that they were lymphatics, an opinion with which he was never fully satisfied, because of the character of the cellular elements of these bodies. If these bodies, as it has been stated by later investigators, are but useless remnants of other organs, they act more or less as foreign bodies and are pre-eminently susceptible to pathologic influence. This is the vital point of Dr. Kirk's paper.

If the studies of Black and Kirk mean anything at all, they mean that a concerted treatment, both local and systemic, is the only logical method of treatment. Dr. Kirk might, at this opportunity, tell us something of his studies on salivary tartar formation based on the known experiments of Rainey. As I wrote in my review of the "American Text-book of Dentistry" —"It was left to Dr. Kirk to apply these researches in a most original manner to the formation of tartar, and supplement them with his own original thought." Although Dr. Black wrote his famous contribution in 1899, it may have been largely forgotten by the multitude of practitioners, and the profession must be grateful to Dr. Kirk for its emphatic repetition. The value and force of many of our great thinkers' statements are lost in passing, and it frequently takes other authorities to imbue them with new life and truth.

Dr. Geo. V. I. Brown, Milwaukee, Wis. The last paper I heard Dr. Kirk read on this subject was a very exhaustive one, and undoubtedly one of the best presentations that has thus far been given of the essential findings of scientific investigators in the broader fields of pathology applied to pyorrhea alveolaris, at the same time giving due consideration to the local manifestations more particularly observed by mental writers in descriptive treatment of this affection. He has evidently designed this essay along somewhat different lines, in appreciation of the difficulty, almost uselessness, of trying to deal with all phases of such a subject within the necessary limits of a single article, and has endeavored to keep in view one particular division. The usual tendency is to complicate this subject too much in its discussion, and to consider the disease pyorrhea alveolaris as an entity quite different from other pathologic processes. That view I am not in sympathy with. We all know that whatever the physical condition of the tissues may be, by placing a foreign body of some kind at the neck of a tooth where it will crowd down and irritate surrounding tissues—whether the irritating substance be a strip of rubber tubing, a ligature, calculus, or anything else of like nature—we can artificially produce all the symptoms which are recognized in pyorrhea. On the other hand, we also know that by the administration of mercury or other mineral poison, in spite of all oral prophylactic or other local treatment one can cause eversion of the gums and destruction of the alveolar structures in a similar manner. What does this mean? It signifies that all of these etiologic factors, both local and constitutional, are important, and as the essayist states—"Tissual derangements induced by toxic substances in the blood plasm warrant us in holding to the belief in the sufficiency of auto-intoxication as a cause of this form of pyorrheal disorder."

With the admission of auto-intoxication as a primary etiologic factor in lowering resistance of the organism by weakening the defensive bodies of the blood, all the influences which find their expression in malnutrition as described bear an important significance, which demands that they be reckoned with in the etiologic consideration of this disease.

Since auto-intoxication may be general as well as local in effect, it is manifest that there must be some reason why the pericementum and its surrounding structures should be so frequently selected to give evidence of such functional disturbance. It is for this reason, then, that particular interest attaches to suggestions such as the "end-organ" theory of Talbot's which is referred to, and the possibility of the gland-like bodies described by Black as being of embryonic origin, offering points of least resistance because of the degenerative type of their cellular elements rendering them perfectly susceptible to bacterial influences, and thus constituting a "*locus minoris resistentiæ*" as suggested by the essayist.

I believe that no modern histologist would agree to the drawings of these glands as they were originally outlined by Black, because they do not seem to be in harmony with our present understanding of the histological structure of the pericementum. On the other hand, there is no reason to believe, so far as I know, that the pericementum does not do its part in lymphatic activities the same as other tissues. The question of embryonic rests is one that has received a good deal of attention, as we all know, particularly in relation to Virchow's theory accounting for the origin of neoplasms. Clinically we recognize that these growths have a tendency to appear very frequently on the sites of chronic inflammations. Whether they are really due to embryonic rests—and these more widely distributed than we have believed, as suggested by the essayist—and therefore subject to the excitant activity of inflammatory influences, so that in these conditions there is a tendency to multiplication of embryonic cells in the mouth, as in other parts of the body, with neoplasms as a result, or whether they are infectious in character, are matters that are still debatable and now very actively under consideration. It would seem to me, however, in applying this point of view to our present subject, that if these embryonic rests really were so frequently present as to be accountable for so common an infection as pyorrhea alveolaris, that if there be any truth in the embryonic theory of cancer, and embryonic rests were so uniformly present in the pericementum, there would be a tendency for cancer to begin more frequently in this region; whereas in my experience the pericementum is not often primarily the seat of neoplasms in their incipience, for the neoplasm usually has its beginning elsewhere and the pericemental tissues appear to be secondarily involved in the course of destructive processes.

There is, however, one other matter which is important, to which I desire to call your attention, and that is the possibility of a selective tendency in bacteria. For example, I recently saw seventeen hearts each with a similar lesion upon exactly the same valvular portion. These seventeen hearts were gathered in one hospital, and study of these cases had led to recognition of the affection as due to a bacterium that had been isolated and definitely proved. For the want of a better descriptive term its discoverers called it a vibrillum. When I asked where this micro-organism gained entrance to the body, it developed that this was not known, but it was believed to be through the mouth. This example merely emphasizes the vital importance of mouth infections, and secondly, another not sufficiently considered element, the selective tendency of the micro-organisms in influencing bodily conditions.

The suggestions of the essay have brought to my mind in a somewhat forcible way the important bearing of two things Dr. Kirk has kept before us for years. First, the question of faulty metabolism in its relation to arthritism and other affections as well as pyorrhea alveolaris; second, the discovery that acid in the mouth precipitates the mucin of the saliva. When considered from a purely dental aspect, the possibilities of this action would appear to be merely relative to dental caries, but if one keeps in mind what it might mean to conditions of ill health along the line of the mucous membrane of the digestive tract to have a medium of that character thrown down which undoubtedly would hold the pathogenic micro-organisms in contact with tissue surfaces, and protect them from those forces which have been provided for their destruction, its pathologic significance becomes one of vastly greater import. For example, we know that in ulcer of the stomach, the acidity of the secretions of that organ is an important factor. We also know in many other diseases that under hyperacid conditions of the general system—to which the somewhat objectionable term acidosis is applied—there is a direct and very vital influence in relation to many kinds of disease. Personally, I believe all these things should have a bearing in the consideration of salivary mucin precipitation, and that this is particularly true in all forms of local oral infection, whether its expression be in one form or another. When a man like Murphy, the great surgeon, publishes illustrations showing cases in which he has resected knee and ankle joints and other portions of the extremities and has found the primary etiological factor could be traced directly to mouth infection, we can no longer question the importance of mouth infection in the pathology of any region of the body, nor can we continue to doubt the susceptibility to circulatory conditions of the so-called end-organs, whether in the teeth or in the extremities.

The vital issue is, after all, a question of resistance, and this depends upon antibodies and various other conditions of the blood that are being actively studied by research workers at the present time. Naturally the diminished circulation of the more remote parts renders them more susceptible to infection. The same principles must apply not only to the pericementum and its diseases, but equally as well to the extremities and their diseases, and to organs that may by chance be weak in the individual.

These are the points that the paper suggests to me today. Dr. Kirk has shown much that leads to the consideration of the etiology and pathology of pyorrhea alveolaris in a direction which is toward unification with the already known laws of general pathology, and in harmony with the developments of modern research workers in this field, and I am so deeply impressed with the valuable and far-reaching possibilities of the salivary mucin precipitations that he has called attention to—if the pathologic effect of this influence could be rightly understood and applied to the prevention and treatment of disease—that this must be my excuse if it should appear that I have traveled too far afield in the course of this discussion, and have in consequence overlooked some of the important features of the paper.

Dr. J. O. McCall, Buffalo. It requires a good deal of temerity on the part of a youngster like myself to come forward and speak on a subject of this character, especially after men like Dr. Kirk, Dr. Brown, and Dr. Hofheinz. I wish, however, to emphasize one or two points that I think of considerable importance, and that perhaps have not been emphasized sufficiently.

Dr. Kirk assumes that we have in most cases of pyorrhea an infection by bacteria, and he gives us to understand that the bacterial infection is the prime cause of the disorder; that is to say, that it is the principal factor in bringing about the destruction of the peridental membrane. Dr. Brown, on the other hand, tells us that this disease is simply a question of resistance—and that is the point I wish to emphasize. We know that wherever a tissue may be, whether in the mouth or in some other part of the body, no bacteria can gain entrance to it and bring about pathological effects unless the resistance of that tissue is lowered. In other words, healthy tissue does not become infected. Dr. Kirk has spoken of the effect of auto-intoxication, the collecting of the various products of auto-intoxication in this tissue. He has spoken also of the accumulation of tartar, and various other phenomena which may bring about a mechanical irritation. To my mind, the mechanical irritation which has lowered the tone of the tissue to such a degree that bacteria can gain entrance to it is an important factor to consider. The essayist's contributions to the consideration of these glandular structures in the pericementum are very interesting, and point out a new field; yet we must consider these cell rests—or whatever they be—as part of this tissue not only in mouths affected by pyorrhea, but also in all probability in mouths which are healthy. In other words, it is no more nor less a portion of the pericemental tissue than the peridental fibers themselves. The question of resistance, therefore, applies to that tissue as well as to any other. Tissue resistance concerns all tissue fibers, whether they be embryonic rests or vital parts of the tissue itself. Therefore we have to consider primarily the irritation which permits the invasion of this tissue by bacteria. That phase has been given much prominence in late years by such men as Dr. Skinner, Chicago, who have formulated a law in dealing with the problem of instrumentation and the maintenance of the tissues in a healthy condition through prophylactic treatment, their idea being that any irritation which may have brought about the lowering of the tone of the tissue must be removed, and the tissue then stimulated so that it may not suffer from further invasion of bacteria. The factors we must carefully bear in mind in considering this subject are the removal of irritation and subsequent stimulation of the tissues.

Dr. N. S. Jenkins, Dresden, Germany, It would be most presumptuous on my part to attempt to criticize with any degree of intelligence such a paper as has been presented to us today by our esteemed Dr. Kirk, for I have not had the privilege of reading the paper beforehand, and moreover it is not a subject which has in any very great degree occupied my attention of late years. I have had, however, a rather rare opportunity of observing the great confusion which obtains throughout Europe in particular in the treatment of this distressing disorder. I have seen all the modern methods of treatment, constitutional and instrumental, from the vaccine treatment—at one time somewhat more in effect in Great Britain than perhaps it *is* today and *was* throughout the whole continent of Europe—to its treatment with reliance only upon instrumentation, and I have been struck with this one remarkable fact: Whatever may have been the theories upon which these various operators have carried on their treatment, wherever there has been complete and thorough instrumental treatment, the result has always been the same.

Dr. Louis Meisburger, Buffalo. I am unfortunately one of the operators who treat this disease with instruments, wood points, and pumice, as Dr. Hofheinz said, but at the same time I appreciate the value of fresh air, water, and cathartics. I am to discuss Dr. Skinner's paper, and what I will have to say on that occasion is what I should say at this time if I attempted to discuss this paper fully.

The question of etiology has been very thoroughly gone into by the essayist, but I do not believe that the idea of prevention has taken hold of the profession as strongly as it should. There seems to be no doubt that the original cause is one of malnutrition followed by auto-intoxication. If food is properly assimilated and eliminated, and the system uses only the amount required for sustenance, no pyorrhea will ensue. As we all know, it is a filth disease, but in my opinion it is due to the tissue being in a state of lowered resistance. A few patients, however, exhibit large collections of tartar and still do not have pyorrhea. Therefore all such mouths should be thoroughly cleaned. Thorough instrumentation, no matter what the systemic conditions be, produces an improvement in cases of so-called pyorrhea, and I believe that true pyorrhea, in which pus is present, is found in people of lowered resistance, usually in hospitals.

I like very much the term used by Dr. Fletcher, in an article published in the *Dental Summary,* in which he refers to the beginning of pyorrhea as initial alveolitis. This is the condition which we are most often called upon to treat in our offices, and if we recognize and treat this condition early enough, we can prevent the distressing symptoms of true pyorrhea.

Dr. Edward C. Kirk (closing the discussion). In making this little effort to present to you in this paper a section of the study of pyorrhea alveolaris, I feel that I have accomplished a triumphant success in at least one direction, and that is the presentation of pyorrhea from the humorous standpoint—for it has always been regarded as a rather serious and solemn affair. Ordinarily, when I have attempted to talk about pyorrhea from the point of view from which I have presented it today, I have noticed that there has been a sudden outpouring of the audience toward the exhibit room, therefore I take it that the humorous suggestions which the discussion has aroused have rather served to pleasantly sugarcoat this rather bitter scientific pill.

In a general survey of the discussion I have observed certain things that always come out in connection with pyorrhea. Men ask what is its cause, and what is its treatment? Is it constitutional or is it local? Now, I want to answer these queries from my point of view, by saying that it is not "it" at all; that the man who asks what is the cause of "it" advertises the fact that he has not gotten hold of the first fundamental proposition—viz, that pyorrhea is not "it" at all, but is "they." Pyorrhea is a group of diseases; it must be a group of diseases, because we do have certain gingival lesions that we group as pyorrhea that are not pyorrhea according to the definition of the word pyorrhea; that is to say, we recognize certain gingival disorders as pyorrhea though they may have no pus accompaniment. We have certain destructive conditions in the retentive structures of the teeth by which they are exfoliated, so far as we can see, without the visible objective production of pus, while pyorrhea alveolaris means the flowing of pus from the alveolus. Therefore that atrophic form which we call pyorrhea is not pyorrhea in a literal sense, but a condition which we have grouped under a general classification of destructive gingivo-alveolar disorders, and to which for convenience' sake we have applied the generic term of pyorrhea alveolaris.

I am glad that somebody has found a definition that pleases Dr. Meisburger—"initial alveolitis,"—that is, literally, the beginning of an inflammation of a hole. I do not know how we can have inflammation of a hole; so I think we shall have to go farther than that for a comprehensive terminology. We have many names for these disorders; many have had a hand in baptizing them, but we will never get a proper terminology to describe these conditions until we first recognize that they are members of a group of disorders having the common factor of causing loss of teeth, that they must be classified according to the symptoms, etiology, and pathology involved, and that they cannot rationally be called by anybody's name. There is a movement to prevent the dental nurse from treating Riggs' disease in Massachusetts, and I have asked what in Heaven's name is Riggs' disease. I think they will prevent her from treating Riggs' disease, because there is no such thing.

The next difficulty is in our conception of the real cause. Sir William Osler said, in his book on the Practice of Medicine, something like this: "Very few people die of the disease from which they have been suffering most of their lives,"—for the reason that we have predisposing conditions of ill health dependent upon or resulting in malnutrition which lead us up to the point where a terminal infection by some kind of pathogenic bacterium sets up a disease process of fatal character and the individual dies. The question is, What is the cause of his death? Was it the terminal infection? or was it the condition preceding the bacterial invasion? We must include the predisposing factor as well as the immediate exciting factor in our conception of the cause, and because that is the proper attitude of mind toward the question of cause, we must take that view into consideration before we can answer the question as to whether it is local or constitutional. My own opinion is that it is both, and I have tried to express it as a local manifestation or a local lesion which is symptomatic of the predisposing constitutional cause, for the reason that these things must be considered together.

Let us get away from the idea that this group of diseases is necessarily either local or else constitutional. We cannot have a local condition without constitutional relations. I do not know of anything in the category of diseases—not even corns—that may not be in some degree the cause or the result of some form of malnutrition. A tight boot which presses on a corn long enough to disturb your appetite for dinner may upset your digestion and start a condition which will bring about for the time being malnutrition, then reduced resistance, and ultimately an infection—all, in a general sense, because your boot has been too tight. That is not a "far cry," but is a possible case.

I want to speak of the importance, to my mind, of determining the nature and character of this particular tissue in the peridental membrane which Dr. Black in the beginning spoke of as lymphatic glands, later expressing a modification of that view by saying that they were lymphatic in character. However, Black still makes the statement that they are not epithelial—and that point is important, because in that statement he ranges himself on the opposite side of the question from those who have preceded him in the embryological study of these structures. Black's investigations are quite independent of those of Malassez, Magitot, and Von Brunn, but the groundwork was very thoroughly gone over by these men. I was surprised to see what a large amount of literature there was upon the question of this phase of the histology of the peridental ligament. A large number of men who have studied the subject from the embryonal beginnings of the tissue up to complete formation of the structure of the peridental membrane regard these gland-like bodies as being of epiblastic origin. Now, it seems to me that above all things the fundamental question to determine is just that point—whether these cells are epithelial in origin or endothelial; that is important in relation to the question of their pathogenic relationship to not only pyorrhea but to a number of other pathological processes, and particularly the etiology of certain neoplasms.

Dr. Brown has spoken of the selective character of certain types of bacteria for certain tissues, and I wish he had gone farther. I am not disposed to doubt that view of the subject, but what I am trying to look at is the selective character of the tissue for the bacterium—if I may put it that way. We have examples of this selective action everywhere. We may expose a pint of milk and a pint of cider to the air, and the two will in time be decomposed into their ultimate end-products, one by putrefaction and the other by fermentation. Now, what makes the difference? Both are sifted full of bacteria of various types, which produces mixed infection, and certain bacteria survive and certain others die, and here we have shown the selective quality of the medium for the particular organisms that can thrive upon it. One view of this fact, that of Dr. Brown, implies intelligence on the part of the bacterium and the other implies the absolute, unassisted, unintelligent action of natural selection, which is the point from which I prefer to view it—and that is what I mean when I speak of the selective character of the tissue. If these peculiar bodies found embedded in the peridental ligament are epithelial, as I believe them to be, and they are degenerative in character, as in the condition to which Dr. McCall referred, when there is a depression of the whole organism and these relatively weak tissues become first infected, they become infected in the order of their relative power of resistance.

The other point which Dr. Brown brought out, and which I had hoped he would elaborate still further, is the question of the relation of these bodies, these cells, to neoplasms. I do not believe we have yet satisfactorily accounted for the thing which he has observed and which I have observed; that is, the development of leukoplakia buccalis from the first symptom, that milky whiteness that appears on the surface of the buccal mucosa, through that fishskin condition which marks the gradual inroad of the invasion of the neoplasm and its subsequent evolution into epithelioma. I would like to have Dr. Brown's view with reference to the possibility of certain types of epithelioma arising from the peridental ligament membrane. I have been looking for these cases with the hope of determining whether or not these so-called rests may not under certain stimuli take on a morbid growth and develop into the neoplasm of epithelioma.

The question was raised by Dr. Hofheinz as to whether pyorrhea might not be produced, at least in its early stages, by auto-intoxication before the infection by bacteria.

Dr. HOFHEINZ. My question was whether it only becomes true pyorrhea after the bacterial invasion.

Dr. KIRK. I do not see how it could be anything else. Dr. Black, even before I was born, laid down the axiom that, in referring to scientific matters, we must use words with precision, and we cannot call it pyorrhea without the "py," which means a result of infection by pyogenic organisms.

Dr. HOFHEINZ. But, as you said before, we must speak of "them," not "it." We classify a number of conditions, for instance, atrophic pyorrhea, where we do not have pus, and yet we call it pyorrhea.

Dr. KIRK. But for the time being we are limiting the discussion to the one in which there is pus infection.

I regret that Mr. Hopewell-Smith is not here, but I believe that this discussion will act as a prolog for the study of the relation of these gingival tissues to pyorrhea, which I understand is the subject of his paper, and I am glad to know that we are to have the benefit of his skilled observations and mature judgment upon this particular thing. It was a coincidence, without the slightest prearrangement, that what I have said is merely a "curtain-raiser" for what he will present, and which may either destroy the fabric of my paper or strengthen it.

I want to thank you for your patient hearing of this timeworn topic.

The meeting then adjourned until the evening session.

THURSDAY—*Evening Session.*

The meeting was called to order at 8 o'clock Thursday evening by Dr. Louis Meisburger.

The first order of business for the evening session was the reading of a paper by Dr. H. J. BURKHART, Batavia, entitled, "The Proposed Plan of Reorganization of the National, State, and District Societies."

Dr. Burkhart in his paper outlined in detail the plan of reorganization of the National Dental Association and the proposed plan on which the state and district societies were to be affiliated with the National.

Following Dr. Burkhart's paper, Dr. William A. Howe, Albany, N. Y., deputy health commissioner of the State of New York, gave a talk on "Oral Hygiene from the Viewpoint of the State Department of Health," in which he spoke of the work of the health department of the state along dental lines. Dr. Howe spoke very highly of the valuable work that the dental lecturers were doing in connection with the work of the board of health, and expressed the hope that more of this work would be done in New York as well as in other states.

The meeting then adjourned until Friday morning.

FRIDAY—*Morning Session.*

The meeting was called to order at 9.30 o'clock Friday morning by Dr. W. A. White, Phelps, N. Y.

The first item on the program for the morning session was the reading of a paper by Dr. J. V. CONZETT, Dubuque, Iowa, entitled "Cavity Preparation for the Gold Inlay."

[This paper is printed in full at page 587 of the present issue of the COSMOS.]

Discussion.

Dr. D. H. SQUIRE, Buffalo. It is extremely difficult to discuss an essay from the pen of a man whose ability as an operator has a national reputation, as every phase of the subject has been well presented. The essay deals with the fundamental principles rather than with the technique of cavity preparation, and an attempt will be made to emphasize a few of the important items mentioned.

Dentistry has passed through a state of evolution; a new era has dawned, and its rays of knowledge have penetrated the darkness of empiricism, and in the light of its advancement we see the necessity of delving deeply into the cause and effect of the processes which are taking place in the oral cavity. We recognize at least the results which our unskilful operations upon the teeth have had upon the health of the surrounding soft tissues. We have learned that we are not always a contributing factor toward the health of those tissues upon which we operate, because we have failed to recognize the great value of recorded observation. This fact has wrought a complete change in the operative treatment of dental caries.

Today the attention of the practitioner is called to the important influence which mouth hygiene has upon the inception and progress of caries, and in recognition of this fact the surfaces of the teeth have been divided into two general classes, according to their environment, as clean and unclean areas.

We are all aware, from our knowledge of the progress of caries, that the bacteria must have protection in order that their acid products may percolate through the enamel structure, and by dissolving the calcium salts, eventually attack the dentin. The rapidity of this process is augmented by the conditions present in the mouth. Therefore any surface of a tooth which, owing to its size, shape, position, or lack of development, is protected from the methods employed in cleansing, or scouring produced by the excursions of foods which pass over its surface during mastication, is a favorable place for the colonization of the bacteria of dental caries. This fact must be considered in the planning of the outline form, and all of the defective tooth structure must be incorporated within the cavity formation.

The essayist asks the question, What is extension? and says that there is no fast rule regarding it, which is amply proved by the observation of every dentist. In mouths which are comparatively clean, and where the teeth are carefully brushed, little caries will be present, and extensive cutting of the cavity walls is not indicated. In such cases it is quite sufficient to bring the extension of the outline form into the embrasures, either by cutting or by increasing the contact. On the other hand, if much caries is present and an utter lack of hygienic conditions exist, extension of the outline form is not only necessary, but imperative. The permanence, then, of all outline forms of cavities will depend solely upon the conception of the existing conditions which are present in the mouth. The direction and the amount of stress exerted upon the teeth during mastication bear the same relation to the cutting of the resistance and retention forms of cavities, as the law of cleanliness bears in determining the outline form.

The essayist calls attention to the tendency which the force of attrition has in dislodging an improperly seated filling, or one which is retained principally by the aid of cement. If we have not at hand a scientific apparatus with which to determine the amount of stress in pounds, a careful observation of the conditions of the crowns of the teeth will give us some idea, at least, of the amount of this force. Broken corners, abraded surfaces, burnished fillings coupled with well-nourished pericementum, indicate hard usage, and while a patient may have strong and well-developed jaws and muscles of mastication, still it is a fact that his full crushing force only becomes exercised in direct ratio to the health of the pericementum. Mechanical retention means a flat seat and step, with frictional resistance along the side walls of the cavity. If inlays are to be serviceable, the castings must have the mechanical support of the dentinal walls. It is of vital importance in the construction of all fillings to have the steps made broad enough and sufficiently deep to hold an adequate amount of material for strength. The essayist's point is well taken that a great many failures are due to carelessness in the cutting of the step formations. The explanation of depending upon cement to retain the inlay needs no further comment.

My own observation in testing the adaptation of cast gold to the cavity walls bears out the essayist's condemnation of butt joints. A mesio-occlusal cavity in an extracted lower first molar, was prepared with flat resistance and retentive forms and perpendicular side walls, with all line angles acute. Gold inlays were made from the cavity by the direct and indirect methods, they were cast by the Taggart, vacuum, and centrifugal processes. The dentin was then removed from the central portion of the body of the crown of the tooth, leaving the gingival seat, the buccal and lingual walls of the approximal portion, and the distal wall of the occlusal step intact. Then the cast fillings were seated firmly in the skeleton cavities. The rays of light were first directed against the mesial surface and exposures made of the several castings; then the light was directed against the internal parts of the crown of the tooth and the inlay, and exposures were again made from the mesial aspect. The microphotographs showed that the gold did not remain in close adaptation to either the gingival seat or to the distal end of the occlusal step. The casting was also deficient all along the side walls of the cavity, from their junction with the gingival seat to the distal margin of the occlusal step, the contraction being greatest along the gingival wall and the distal wall of the step. It is impossible to make a butt joint which is watertight, and in order to overcome the contraction of the gold, the enamel wall must be so cut that a flange of gold will protect the rods and can be burnished over the cavo-surface angle in order to seal the cavities.

In the restoration of the surfaces of the teeth, one should be well acquainted with their anatomic features. The study of dental anatomy is the foundation of all operative procedures. We cannot expect ideal results without a comprehensive knowledge of this subject. I am of the opinion that the essayist considers occlusal restoration of equal importance with approximal. The cusps, triangular ridges, sulci, and developmental grooves may be easily carved in the wax model with properly shaped orange-wood sticks. The alignment of the teeth is greatly impaired by a total deficiency in the reproduction of the anatomic features of this surface.

Orthodontists have been unable to hold an established occlusion because of utter disregard of the importance of properly restoring the occlusal surfaces of the bicuspids and molars.

The proper size of a contact point on the approximal surface may be determined by the following measurement:

A silk ligature, about 2½ or 3 inches in length, is passed between the approximating teeth; the ends of the strands are held parallel with each other and pulled tight. If the distance between the strands is not more than 2 mm. when held in the direction of the horizontal and vertical planes of the teeth, its size will be sufficient to protect the septal tissues from injury.

If 5 per cent. of platinum is added to the pure gold, a much harder metal may be obtained, and stretching of the casting will not occur. Malleted gold will stand more stress than cast pure gold on account of its molecular tension being raised by hammering. If either 20-karat or coin gold is used, the individual movement of the teeth during mastication will wear away the contact; therefore it would seem best to make all contact points of gold of a lower karat.

In the finishing of the enamel margin in the region of the gingiva, I have used the Wedelstaedt chisels, which the essayist recommended at the Chicago clinic last year, and which are a great adjunct to the gingival marginal trimmers. The portion of the finished casting which covers the gingival area must be smooth and well polished, and great care should be exercised in removing every portion of cement. Injury to the septal tissues during the operation, or irritation of these parts afterward, will not only change the reaction of the secretion of the mucous follicles, but, if continued, will eventually destroy the tissue itself. Under normal conditions, the alkalinity of this fluid and the presence of the septal tissues in the interproximal space plays an important part in the preservation of the tooth structure from caries.

Dr. J. W. Cowan, Geneseo, N. Y. The essayist has stated that cavity preparation has become a science within the last twenty years—it has been an applied science for forty years or more. I will admit that the great majority of dentists in the old days did not have a clear comprehension of the correct principles of cavity preparation. But a great many who understood these principles were capital operators, and they contributed their full share toward the work upon which Dr. Black of Chicago put the finishing touches. I do not want to detract one particle from the credit due to Dr. Black, but the other operators shall not be denied the credit that is due them.

Over twenty years ago, I came into possession of a lot of correspondence that passed between Dr. W. C. Barrett of Buffalo and Dr. Franklin E. Howard, then of Geneseo, in which this question of extension for prevention was thoroughly discussed and clearly defined. The letters were written away back in 1879.

Dr. Black has developed a terminology for the details of cavity preparation and reduced the whole question to a thoroughly teachable science, and for that he has our most sincere gratitude. But, as I said before, I want to have the other operators receive the credit to which they are entitled.

In describing his method of preparing the gingival seat, Dr. Conzett said that he uses an inverted-cone bur, and usually with one sweep across can level off the floor of the cavity satisfactorily.

In my hands, an inverted-cone bur in an angle handpiece is the most unmanageable device in my armamentarium. It gets out of hand, it runs amuck and rips out between the teeth, doing a little extension on its own account, but we could hardly call that extension for prevention. I have memories, and I believe some of my patients have painful recollections, of my exploits in this particular detail. I have, therefore, abandoned these deeds of daring with an inverted-cone bur, and use, instead, the safe-sided, end-cutting instrument alluded to by Dr. Conzett.

In his description of marginal preparation, the essayist has alluded to the instruments he uses, among which I prefer the two small spade-shaped chisels, which are simply Rhein approximal trimmers, the file faces being ground flat. I use these for the preparation of the pulpal walls generally. Four, which I have labeled 1, 2, 3 and 4, are made from small straight chisels of the regular S. S. White set, by putting the blade in a small vise, directing the flame of a blowpipe on the neck of the instrument, bending to whatever angle desired, and retempering them to the utmost hardness of steel.

Dr. H. L. Wheeler, New York. I want to ask Dr. Conzett if I understood him to say that the force or stroke in mastication is directed upward and forward in the lower jaw? I cannot see, from my knowledge of the anatomy of these parts, where he gets that idea. I will try to show on a blackboard the path of the condyle and its relation to the eminentia articularis, also that it is impossible to get a forward and upward stroke when the lower jaw is brought up.

It requires some little courage to question the essayist's statements. I believe only partially in extension for prevention. I know that no one here has any desire to question the accuracy of Dr. Black's experiments and researches. We all appreciate that he is probably one of the greatest, if not the greatest living member of the profession, and the amount of work which he has done and the success he has made are simply staggering to me. Nevertheless, in my opinion, this theory of extension for prevention is sometimes overdone. In a case where there is practical immunity or little tendency to dental caries, with perhaps an occasional approximal cavity, I see no reason to assume, if the cavity is not already extended to the lines advocated by the average enthusiast for Dr. Black's theory, that the carious process will extend farther after a filling has been inserted. I cannot see why I should cut away a lot of tooth structure to conform with a theory in an instance of that kind. When it comes to a cavity on the cervical margin which extends on the buccal surfaces of a bicuspid or molar and around the entire buccal margin without involving the approximal space, where are we to extend it to?

Dr. Conzett. Only to the angles.

Dr. Wheeler. A good many cases of that kind have puzzled me to such an extent that I accept this system only partially. The greatest adverse argument is, Why, if an individual of fifty or sixty years develops a small approximal cavity, should we assume that this cavity should extend over a very much greater area. On the other hand, in a mouth with an evident tendency to extensive caries, and with cavities invariably extending into the interproximal space, I believe that extension for prevention can be used intelligently.

If I remember correctly, Dr. Conzett assumed that the preparation of the cavity should be the same in all cases, but later he qualified that statement, much to my satisfaction. I believe it is essential for every operator to consider the phenomenon of immunity and the health conditions as reflected by the teeth. I must confess that the older I grow, the less I find myself inclined to decide a case until after I have observed the patient for some years, and have concluded as to what is the best course of treatment to follow in his mouth, because I find it desirable to adjust treatment to the general conditions presented. For that reason I find myself unable to accept the general rule regarding extension for prevention.

In regard to cavity preparation, however, I think Dr. Conzett to be correct.

I wish now to show in a rough way the movement of the mandible. [In making this demonstration Dr. Wheeler showed the movement of the mandible of one of the audience.] The condyle fits in the glenoid fossa, and is unable to move back in this direction except slightly, in compressing the cushion where the condyle sits in the glenoid fossa. The general direction of the condyle path where the condyle slides when the lower jaw opens is downward and forward; when it opens in the least, the condyle slides downward and forward. The lingual surfaces of the incisors and canines are on an angle which opens forward and inward, for the reason that, when the jaw is opened, it slides down here [illustrating], and when it closes, it slides backward and upward, and the anterior teeth slip backward and upward against the superior incisors. It is impossible, therefore, in most cases, for the lower jaw to go shut except backward and upward, and the angle of the condyle path depends on the prominence of the eminentia articularis. How Dr. Conzett makes it possible to get the greatest stress with the jaw moving in the opposite direction, I cannot understand.

Dr. Conzett. Because it does move in the opposite direction. A hinge, as it goes upward, has to go forward, and we cannot have a hinge joint that goes backward as it closes. We have with us today an authority on occlusion, Dr. Wilson, and I would like to hear his opinion on this subject. As the hinge goes forward, with the bolus between the teeth, stress is exerted upon that bolus before the teeth are entirely closed, and when it strikes the occlusal planes of the incisors there is a slight backward movement,. but the major movement is forward and upward. Everyone has had the experience of having fillings forced out of the mesial surfaces of upper teeth and the distal surfaces of the lower teeth, the reason—which is a question of mechanics—being that, as the hinge goes forward, it goes up. Am I right, Dr. Wilson?

Dr. Wilson. I hardly think you are right. The condyle is hardly like a hinge—the head goes back when the jaw closes. The mandible really is pulled back when the mouth closes.

Dr. Conzett. Nevertheless the fact remains that we have fillings forced out on the mesial surface of the molars.

Dr. Wilson. Is there not some other reason for that?

Dr. Conzett. I know no other reason. We find fillings with insufficient anchorage forced out of the distal surfaces of the lower teeth, but never find them to be forced out in any other direction. Therefore, while there may be a slight amount of force due to the movement of the condyle, the major portion of the stress is directed upward and forward.

Dr. WHEELER. This is the basis upon which all anatomical articulators are constructed: Arrangement is made so that the artificial teeth execute the same motion, when the jaws are brought into occlusion, as we have in the natural jaw, and invariably this is the proposition [illustrating]. It is impossible otherwise, because the mandible is not a hinge, it is a joint, which, when it moves, has to slide forward, and, when the jaw is open, it slides clear to the eminentia articularis, and when it closes it slides back, and you can see that in closing these teeth can be brought together in the anterior portion of the mouth, and when they are so brought together the condyle invariably slides downward and forward, and the molars cannot be brought together again without bringing the condyle back into the glenoid fossa, the lower teeth sliding on the interior planes of the upper jaw.

I do not question the statement of Dr. Conzett that fillings are forced out in the direction mentioned, but I believe he is incorrect in regard to the reason. Perhaps we will today be able to give him a problem of this kind to solve. While I have unbounded admiration for the technical part of Dr. Conzett's paper, he has, in my opinion, misinterpreted the movement which dislodges fillings, and a careful study of the relation of the mandible, the glenoid fossa, and the condyle path will convince him of that.

Dr. G. H. WILSON, Cleveland, Ohio. I do not feel competent to discuss the subject of the paper, as it is entirely out of my line. In regard to occlusion, however, Dr. Wheeler seems to be correct, because the head of the condyle is not like an ordinary hinge. The temporomandibular articulation does not work from a solid center; the center of working is below the neck of the condyle down at this point [illustrating], that being the fixed point and the head of the condyle the short arm working forward and backward, the eminentia articularis guiding the mandible backward. The incline of the lingual surfaces of the incisors, and probably the preponderance of force of the muscles of mastication is backward; therefore it is more than probable that Dr. Wheeler is right in his statement.

Dr. L. M. WAUGH, Buffalo. The question has been raised regarding the direction of the movement of the head of the condyle in its path in opening and closing the jaw. The head of the condyle is not a fixed point, like the hinge joint; it moves in its path, as anyone can prove by placing the finger on the jaw and feeling the point of movement of the mandible and its movement in opening and closing the teeth. We can feel this movement here [illustrating] forward and backward; it varies in individuals from ten to thirty degrees, also on either side of the jaw of the same individual. Dr. Conzett's contention as to the dislodgment of fillings I think is correct. We do not find normal occlusion of human teeth very often, and I think his observation is correct that fillings are dislodged in the directions stated. This is due to malocclusions and deviations from normal occlusion; these bring about such dislodgment of fillings. While his observation based on the movement of the jaw is not quite right, I think the practical side of his statements is correct, because we find normal conditions only in a few cases. Since the teeth are arranged very closely to one another, a very slight change in their relative positions can bring about this dislodgment of fillings.

Dr. Squire stated that it is absolutely necessary to pay strict attention to the occlusal form of restorations. We can do quite as much, I believe, toward retention by so arranging the occlusal planes in a filling that, each time the jaw is opened and closed, it will strike an inclined plane which will drive the filling into the cavity rather than out of it. If the metallic inlay had merely given us the opportunity of studying these occlusal contacts, it would have been worth while for that reason alone.

By way of digression, I would briefly take up the relative points of merit in the direct and indirect methods of making inlays. To my mind, it is not a question of whether an operator can make a good inlay by the direct or the indirect method; if he masters the technique, he will be capable of making a well-fitting inlay by either method. But the indirect method, in my opinion, offers superior possibilities in regard to the occlusal topography of our fillings, which alone is sufficient cause for its universal adoption. We can take an impression of the cavity and reproduce it by an amalgam die, take the bite, form the occlusal surface of the filling and fit the wax form to this cavity in such a way that all the occlusal contacts are established, thereby not only retaining the teeth in proper relationship, but also insuring valuable retention for the filling itself. If looked at from this standpoint, I believe the indirect method offers possibilities for better work and greater durability of fillings than any direct method.

Dr. Conzett (closing the discussion). There are two or three points which have been brought out in the discussion and which I would like to elucidate. The first one concerns the butt-joint shrinkage of the inlay. While I do not wish to go into the subject of the casting of different metals and their shrinkage, which is too big a problem to open up at this time, I want to say that there is shrinkage in the casting of any metal, and, in the butt joint, this is particularly observable. It will be found in making a butt joint at the gingival angle that there is no macroscopic appreciable discrepancy between an inlay and a filling, but there is a microscopical discrepancy, and we are dealing with microscopy when dealing with bacteria.

As to the occlusal step cavity, the cavity is so shaped that it is leaning toward the gingival aspect of the cavity, so that before we introduce the metal, we trim off a slight portion of the occlusal step, and when the finished inlay is set in the cavity, it can be malleted down that much farther in the cavity, and set upon the gingival and occlusal steps. Then the cavity is perfectly sealed all over, and the margin, which has been made with a flange, can be burnished down so that a microscopically perfect joint is obtained. I do not believe it possible to obtain a perfect joint, but one that is almost perfect, so that there is no danger.

I do not wish to claim for a moment that Dr. Black originated all the facts which makes cavity preparation a science today. We recognize that great work had been done by men in the past, and I tried to guard in the paper against any misunderstanding by saying that we do not wish to arrogate to Dr. Black or to ourselves all the credit for scientific cavity preparation. Dr. Black systematized the work which other men did—Taft, McKellops, Barrett, Webb, all of these men did wonderful work, and Dr. Black simply gathered up their work and then, by his remarkable genius, combined and systematized it. Of course, he did a lot of original research himself, and then gave us the science of cavity preparation. I still adhere to the statement that, previous thereto, we had no science of cavity preparation.

In regard to Dr. Wheeler's stricture upon the theory of extension for prevention, I want to say that I tried to guard against that too. We do not have any hard-and-fast rules, we have to exercise judgment, and study, and meet the conditions which the case presents with the fundamental principles laid down by the science of cavity preparation. It would be foolish, of course, to cut some teeth as far as others, and all teeth alike, but we must use intelligent judgment, and must cut cavities in teeth in such a way that will be able to best preserve the teeth for future usefulness. I agree with much that Dr. Wheeler has said, but, at the same time, in all cases the lines of a cavity should be carried to safe territory. There is a difference in that territory in different mouths. In some mouths certain territories are kept clean that are unclean in others, and we have to differentiate in the individuals as well as in the teeth we are operating upon.

I hardly dare to answer the other question, because while my observation is correct that fillings placed in mesial and occlusal surfaces of upper teeth and in distal surfaces of lower teeth are displaced, I had supposed this to be owing to the forward and upward movement of the mandible, and I dislike to contradict Dr. Wheeler and Dr. Wilson. Dr. Brady of Kansas City once said that when we get the perfect operative dentist, orthodontist, and prosthodontist, we shall have the perfect occlusionist. I am an operative dentist, know little of prosthodontia and orthodontia, and have much to learn along these lines, and for that reason I am glad of Dr. Wheeler's remarks. As soon as I get home, I shall study Dr. Wilson's book, and perhaps I can make up for my shortcomings in this field. I am glad that Dr. Waugh gave such a clear explanation of the question at issue. I insist, however, that my observations have been correct, although my deductions may have been incorrect.

The next order of business was the reading of a paper by Dr. F. H. Skinner, Chicago, Ill., entitled "A Few Suggestions on Oral Prophylaxis."

The meeting then adjourned until the afternoon session.

(To be continued.)

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

PUBLISHED BY

THE S. S. WHITE DENTAL MFG. CO., PHILADELPHIA, PA.

Subscription Price, including postage, $1.00 a year to all parts of the United States, Hawaiian Islands, the Philippines, Guam, Porto Rico, Cuba, and Mexico. Canada, $1.40. To other foreign countries, $1.75 a year.

Original contributions, society reports, and other correspondence intended for publication should be addressed to the Editor, Lock Box 1615, Philadelphia, Pa.

Subscriptions and communications relating to advertisements should be addressed to the Business Manager of the Dental Cosmos, Lock Box 1615, Philadelphia, Pa.

PHILADELPHIA, JUNE 1913.

EDITORIAL DEPARTMENT.

WHY NOT TELL THE TRUTH?

The ethical sense—when it is a sense at all—appears to be an evolutional product. Indeed, in its broad signification as the science of right conduct, ethics is distinctly an outgrowth of the social or communal life of a man, involving his conduct in a relative sense to the rights of others; hence there can be no such thing as ethics as an individual endowment, any more than there can be such a thing as sound upon an uninhabited island—the term "sound" involving as it does not only atmospheric vibrations of a given amplitude and intensity, but their appreciation by an intelligent mentality.

Among the fundamental ethical conceptions earliest in the order of evolution is that which recognizes the harmfulness to others of misrepresentation of certain categories of fact. One may cause the death of another by inducing him to drink poison by misrepresenting the draught to be wholesome or harmless. One may also destroy the faith of the community in a given individual by misrepresentations as to his character, or as to his acts as indicative of character; and in both instances the harm done, be it material or spiritual, direct or remote, constitutes an offense against the ethical sense of the community. Such offenses have become embodied in the ethical or moral codes of peoples, and constitute the standards or norms by which conduct in its social relations is gaged, and departures from which constitute offenses punishable in accordance with established communal standards of their relative magnitude.

Notwithstanding the fundamental importance of correctly stating the truth, and the recognized harmfulness of distorting the truth, and notwithstanding the fact that "Thou shalt not bear false witness against thy neighbor" is as clearly an established provision of the accepted ethical code of our social organization as any other item of the decalogue prohibiting crimes and misdemeanors against persons or property, it nevertheless appears that infractions of the prohibition against bearing false witness are more prevalent and are regarded more lightly than the breaking of any other prohibition of the venerable code. The peculiar and seemingly inconsistent thing about it all is that less flagrant wrongs of less importance to the individual or communal welfare are promptly punished or the offender is indignantly ostracized; whereas the liar, the perverter of the truth for his own selfish ends—not to speak of the ordinary ignoramus and egotist who distorts the truth in order to enhance his importance and flatter his own vanity—often goes on his misguided way unscathed and unrebuked until Nemesis in the form of outraged truth overtakes him and shows him up in all of his naked depravity.

There is a form and kind of misrepresentation that lacks the positive motive of dishonesty and self-interest, which therefore excludes it from the category of plain ordinary lying, but which nevertheless is negatively harmful in that it conveys false impressions, and thus constitutes an obstacle to the propagation of the truth—viz, the form of misrepresentation commonly called exaggeration. The tendency to overstate things is a natural human peculiarity, and it is just that tendency which constitutes and probably always will constitute the greatest obstacle to scientific progress; for it is the business and end of scientific research to ascertain the exact truth, which when ascertained and systematized into an organized grouping of data is what constitutes science. Every misrepresentation of fact, therefore, impedes the growth of science, and the tendency to misrepresentation prostitutes the intellect of the scientific worker so afflicted, and advertises his incompetency for such work.

Exaggeration may be wilful or it may be thoughtless and unintentional, but in either case its effect is harmful because it is misleading.

How often do we read—for a concrete example—that in some paper on dental education its author asserted that the colleges are to blame because they do not teach this or that subject? or that the colleges are responsible for the low standard of ethics of the young men who are now coming into the profession? or that the colleges do not do this or that thing that they ought to do, and that the colleges do this or that thing that they ought not to do? —with the implied conclusion that "there is no health in them." The same criticisms are made collectively of state examining boards, and of everything in general, by the type of individual who has a penchant for exaggeration, and whose experience is usually limited to the observation of a single instance or two upon which he bases his sweeping and inclusive generalization that the wrong of which he complains is epidemic in scope.

It is highly probable that if our whole scheme of dental education as well as of dental legislation were critically examined in detail, it would be found that in the half-hundred or more faculties and examining boards respectively engaged in the work there would be found here and there enough deficiencies in kind and degree to collectively warrant active attempts at reform. On the other hand, the sweeping generalizations made by individuals who base their criticisms of our colleges upon what they actually know from an experience of one or two observations constitute examples of the widespread tendency to draw upon the imagination for data—a tendency which may not mean wilful misrepresentation, though its effects are often equally pernicious. Would it not be worth while, in this time of social reform movements, for some inspired individual to start a propaganda of plain ordinary truthfulness as an ethical motive just for the sake of testing out its practical usefulness to society.

Review of Current Dental Literature.

THE ACTION OF ARSENOUS OXID UPON THE PULP AND PERICEMENTUM. By PROF. DR. H. SCHROEDER, BERLIN.

[*Oesterreichisch-ungarische Vierteljahrsschrift fuer Zahnheilkunde*, Vienna, January 1913.]

THE INFLUENCE OF ARSENOUS OXID UPON THE PULP TISSUE. By PROF. DR. JULIUS SCHEFF.

As the result of his own observations and those of numerous other investigators regarding the action of arsenous oxid upon the pulp and pericementum, and illustrating his deductions by a series of beautiful photomicrographs, Schroeder arrives at the following conclusions: The most conspicuous and ever-present phenomenon following the application of arsenous oxid to the pulp is the remarkably pronounced fulness of the bloodvessels and the presence of multiple hemorrhages, especially from the capillaries. Numerous thrombus-like formations are found in the vessels, varying in appearance according to the more or less advanced decomposition of the red blood corpuscles. The changes are to be ascribed to an elective effect of the arsenic upon the bloodvessel walls, and may be observed almost simultaneously in all parts of the pulp, so that one cannot speak of a gradual advance toward the root-apex, there being no areas of abrupt transition or special zones of demarcation. This rapid progress of alteration of the vessels involving the whole pulp is to be attributed to the ready resorption of the arsenic. In a like manner the change occurring in the nerves is to be explained by the direct chemical action of the arsenic, which is even more rapid here than in the vessels. In the same way the cell elements, including the odontoblasts and the connective tissue substance, are affected by the toxic action of the arsenous oxid; so that the necrosis of the pulp is to be attributed neither to the superficially caustic action of the arsenous oxid nor to its precipitating action upon albumin, but rather to its character as being a plasma poison.

Concerning the action of the arsenous oxid beyond the apex, the writer finds that the necrotic effect of the drug is considerably checked at that point, presumably by the anatomical conditions, which are unfavorable to resorption. Experiments conducted in dogs, in whose canines the acid was sealed for a week and longer, showed that the drug had lost its toxic effect upon its journey from the place of application to the root-apex to such a degree that it no longer destroyed the apical tissue and the pericementum directly, but only set up an inflammation aggravated by the masses of necrotic pulp tissue. A great number of leucocytes are found to penetrate from the deeper layers of the periapical tissue into the vessels that enter the pulp, these leucocytes proving the strongly chemotactic action of the necrosed masses of pulp saturated with arsenic. Of the other phenomena which have been observed as marking the direct action of the arsenic, multiple hemorrhage and cell changes are not observed in the pericementum, neither can any changes be observed in the nerve fibrils ramifying from the inferior dental nerve to the root-apex. This does not exclude the possibility of a destructive necrotic action of arsenous oxid upon the pericementum and surrounding periapical tissues in cases of wide foramen, in young teeth, and under favorable conditions of resorption. Such cases have been reported, and we also know that if an idiosyncrasy is present, extensive necrosis may occur in the vicinity of teeth that have been treated with arsenic.

The pericementitis which frequently follows the application of arsenous oxid is set up and maintained by the products of decomposition in the pulp tissue that are saturated with the acid. The hypersensitivity generally ceases soon after the pulp has been removed. If the acid acted directly upon the pericementum, the pain could not possibly last for several days, as is so often observed, since the nerves of the pericementum would surely succumb as readily as those of the pulp to the action of the acid. In most cases, therefore, the painful inflammatory irritation of the apical pericementum following the application of arsenous oxid can be attributed not so much to the direct chemical action of the drug, as to irritation produced at the apical foramen by the decomposition of the pulp.

Scheff's investigations upon this subject have led him to the following conclusions, which are interesting when compared with those of Schroeder: The action of arsenous oxid upon the pulp consists in a pronounced hyperemia observable within a few hours, followed by edematous infiltration of the connective tissue of the pulp. On the third and fourth days the vessels and capillaries are filled to the utmost capacity, on the sixth day thrombosis of all the vessels bordering the necrotic portion is observed. At the same time ensues the emigration of polynuclear leucocytes into the pulp tissue, the elements of which exhibit clear signs of beginning necrosis, starting from the point of application of the arsenic and gradually progressing downward. Even after fifteen days of arsenical application, the pulp is not fully necrosed, reparatory processes, viz, proliferation of the connective tissue elements, being set up from the central portions, which are more or less clearly separated from the necrotic periphery of the pulp by a wall of leucocytes and lymphocytes. The arsenous oxid employed in these observations was combined with oil of peppermint, this paste acting in the same manner as pure arsenous oxid. Other admixtures, however, to the oxid, the author admits, may produce phenomena in the pulp tissue different from those observed by him.

[*Le Journal Dentaire Belge*, Brussels, November 1912.]

WHY THE ARABS SO FREQUENTLY CLEAN THEIR TEETH AND MOUTH.

According to their religion Mussulmans must, before prayers, give themselves up to ablutions of the entire body in order to purify it. The care of the mouth is a part of these ablutions. Tradition relates that Mohammed cleaned his mouth after meals with a stick of licorice wood, which had previously been masticated, so that one of the extremities consisted only of woody fibers which formed a kind of brush, and was used as a tooth-brush. If, at the time of his ablutions, the Arab had not ready those substances with which he is accustomed to clean his teeth, he simply rinsed his mouth, and if he had no water he confined himself to simulating the ablution. Here is an extract from the Arab precepts as regards hygiene, taken from the philosophy of Sidi Khalil: "It is necessary that every Wednesday a man should perform ten things revealed by our Father Abraham, or at least some of them if he is not able to accomplish all; one of these ten instructions is to use *souak* for the mouth."

Souak is used by the Arabs for the care of the mouth, but some, especially among the women, like to use this drug for cosmetic purposes. The Arab woman takes a fragment of bark three or four centimeters long and a centimeter broad, and chews this substance for half an hour, after which she uses it to rub the teeth and gums. Under the action of this product the teeth become very white and the gums and lips take on a beautiful red color. Certain Arab women in order to perfume the breath and to complete this cleansing of the mouth masticate for a portion of the day a resinous gum which is known in Tunis by the name of *elloubane*. This resinous gum of which we have received a specimen is no other than olibanum (frankincense). Souak is used in many of the countries of Northern Africa, such as Tunis, Algeria, and Egypt, in Asia Minor, etc. In all these countries it is an important article of commerce; its cost varies from Fr. 3.00 to Fr. 8.00 a kilo. Arabs chiefly use it, but other people living in contact with them, having learned to appreciate its advantages, also make use of it.

Throughout the East betel is used, especially as a masticatory. It is a complex product whose principal constituent is the leaf of a climbing plant of the family of piperaceæ mixed with lime and areca nut. This substance has a certain physiological action which orientals cannot dispense with without the risk of bringing on a cachexia.

Among the Senegalese *sotiou* is used; it is a real natural tooth-brush. This brush, or sotiou, is nothing more than a little stump of a branch or root obtained from certain trees or bushes; its length is usually 10 to 15 centimeters, and it is about as thick as a pencil. In order to make a sotiou the bark is removed from a part of the little branch and its end is chewed until it is quite clean, so that one has a kind of brush with very short (about 2 centimeters) but very stiff bristles, with which the teeth are vigorously rubbed from right to left and from above downward. A great number of trees furnish this brush; they chiefly belong to the family of leguminosæ, examples of which are acacias, tamarinds, etc. The use of this preliminary toothbrush has spread throughout Central Africa, even to the western side, and is found in Nigeria, the Congo, etc.

The Malgaches take great care of their teeth, and use a powder made from rice, which is calcined and pounded. The negros of the Antilles also use, for the preservation of their dentition, little branches and roots of certain plants.

This brief review shows how the custom of some still savage or half-civilized nations leads one to think that they all take the greatest care of their teeth, and that the cleanliness of the mouth and teeth appears instinctive among these primitive races. It might be added that it is disquieting that it is not always so among civilized people.

[*New York Medical Journal*, January 11, 1913.]

PYORRHEA ALVEOLARIS AND THE VACCINES. [EDITORIAL.]

The disease to which the symptomatic name of pyorrhea alveolaris has long been given forms the subject of a valuable contribution to the DENTAL COSMOS, in its issues for January and February 1913, from the pen of Dr. Leon S. Medalia. The value of the paper lies in the advice as to treatment of this resistant affection, which the writer prefers to call chronic alveolar osteomyelitis, advice which seems likely for the first time to lead to definite and permanent remedial results. Dr. Medalia has treated 115 cases in all stages with a percentage of cures in the incipient stage of ninety-two per cent., in the moderately advanced stage of ninety-three per cent., in the far advanced stage of forty-three per cent. These results are of particular interest to our readers, not only on account of our repeated emphasis on the importance of the condition as a symptom of certain constitutional dyscrasiæ, but because the curative results were obtained by the use of vaccines, to which we have recently devoted a large amount of space. The coincidence is interesting, in view of the impartial discussion we have presented as to the relative merits of the stock heterogenous vaccines and the clinical autogenous, that the Boston writer uses a mixture of the two.

Local measures formed an important part of this new treatment, but these were along the old lines and have never by themselves producd results at all encouraging; they were carried out by the various dentists who sent the patients to Dr. Medalia, and in many cases sent with them the statement that used alone they would be hopeless. We believe that no more striking testimony of the value of vaccine therapy could be adduced than the encouraging outcome in these cases of a disease which has hitherto resisted absolutely the most painstaking and ingenious oral surgery.

Among the author's conclusions are that the tooth sockets are enlarged medullary spaces, while the so-called peridental membrane is in reality a ligament which holds the tooth suspended in the alveolar cavity; mechanical causes are responsible for starting chronic alveolar osteomyelitis, while the pyogenic bacteria, particularly the pneumococcus in chains, are responsible for keeping it up; again, and this is where our repeated opinion is corroborated, a great many rheumatic diseases, so called, are directly related to the osteomyelitis, and vaccine treatment, together with the proper dietary regimen, cures or relieves the systemic disease as well as the local trouble.

The neglect of this foul and obvious condition has long been a reproach to diagnosticians. Here the dental surgeon's work can take its proper place in relation to the physician's as an inseparable section of general medicine, working toward a result of the highest importance to the health and satisfaction of the victim. The physician will no longer carelessly turn the patient over to the dentist, to the latter's despair, but labor with him to the great comfort of the individual and the protection of the community against one of the most contagious and obstinate of pathological conditions.

[*Oesterreich.-ungarische Vierteljahrsschrift fuer Zahnheilkunde*, Vienna, No. 4, 1912.]

THE ETIOLOGY OF DENTAL CARIES. By Professor Matti Ayrapaa, Helsingfors.

The writer reviews the theories advanced by more recent writers on the etiology of dental caries. His own views regarding this important question can be summed up as follows: The chief etiologic factors in the production of dental caries are—

First: Lack of use, due partly to lack of opportunity, partly to bad habit, indolence, or inability to masticate.

Second: Poor or unsuitable food, which either does not contain the constituents necessary for the development and the life of the teeth, or from which these constituents have been removed, or which has been prepared, viz, softened in such a way that the teeth have no opportunity to carry out their functions.

Third: Defective cleanliness, due either to lack of natural cleansing by mastication and the concomitant liberal flow of saliva, or to lack of artificial cleansing by brushing and rinsing. It must not be overlooked, in this connection, however, that artificial cleansing is of little efficiency if compared with nature's own cleansing process.

Fourth: The abuse of stimulants, such as alcohol, absinthe, opium, etc., exert a degenerating influence on the human organism and possibly upon future generations.

In the matter of prophylaxis the chief stress is to be laid upon vigorous mastication, which is nature's most efficient means of preserving the integrity of the teeth. This must be constantly reiterated in our communities of hyper-refinement, and subsisting on a dietary deficient in mineral salts.

[*New York State Journal of Medicine*, November 1912.]

AN ELABORATION OF A PREVIOUSLY REPORTED DEATH WHILE USING NITROUS OXID AND OXYGEN AS AN ANESTHETIC. By P. J. Flagg, M.D., Yonkers.

In a paper read before the Westchester County Medical Society, January 16, 1912, and published in the *New York State Journal of Medicine* for April, a series of one hundred cases of nitrous oxid-oxygen anesthesia were reported. Case No. 77 is reported to have died. Space did not permit of a detailed report of this case, but as deaths on the table while using nitrous oxid and oxygen as an anesthetic are of importance and interest at the present time, this report perhaps deserves more than a passing notice.

It is an open question as to whether or not this death occurred as the result of the use of nitrous oxid-oxygen ether as an anesthetic. The reader may judge for himself from the following facts:

Patient, a large, fleshy colored woman, aged twenty-five. She had been bleeding almost continuously for a period of four or five months. Two years ago her right tube and ovary were removed. Before the operation a tentative diagnosis of uterine fibroid was made. The enlargement upon the body of the uterus which gave rise to this diagnosis proved later to be occasioned by adhesions about the proximal end of the tube, which had been tied off by a heavy silk ligature. No fibroid of the uterus or appendages could be found.

The patient was reported to have had an attack of syncope shortly before the operation. About twenty minutes before being anesthetized she received ¼ gr. morphin and 1-150 gr. atropin hypodermically. When she entered the operating room she was in a very nervous frame of mind. The examination of her heart had been negative. The apex beat, however, was heaving and forceful. Anesthesia was induced at 4 P.M. The patient went under quietly. As there was evidence of shallowness in her anesthetic state ether was given to the extent of about one dram. Shortly after this the respirations were obstructed by masseteric spasm. The cervix was dilated and the uterus curetted. The respirations then were irregular and obstructed. The operator made the remark that the blood looked dark (the black skin made it difficult to properly judge the normal color). The ether and gas were stopped and a large proportion of oxygen was given. The patient was replaced in the dorsal position and the breathing immediately improved. When the abdominal incision was made the tissues looked extremely anemic. Moderate muscular relaxation was present. The pulse was of good quality but variable, rapidity about 120. The corneal reflex was active and the pupils were contracted. During the course of the operation (which occupied 1.17 hr. from the induction to the cessation of the respiration), the breathing was irregular, slowing to from three to four a minute and then increasing in rapidity. While the abdominal work was being done it was thought that this condition was due to pulling on the viscera, there being an absence of signs of deep anesthesia. Toward the end of the operation the cheeks and forehead became cold, as though the patient were suffering from shock. This condition was not warranted by the nature of the operation or the loss of blood. The mask was removed several times from the face, and the patient rapidly came out. When the mask was replaced a large proportion of oxygen was given. Several times the corneal reflex was lost, only to reappear again almost immediately. The breathing improved as the operation was concluded. When the patient was raised from the Trendelenburg it improved markedly. At this time the operator said: "She is pretty rigid." As the patient had been behaving badly no ether was given her, but oxygen instead, in the hope that the rigidity was of an asphyxial nature. While the old scar in the skin was being cut out the patient showed the effects of peripheral stimulation by breathing more deeply and more rapidly. The corneal reflex was active and the pupils were contracted. Suddenly irregular breathing, simulating that which had frequently occurred during the operation, again made its appearance. The patient made a low crowing sound as though about to come out. This was followed by slow, deep respirations. The respirations ceased. As this had occurred several times before, it was not in itself particularly disturbing. The pulse could no longer be felt, however, the pupils dilated suddenly and the corneal reflex completely disappeared. In the presence of these signs artificial respiration was immediately begun, accompanied by every possible form of stimulation. The attempted resuscitation was entirely unsuccessful.

The following facts were noted:

The slow pulse of asphyxial rebreathing did not occur.

Patient was in a light anesthetic state when she died.

She showed evidence of shock some twenty minutes before.

The color was difficult to make out, but seemed satisfactory.

There was masseteric spasm with ether. This did not appear to seriously hamper the respirations, but it showed a tendency to persist even when air and oxygen was given in abundance.

The rigidity appeared to be due to shallow anesthesia, not to asphyxia.

Death is thought to have been due to cardiac failure, the remote cause being previous protracted hemorrhages, the immediate cause being the strain thrown upon the vasomotor system by respiratory obstruction incident to a badly accepted anesthetic.

MERCURY CONTAINED IN THE AIR SURROUNDING MEDICAL MEN AND DENTISTS, AND ITS DANGER. By Dr. Arvid Blomquist, Stockholm.

Blomquist has found that in the Physiologic Institute of Stockholm every 4000 liters of air contained from 0.1 to 0.3 mg., in the laboratories from 0.5 to 1.0 mg., and in the Medico-chemical Institute from 0.3 to 0.4 mg. of mercury. Specimens of the dust collected in the last institution yielded 0.07 per cent. of mercury. The urine of persons employed in these institutes also contained mercury, the quantity of the metal resorbed per person in a day of eight working hours amounting to from 0.4 to 1.0 mg., which observation clearly shows the great danger of intoxication. As early as 1909, in persons connected for some length of time with the same institutes, Goethlein had observed symptoms of intoxication, 80 per cent. of these cases exhibiting great fatigue, 65 per cent. stomatitis, 50 per cent. lack of appetite, and 45 per cent. affections of the stomach and intestines. In other institutes and hospitals similar phenomena were observed.

Dentists, of course, are especially exposed to the risk of chronic mercurial infection, particularly if, for the sake of convenience, the excess of mercury is squeezed out in the palm of the hand or between the fingers—which practice cannot be too severely condemned from practically every point of view. Blomquist found that the urine of one dentist contained no less than from 3.0 to 4.0 mg. of mercury per liter of urine. These observations clearly show the necessity of great care in the manipulation of mercury by dental practitioners.

Periscope.

Avoiding Air-spaces in Pouring Impressions.—To prevent air-spaces in pouring impressions, a medium-sized, rather coarse paint-brush should be used, and the plaster painted on the impression, as in inlay work. After use, the brush is immediately immersed in water and a few shakes will leave it ready for the next use.—W. I. Prime, *Dental Digest.*

Cleaning Rubber Files.—Files used in the laboratory for finishing vulcanite work soon become clogged by the rubber wedging in the depressions between the teeth. Pouring chloroform over the file causes this rubber to curl up and loosen, so that it can be readily removed by any kind of a brush, thereby making the file cut like a new one.—Dr. W. H. Craft, *Dental Brief.*

Easy Method of Repairing Defects in Gold Crowns and Bridge Work.—Mercury and filling gold are mixed in the same way as amalgam. The mixture is packed over the hole in the crown or the defect in bridge work to be repaired. With soldering pliers the crown is held high over the gas flame so as to heat very slowly. As the mass reaches 350 C. the mercury volatilizes, leaving the pure gold covering the hole or filling the defect. This gold is burnished to a smooth surface, and the operation is complete.—C. O. Dobson, *Dental Summary.*

Method of Strengthening Partial Plates.—We often have trouble from the breaking of partial plates. Leaving the outer rim off weakens the piece, and wires and bars recommended by supply houses for this purpose are usually of very little use, for the reason that rubber does not adhere to the metal. Victoria metal seems to fill a long-felt want for this work, and strengthens the denture very much, because the rubber passing through holes countersunk on the lingual side forms rivets, thereby adding great strength to the denture and allowing it to be made of a minimum thickness.—L. G. Beerbower, *Dental Summary.*

Replacing a Broken Facing on a Bridge.—The old pins left in the bridge are burred out, and a new facing is fitted. A piece of gold tubing is made with the hole small enough so that, when sprung over the pins in the new facing, the seam in the tube will open enough to admit a minute piece of solder. The pins are cut off on the new facing, leaving just enough to hold the tubes upright. A small ball of asbestos fiber is wet, and the facing is pressed into it. The asbestos is thoroughly dried, and the tubes are soldered to the facing. The facing is refitted to the bridge, reaming out holes of the desired size, and cutting off the tubes so that they extend just through the backing. Then holes are countersunk on the lingual side of the bridge. The facing is cemented into place, and the tubes are spread on the lingual side and burnished.—C. M. Roberts, *Dental Digest.*

Replacing a Lateral by Bridge Work.—The palatal side of the canine is trimmed just sufficiently to level the surface, and a slight space is left between it and the occluding teeth. Three holes, No. 20 gage, are then drilled directly in the line of the root. The holes at the approximal sides are to occupy that section of the tooth structure—such as is generally included in cases of approximal caries—which does not expose the pulp. At the cervical palatal section, the hole can be only a shallow one. The angle at which these pins are placed in the tooth structure should be such that the line of pressure in use will prevent their displacement. A little plate of platinum, 38 gage, is swaged and fitted, and the pins are then soldered in position with pure gold. The plate is again fitted, the edges are trimmed to the proper size and shape, and a little more pure gold is flowed over the entire surface. Next the plate is again fitted, the porcelain tooth properly adjusted, removed with the plate and connected with solder, some of which is flowed over the plate to additionally strengthen it. A spur may be allowed to rest on the central.—G. Evans, *Items of Interest.*

Repairing a Gold Filling.—Difficulty is usually experienced in attempting to repair a gold filling when retention of the added portion depends upon welding it to the old filling. Carefully washing the surface with alcohol, chloroform, or other cleansing agent and roughening it, will at times prove effective, especially if the surface is large. Where this fails, annealing the surface by means of a tiny alcohol flame—when it can be done—usually insures a reliable union between the old and the new layer of gold. A pellet of cotton wrapped on the end of an instrument, dipped in alcohol and ignited, will furnish sufficient heat. Where they can be made without weakening the old filling, carefully placed and properly shaped retaining pits or grooves are always desirable, and form by far the most reliable bond between the old and the new gold. The difficulty is not entirely due to deposits upon the surface of the old filling or infiltration through its mass of some constituent of the oral fluids. A well-consolidated gold filling that has become wet with oral secretions is not receptive to additions depending upon welding. While the gold can be built upon it and be sufficiently well retained to withstand shaping and polishing, the more severe test of actual use, in spite of all precautions, may cause a separation later. Repaired fillings may last for years, nevertheless they are always objects of suspicion, and every precaution possible should be taken to make the bond of union secure.—W. H. Trueman, *Dental Brief.*

Post-Operative Treatment Following the Extraction of Teeth.—The after-treatment of extraction is purely surgical. Any laceration of the soft parts should be trimmed smooth, and any areas which might slough should be cut away. All loose particles of process should be cleared away, and any exposed bone should be cut away with the bone-forceps, and a gauze dressing applied if indicated. A dressing will be indicated if the operation has been at all severe, that is, if the parts have been so disturbed that healing by first intention would not be likely. When a dressing is used from the first, we seem less likely to encounter the sluggish condition known as dry socket, which is only a step removed from necrosis. When dry socket exists, the packing should of course be maintained with irrigation at regular intervals, and stimulating medicaments, either silver nitrate or aromatic sulfuric acid, should be applied occasionally.

The treatment of abscessed teeth after extraction is a point which deserves special attention. The tooth socket should be thoroughly irrigated with a non-irritating solution, after having used a curet and scraped the abscess cavity in order to remove any pyogenic membrane or débris which might remain after the extraction. The socket having been thus cleansed, it should be lightly packed with 5 per cent. iodoform gauze, and the dressing renewed and the socket irrigated with an antiseptic solution in from twenty-four to forty-eight hours, and as often thereafter as may be necessary, according to the severity of the infection from the abscess.—J. F. Hasbrouck, *Items of Interest.*

Excision of Diseased Roots and Molars.—Sometimes it is advisable to save part of a molar, rather than lose the whole tooth. This can be accomplished by excising the diseased root. The crown of the tooth will, of course, have to be trimmed accordingly, or reshaped by means of a crown or inlay. In cases of lower molars, the crown can be cut in halves, thus making a bicuspid of the remaining part of the tooth, and the excised portion can be replaced by means of a bridge.

The conditions that call for a complete excision of a root are—

(1) When one root has become completely denuded of its pericemental attachment, caused by (*a*) pyorrhea on the lingual root or one of the buccal roots of an upper molar, or on one of the roots of a lower molar; (*b*) chronic alveolar abscess of one of the above-mentioned roots; (*c*) interproximal abscess; (*d*) abscess from adjoining tooth.

(2) When there is a chronic alveolar abscess, with a sinus from one root which will not yield to treatment, and when it is not wise to amputate the end of such a root.

(3) When one root-canal has been accidentally perforated and it is impossible to close the perforation.

(4) When one root has already been cut off through extensive caries, which occurs sometimes under an ill-fitting crown.

(5) When from some cause or other an abscess is located between the roots of a molar, and it is impossible to cure it.

In such cases the technique and treatment will of course be according to the operator's judgment as regulated by his experience.—A. W. Ellis, *Dominion Dental Journal.*

A Method of Overcoming Shrinkage in Cast Inlays.—The cavity for the reception of the inlay is prepared in the usual manner. An impression of the cavity is taken by the use of a small tray of German silver bent to conform to the tooth, and modeling compound softened with dry heat as an impression material. Before removing the impression, a blunt instrument is forced between the tray and the adjoining tooth to insure an accurate impression of the gingival margin. Before being dismissed, the patient is requested to bite into a cone of inlay wax; this furnishes a guide to the occlusion and contour of the finished inlay.

The impression of the cavity is invested in a cone of soft plaster, or in plaster held by the rubber ring of the Melotte outfit, deeply enough to give the model strength and to make it of convenient size to work with.

Amalgam is packed carefully into all parts of the impression, to insure a model with good sharp margins. The wax inlay is then placed in the amalgam model, and the carving completed. The inlay, after casting, is again carried to the model for the final burnishing of the margins to the model. The inlay is polished with stones and disks, always polishing toward margins.

The inlay is then ready to be cemented, very little work for the fitting being required, and polishing after cementation being avoided. Working on models provides a margin to burnish and spin the gold against, thus overcoming the little inequalities caused by the shrinkage in casting. In the event of a failure in casting, another inlay can be made.

This impression method is particularly useful in inaccessible cavities for both gold and porcelain. A Chase forceps, which will hold an ordinary copper rivet carrying softened modeling compound, is used in labial cavities, enabling the operator to secure a very accurate impression. The amalgam model is made, a matrix swaged, and the inlay baked. By this method the rocking movement so frequently noticed in these difficult and tedious cavities is overcome.—W. H. Scherer, *Dental Brief.*

Hints, Queries, and Comments.

WARMING ALCOHOL FOR APPLICATION ON COTTON.

To the Editor of the Dental Cosmos:

Sir,—In "Hints, Queries, and Comments" for April, is not the elaborate method of warming alcohol so as to apply on a pellet of cotton to a cavity, a waste of time, and entirely unnecessary? A very simple and time-saving method would be to dip the pellet in alcohol, then touch it to the flame of the lamp and immediately blow out the flame on the pellet; the alcohol and pellet are then as warm as desired. Time consumed, less than one second.

Geo. A. Maxfield, D.D.S.

Holyoke, Mass.

To the Editor of the Dental Cosmos:

Sir,—In the April Cosmos, Dr. Fischler, alluding to the pain provoked by applying cold alcohol to a cavity, suggests a method of warming it by putting a few drops of alcohol into a heated metal receptacle—an aluminum thimble. For many years I have adopted a much simpler plan, though whether the hint was given me by someone else or not, I cannot remember.

A pledget of wool is dipped into absolute alcohol and passed rapidly through a flame, where it ignites. It is carried quickly toward the patient's mouth, and during the passage I blow it out. The alcohol is burning for perhaps one second, and is heated sufficiently to make its application unnoticeable to the patient. One or two trials will teach the operator exactly the length of time that the alcohol should be alight. This plan, besides being an enormous saving in time and trouble over that suggested by Dr. Fischler, has the still greater advantage of insuring that the alcohol always has the proper temperature, which I do not think will be the case in his method.

Obituary.

DR. THOMAS W. CLEMENTS.

Died, at his home, Brookline, Mass., on Sunday, April 13, 1913, Dr. Thomas W. Clements.

The dental profession, as well as humanity at large, has sustained an irreparable loss by the death of Thomas W. Clements, D.M.D., which occurred at his home, in Brookline, Mass., on April 13, 1913.

Dr. Clements was born in Weymouth, N. S., and as a child moved with his parents to Calais, Me., where he lived until the outbreak of the civil war. He enlisted in company K, 12th Maine Infantry, and was later commissioned as first lieutenant. He served under Butler in New Orleans, being at one time officer in charge of the mint. He served the government during the whole period of the war, and, after being honorably discharged, took up the study of dentistry.

In 1872, the deceased was appointed professor of operative dentistry in the Boston Dental College. In 1891 he was elected a member of the Executive Board of the American Academy of Dental Science, and was afterward president of its alumni association for three years. He was also for many years librarian of the Massachusetts Dental Society.

Dr. Clements was a member of Beth-Horan Lodge, F. and A. M., being its Worshipful Master for two years; also Past Commander of C. L. Chandler Post, G. A. R.

In every relationship of life the deceased proved himself a model citizen, and he was greatly loved by all who knew him.

"His was a gentle life,
And the elements so mixed in him
That Nature might stand up
And say to all the world: This was a man."

"IN MEMORIAM" RESOLUTIONS.

Dr. Wm. P. Richards.

The following resolutions were passed by the Central Dental Association of Northern New Jersey on the death of Dr. William Price Richards:

Whereas, Dr. William Price Richards, an honored member of this society, has been removed from us by Divine Providence, it is fitting that we should, at this time, make record of the event, and of the great loss thereby sustained; therefore be it

Resolved, That by his genial disposition, estimable character, and love for his chosen profession, he has endeared himself to his associates and won their lasting esteem and affection by his untiring efforts in their behalf and for the advancement of dentistry; as a true friend and earnest worker he will never again take part in our proceedings; never again will the warm grasp of his friendly hand be felt; no more will his cheery words be heard, nor will his smile help to brighten our meetings; and be it

Resolved, That our sympathies and condolence be extended to his family in their bereavement; while such a loss is irreparable, we cannot but be grateful to the Giver of all good that our friend was permitted to live such a long and useful life, by which we have all profited; and be it further

Resolved, That these resolutions be incorporated in the minutes of our society, and that a copy be transmitted to the family of the deceased, and also to the dental journals.

W. F. Barry,
H. S. Sutphen,
G. W. Wakeley,
N. M. Chitterling,
Ralph Waldron,
Committee.

Dental Legislation.

DENTAL LAW OF THE STATE OF ARIZONA.

AN ACT

To Regulate the Practice of Dentistry, and to Provide for the Issuance and Revocation of Licenses Therefor.

Be it enacted by the Legislature of the State of Arizona:

Section 1. Any person shall be deemed to be practicing dentistry who for a fee, salary, or reward, paid directly or indirectly to himself or to some other person, shall attempt to or shall perform an operation of any kind upon, or treat diseases or lesions of, or correct malpositions of, the human teeth or jaws.

Nothing herein contained shall prevent any person duly licensed to practice medicine or surgery in the State of Arizona from extracting teeth in the practice of oral surgery or the treatment of diseases of the mouth.

Sec. 2. It shall be unlawful for any person who is not duly licensed to practice dentistry in the State of Arizona to practice dentistry in the state, or by the display of a sign or in any other manner advertise himself as being engaged in the practice of dentistry in the state.

Any person who shall violate any of the provisions of this section shall be guilty of a misdemeanor, and upon conviction thereof shall be punished by a fine of not less than one hundred dollars nor more than three hundred dollars, or by imprisonment in the county jail for not less than three months, nor more than six months, or by both such fine and imprisonment.

It shall be the duty of the county attorney of each county of this state to prosecute any violations of this section in the courts of their respective counties in which such violations occur.

In any prosecution under this section a certificate under the hand and seal of the Secretary of State stating that he has examined the list of licensed dentists on file in his office, and that the name of the defendant does not appear thereon, shall be competent evidence and *prima facie* evidence that the defendant is not and was not at the time of the commission of the alleged offense a licensed dentist.

Sec. 3. Only the following persons shall be deemed licensed to practice dentistry in the State of Arizona:

(*a*) Persons duly licensed and entitled to practice dentistry in the State of Arizona at the time of the taking effect of this act;

(*b*) Persons duly licensed to practice dentistry in the state after the passage of this act.

Sec. 4. A Board of Dental Examiners, to consist of five duly licensed, resident, practicing dentists, is hereby created, whose duty it shall be to examine all applicants for license to practice dentistry in the State of Arizona, and to recommend the licensing of all such applicants as in their judgment are qualified to practice dentistry in the state.

It shall be the duty of the board to adopt such rules and regulations for the conduct of such examinations as in its judgment may seem proper; to report to the proper officers all violations of the law whenever the same shall come to its knowledge; to keep a true and correct list of all the duly licensed dentists practicing in this state, with the address of each; to recommend the revocation of any license whenever, in its judgment, there appears to be sufficient cause therefor, and to furnish such evidence as it may have in its possession to substantiate such recommendation; and to perform such other duties as may be imposed by law.

Sec. 5. The members of this board shall be appointed by the Governor of the state for a term of five years; provided, however, that the members of the first board, if otherwise qualified as herein provided, shall be the present Board of Dental Examiners, whose terms shall be so made and arranged by the Governor that one term shall expire January 1, 1914; one January 1, 1915; one January 1, 1916; one January 1, 1917, and one January 1, 1918. All vacancies occurring in said board shall be filled by appointment by the Governor.

No person shall be eligible to serve on said board unless he be a qualified elector of Arizona, and has been duly licensed to practice dentistry in Arizona for five years next preceding his appointment, and of good moral character; and the recommendation of the Arizona Dental Society shall be taken and considered by the Governor as *prima facie* evidence of such eligibility in making appointments to said board.

SEC. 6. It shall be the duty of said board to organize by the election of one of its members as president, and one as secretary; to adopt a seal which shall be the official seal of the board; to meet at least once, but not more than twice, in each year, at such time and place in this state as the board may designate, for the purpose of examining applicants and transacting such business of the board as may be required. Written notice of the time and place and object of such meeting shall be mailed by the secretary of said board to all members thereof, and to all persons whose application for examination shall be on file with the Secretary of State, as provided in Section 8, at least fifteen days before the time of meeting.

Three members of said board shall constitute a quorum for the transaction of the business of said board, and for the purpose of examining applicants for license to practice dentistry in the state.

The secretary of the Board of Dental Examiners shall keep a record book, into which he shall transcribe and keep a true record of all proceedings of the board.

It shall be the duty of the Board of Dental Examiners at its first meeting to ascertain and determine the names of all persons who are duly licensed and entitled to practice dentistry under the provisions of this act, and to file with the Secretary of State a true and correct list thereof.

The Secretary of State shall keep a record book, into which he shall transcribe and keep a true list of dentists licensed to practice in this state, and necessary records of all proceedings relating to revocation of licenses.

SEC. 7. The Governor shall have the power to remove from office any member of said Board of Dental Examiners, at any time, for the continued neglect of duty, or for incompetency, or for dishonorable conduct.

SEC. 8. Any person who shall desire to begin the practice of dentistry in the State of Arizona, after the passage of this act, shall file a sworn statement of his qualifications and shall make application to the Secretary of State for an examination by the Board of Dental Examiners, on a blank furnished by the Secretary of State, and shall pay the Secretary of State an examination fee of twenty-five dollars, which examination fee shall in no event be refunded if the applicant is eligible for examination; provided, that any applicant failing to qualify for license upon his first examination shall be entitled to one additional examination by the said Board of Dental Examiners at any subsequent meeting thereof, without charge.

SEC. 9. No person shall be eligible for examination by the Board of Dental Examiners who shall not—(1) Have been duly licensed to practice dentistry elsewhere in the United States; or (2) have a diploma from some reputable dental college, or dental department of a university.

SEC. 10. Examinations by the Board of Dental Examiners shall be of two kinds, viz—(1) theoretical, and (2) practical. The theoretical examination shall be written in the English language and consist of questions and answers upon such subjects as are included in the curriculum of reputable dental colleges; provided, that the board may conduct additional examination, orally, on such subjects, and no member thereof shall be prevented from examining any applicant on all such subjects. The practical examination shall consist of demonstrations in skill in operative and mechanical dentistry.

In grading all examinations the theoretical examination and the practical work shall be graded at fifty per cent. each; provided, that the board may allow applicants who have been engaged in the practice of dentistry for five years, sixty-six and two-thirds per cent. for their practical work, and thirty-three and one-third per cent. for their theoretical examination.

It shall be the duty of the Secretary of State, upon presentation to him of a certificate by the Board of Dental Examiners, certifying under the seal of the board that the person named therein is possessed of the necessary qualifications and is entitled to practice dentistry in the state, to indorse thereon under the seal of the State of Arizona, a license to practice dentistry in the state.

SEC. 11. Whenever it shall appear to the Secretary of State that any licensed dentist practicing in the State of Arizona has been guilty of fraud, deceit, or misrepresentation in obtaining a license; or of gross immorality, habitual use of intoxicants or drugs, rendering him unfit for the practice of dentistry; or of malpractice, gross ignorance, incompetency, or wilful negligence in the practice of dentistry; or of employing unlicensed persons to perform work which, under this act, can only be legally done by persons holding a license to practice dentistry in this state; or of committing any crime involving moral turpitude, either before or after conviction in court; or of practicing deceit or other fraud upon the public or individual patient, in obtaining or attempting to obtain practice; or of false advertisement, publication, or circulation of exaggerated claims, or fraudulent, or misleading statements of his art, skill, or knowledge, or of his methods of treatment or practice, he shall revoke the license of such person.

Sec. 12. An accusation may be filed with the Secretary of State charging any licensed dentist with the commission of any of the offenses enumerated in the preceding section.

Such accusation shall be in writing, signed by the accuser and verified under his oath, and corroborated by at least two reputable citizens of the state, likewise under oath, who are familiar with the facts.

Whenever such accusation is filed the Secretary of State shall set a day for hearing, and shall transmit to the accused a true copy of all papers filed with him relating to such accusation, and shall notify the accused that on the day fixed for hearing he may appear and show cause, if any, why his license to practice dentistry in the State of Arizona should not be revoked. And for the purpose of such hearing the Secretary of State is hereby empowered to require the attendance of witnesses, administer oaths and hear testimony, either oral or documentary, for or against the accused. And if, after such hearing of the accused, the Secretary of State shall be satisfied that the accused has been guilty of the offense charged in the accusation, he shall thereupon without further notice revoke the license of the person so accused.

Sec. 13. The Governor, the Superintendent of Public Instruction, and the State Auditor shall be and they are hereby constituted a board of review, with power and authority to review any and all actions of the Secretary of State in revoking or refusing to revoke any such license; and the determination of the said board of review upon any and all matter submitted to it shall be final.

Any person who may feel himself aggrieved at the revocation of his license may have the action of the Secretary of State in revoking the same reviewed by the board of review in the following manner: The person seeking such review shall file with the Secretary of State his affidavit, verified in the manner required by law, setting forth the fact of the revocation of his license, and that there has been a miscarriage of justice or error committed by the Secretary of State, or that the decision of the Secretary of State was contrary to law, or was not supported by the evidence adduced at the hearing.

In the same manner the Board of Dental Examiners may have the action of the Secretary of State in refusing to revoke the license reviewed by the board of review.

When such affidavit has been filed with the Secretary of State it shall be his duty within ten days thereafter to transmit the same, together with all the papers, records, and documents pertaining to the case, to the Governor, who shall at such reasonable time as he may determine, and upon proper notice to all parties interested, convene the board of review at such place as he may determine.

Sec. 14. All expenses incurred by the Board of Dental Examiners for rents, lights, supplies, and other necessary disbursements in holding the meetings of said board shall be paid in the same manner as the compensation of the members of said board. Upon the presentation of an itemized statement of such expenses, verified by the secretary of said board, to the State Auditor, he shall draw his warrant on the State Treasurer, payable to said secretary of said board, for the amount specified in such statement.

Sec. 15. The compensation of the members of the Board of Dental Examiners shall be ten dollars *per diem* each, while actually engaged in the business of said board, and necessary traveling and hotel expenses incurred by them in the discharge of their duties. Upon a verified statement of the State Auditor of the amount due each member of this board, the State Auditor is hereby authorized and directed to draw his warrant on the State Treasurer for such amounts, and the State Treasurer is hereby authorized and directed to pay the same.

Sec. 16. All duly licensed dentists shall be exempt from jury duty in any of the courts of this state.

Sec. 17. All acts and parts of acts in conflict with the provisions of this act are hereby repealed.

Society Notes and Announcements.

DENTAL SOCIETY MEETINGS:

June and July.

JUNE.

ALABAMA DENTAL ASSOCIATION. Birmingham. Three days: June 10th to 12th.

AMERICAN MEDICAL ASSOCIATION—STOMATOLOGY. Minneapolis. June 17th to 20th.

AMERICAN SOCIETY OF ORTHODONTISTS. Chicago, Ill. Three days: June 30th to July 2d.

CALIFORNIA STATE DENTAL ASSOCIATION. Oakland. Four days: June 2d to 5th.

COLORADO STATE DENTAL ASSOCIATION. Manitou. Three days: June 19th to 21st.

DISTRICT OF COLUMBIA DENTAL SOCIETY AND MARYLAND STATE DENTAL ASSOCIATION. Washington, D. C. June 12th to 14th.

FLORIDA STATE DENTAL SOCIETY. Atlantic Beach. Four days: June 24th to 27th.

GEORGIA STATE DENTAL SOCIETY. Columbus. Three days: June 12th to 14th.

MAINE DENTAL SOCIETY. Portland Harbor. Three days: June 25th to 27th.

MARYLAND STATE DENTAL ASSOCIATION AND DISTRICT OF COLUMBIA DENTAL SOCIETY. Washington, D. C. June 12th to 14th.

MINNESOTA DENTAL ASSOCIATION. Minneapolis. Two days: June 13th and 14th.

MISSISSIPPI DENTAL ASSOCIATION. Meridian. Three days: June 24th to 26th.

MONTANA STATE DENTAL SOCIETY. Butte. Two days: June 13th and 14th.

NEW HAMPSHIRE STATE DENTAL SOCIETY. Weirs. Three days: June 18th to 20th.

NORTHERN OHIO DENTAL ASSOCIATION. Cleveland. Three days: June 5th to 7th.

PENNSYLVANIA STATE DENTAL SOCIETY. Philadelphia. Three days: June 24th to 26th.

SOUTH CAROLINA STATE DENTAL ASSOCIATION. Isle of Palms. June 25th to 27th.

SOUTHERN WISCONSIN DENTAL ASSOCIATION. Delavan Lake. June 13th and 14th.

TENNESSEE STATE DENTAL ASSOCIATION. Nashville. Three days: June 5th to 7th.

WASHINGTON STATE DENTAL SOCIETY. Seattle. Three days: June 16th to 18th.

JULY.

DELTA SIGMA DELTA FRATERNITY. Kansas City, Mo. [During N. D. A. meeting.]

NATIONAL ASSOCIATION OF DENTAL EXAMINERS. Kansas City, Mo. July 7th.

NATIONAL ASSOCIATION OF DENTAL FACULTIES. Kansas City, Mo. July 4th.

NATIONAL DENTAL ASSOCIATION. Kansas City, Mo. Four days: July 8th to 11th.

NATIONAL DENTAL ASSOCIATION—SOUTHERN BRANCH, AND VIRGINIA STATE DENTAL SOCIETY. Old Point Comfort, Va. Four days: July 22d to 25th.

NEW JERSEY STATE DENTAL SOCIETY. Asbury Park. Three days: July 16th to 18th.

XI PSI PHI FRATERNITY. Kansas City, Mo. [During N. D. A. meeting.]

VIRGINIA STATE DENTAL SOCIETY AND NATIONAL DENTAL ASSOCIATION, SOUTHERN BRANCH. Old Point Comfort, Va. Three days: July 22d to 24th.

Examiners' Meetings.

ALABAMA BOARD OF EXAMINERS. Birmingham. June 5th.

CALIFORNIA BOARD OF EXAMINERS. San Francisco, June 7th; also Los Angeles, June 20th.

CONNECTICUT DENTAL COMMISSIONERS. Hartford. June 12th to 14th.

FLORIDA BOARD OF EXAMINERS. Tampa. June 21st to 24th.

IDAHO BOARD OF EXAMINERS. Boise. July 17th.

ILLINOIS BOARD OF EXAMINERS. Chicago. June 4th.

INDIANA BOARD OF EXAMINERS. Indianapolis. June 9th to 14th.

IOWA BOARD OF EXAMINERS. Iowa City. June 2d.

MASSACHUSETTS BOARD OF REGISTRATION. Boston. June 4th to 6th.

MICHIGAN BOARD OF EXAMINERS. Ann Arbor. June 16th to 21st.

MISSISSIPPI BOARD OF EXAMINERS. Jackson. June 17th.

MONTANA BOARD OF EXAMINERS. Helena. July 14th to 17th.

NEBRASKA BOARD OF EXAMINERS. Lincoln. June 16th to 18th.

NEW JERSEY BOARD OF REGISTRATION. Trenton. June 30th to July 2d.

NORTH DAKOTA BOARD OF EXAMINERS. Fargo. July 8th to 11th.

PENNSYLVANIA BOARD OF EXAMINERS. Philadelphia and Pittsburgh. June 11th to 14th.

RHODE ISLAND BOARD OF REGISTRATION. Providence. June 24th to 26th.

SOUTH CAROLINA BOARD OF EXAMINERS. Isle of Palms. June 20th.

TEXAS BOARD OF EXAMINERS. Houston. June 23d.

VERMONT BOARD OF EXAMINERS. Montpelier. June 30th to July 3d.

VIRGINIA BOARD OF EXAMINERS. Richmond. June 10th.

WISCONSIN BOARD OF EXAMINERS. Milwaukee. June 16th.

WYOMING BOARD OF EXAMINERS. Cheyenne. July 1st to 3d.

GOLDEN JUBILEE OF PHILADELPHIA DENTAL COLLEGE.

THE assertion in the circular letter of invitation sent out for the above celebration that "as fifty years of uninterrupted business activity was a notable achievement in the life of an individual, even more important was the continued prosperity of an educational institution during a similar period," was verified by the interest shown on the part of alumni who came from far and near to participate in the exercises of the semi-centennial of the above institution.

Invitations were sent to all of the three thousand and more graduates whose names and addresses on the college register could be verified, and while several hundreds were present in person, others who could not attend sent greetings and well-wishes by letter, telegram, and cablegram. Responses were received from half the states in the Union and a score of foreign countries, signed in some cases by groups of alumni in certain sections and in others by officers representing dental associations. The interest shown was highly appreciated by those at present responsible for the well-being of the institution, and indicated in an unmistakable manner the loyalty of those who had secured their professional training within its walls.

The Philadelphia Dental College was organized and began its first term in the fall of 1863, graduating its first class of six members in the spring of 1864. Dr. John H. McQuillen of Philadelphia was the originator and dominant spirit of the new institution, which was the fourth then in existence in the United States. Its first faculty consisted of Drs. McQuillen, Kingsbury, Flagg, Wardell, and Morton, all able and influential men, the last of whom, Professor Flagg, died some fifteen years ago. Of the first class graduated, one is still living; of the second class two survive, one of whom, Dr. Jas. McManus, was present and took an active part in the exercises.

Two days were set apart for the celebration. April 15th was devoted to a general reception, reunions of various classes, inspection of the teaching facilities of the institution, and a surgical clinic; followed in the evening by a theater party tendered to the visiting alumni. On the following day the commemorative exercises were held in the college ampitheater in the morning, and after luncheon a purely dental clinic, occupying more than thirty operating chairs and tables, occupied the afternoon. The evening was devoted to a banquet, which was largely attended and at which different classes occupied separate tables.

The morning and evening events of this second day were the most interesting from an historical and social point of view.

Dr. Conwell, president of Temple University and by consequence the head of the Dental College, which since 1906 has been a department of the said university, opened the morning exercises with an address entitled "Our Affiliation with Temple University, and What it Means for Us."

Dr. Jas. McManus (class of '65), Hartford, Conn., followed with a paper on "The Genesis of the P. D. C. and Its First Faculty" in which, as one of the oldest living graduates he gave his impressions of the men who founded the school and established the first course of instruction in the institution, and paid a high tribute to their ability and zeal.

Dr. Chas. S. Butler ('76), Buffalo, N. Y., had as his subject "Some of the Men whose

Character and Teaching have Made the P. D. C. Famous." The address was illustrated with the lantern, and slides were shown of Drs. McQuillen, Kingsbury, Flagg, Garretson, Stellwagen, Burchard, Dorr, and many others—the special qualifications and accomplishments of each being dwelt upon as the pictures appeared.

Dr. M. H. Cryer ('76), Philadelphia, followed with an address upon "How the Hospital of Oral Surgery Came into Being." Dr. Cryer's intimate association with Professor Garretson in establishing the first Hospital of Oral Surgery enabled him to give a very interesting account of the crude beginnings of the infant hospital and its beneficent work up to the time of Dr. Garretson's death in 1895.

Dr. H. L. Gilmour ('67), Philadelphia, in his paper on "The Early Struggles and Also the Good Times We Had at Tenth and Arch" was in lighter reminiscent vein and was liberally punctuated with the droll humor which always enlivens his public and private utterances.

Dean Guilford was scheduled for a paper, "A Review of Some Worthy Accomplishments of the P. D. C. in its Half-century of Existence," but as the morning hours had passed the paper was not presented.

After luncheon the large clinic held the attention and interest of the visitors during the entire afternoon.

In the evening, as many as could remain gathered at Kugler's for the Alumni Banquiet, and were feasted and entertained for four or five hours. Dr. Butler of Buffalo presided as toastmaster, and after a welcoming address in his happiest style introduced the speakers.

Dr. Conwell spoke to the toast "The Lessons of Fifty Years." Briefly reviewing the advances in dental practice during a half-century, he dwelt at greater length upon the development of dental education during the same period, speaking with enthusiasm of its present status as compared with that of years gone by. He also took occasion to point out to the older alumni the manner in which the old Philadelphia Dental College had become affiliated with Temple University, and the great advantages to both institutions accruing therefrom. He predicted a great future for the dental department and promised a new building for its sole use in the near future.

Dr. J. W. Moffitt ('72), the next speaker, responding to the toast "How the P. D. C. Obtained Its Charter," told of the difficulties encountered in obtaining a charter from the state legislature in the early days, and how he (then living in Harrisburg, Pa.) had been instrumental in aiding Dr. McQuillen to secure the P. D. C. charter in 1863.

Dr. J. N. Wunderlich ('66) followed with an account of "Fitting-up the First Hospital of Oral Surgery"—in the old building at Tenth and Arch sts., when Dr. Garretson decided that such a hospital was needed in connection with a dental school.

Professor Guilford, in forecasting "The Future of the P. D. C.," first reverted to the eminent teachers he had been privileged to associate and work with in the thirty-two years of his connection with the college, and then after explaining the policies which had guided the institution in the past, told of the plans and provisions which he expected would lead to greater efficiency in dental instruction in the future.

Prof. Inglis ('86), in his reply to the toast "Thirty Years Ago and Now," took occasion to point out in detail some of the advances made in dental instruction since the time when he was a student, and emphasized the advantages enjoyed by the dental student of today.

Other toasts were then offered and responded to by the president of the present Senior class and by the president of the Garretsonian Society.

As a fitting close to the speech-making, and an unusual feature as well, came short addresses by members of the graduating class from foreign countries. Eight countries were represented, and in each instance but one the remarks were made in English, much to the credit of those who could not be expected to be overfamiliar with a language foreign to their own. The evening ended with the singing of college songs and an interchange of greetings between the various classes.

Throughout the entire exercises of the two days' celebration there was manifested a strong feeling of loyalty to the college on the part of the alumni, and a frequently expressed satisfaction with the work being done along the lines of advanced dental education.

S. H. G.

NATIONAL DENTAL ASSOCIATION.

The 1913 Session of the National Dental Association will be held in Kansas City, Mo., July 8 to 11, 1913. The reorganization of the association should make this the most important meeting in its history. Every state society that has met since the new constitution and by-laws were adopted—at the Washington meeting—has voted to become a constituent society, and we can all appreciate the influence of such an organization if all the state societies take similar action.

Program.

The officers and committees have been active in preparing an exceptionally interesting program. At this date the following literary program is tentatively announced:

Dr. Frank O. Hetrick, Ottawa, Kansas: President's Address.

Dr. Adolph Fenchel, Hamburg, Germany: Subject to be announced later.

Dr. Weston A. Price, Cleveland, Ohio: "Scientific Foundation Fund."

Dr. Roscoe A. Day, San Francisco, Cal.: "Orthodontia and Its Relation to Dentistry."

Dr. Marcus L. Ward, Ann Arbor, Mich.: "Metallurgy."

Dr. Richard L. Simpson, Richmond, Va.: "Unbanded *vs.* Banded Crowns."

Dr. Percy R. Howe, Boston, Mass.: "The Saliva."

Dr. Arthur D. Black, Chicago, Ill.: "Something of the Etiology and Early Pathology of Diseases of the Peridental Membrane, with Suggestions as to Treatment."

Dr. Hermann Prinz, St. Louis, Mo.: "A Preliminary Report on Action of As_2O_3."

Dr. Howard R. Raper, Indianapolis, Ind.: "The Value of the Radiograph in the Practice of Modern Dentistry."

Dr. G. S. Junkerman, Cincinnati, Ohio: "Dental Educational Harmony."

Dr. Clarence J. Grieves, Baltimore, Md.: "Periapical Infections."

Dr. Burton Lee Thorpe, St. Louis, Mo.: "Prophylaxis."

Dr. H. B. Tileston, Louisville, Ky.: "Diagnosis and Treatment of Diseases of the Dental Pulp."

The Clinic Committee has been very energetic in preparing their program, and we have every reason to expect that they will present a very strong list of clinicians.

Information regarding transportation from any point may be secured from any local railroad agent, as they have full information with reference to all rates granted by various passenger associations in their particular territory.

All reputable practitioners of dentistry and medicine are cordially invited to attend this meeting.

Hotels.

The Local Committee of Arrangements are providing ample facilities for a large meeting, and have selected the Baltimore Hotel as headquarters. Those desiring to make hotel reservations in advance should address the Baltimore Hotel, or the chairman of the Local Committee of Arrangements, Dr. Charles C. Allen, 507 Rialto Bldg., Kansas City, Mo.

Below is given a list of the principal hotels, with their rates:

S = Single, without bath. *Sb* = Single, with bath.
D = Double, " " *Db* = Double, " "

Hotel Baltimore: *S* $1.50 and $3.00 per day, *Sb* $2.50 and $6.00 per day, *D* $2.50 and $3.00 per day, *Db* $4.00 and $7.00 per day.

Sexton Hotel: *S* $1.00 per day and up. *Sb* $2.00 per day and up.

The Coats House: *S* $1.00 to $2.00 per day, *Sb* $1.50 to $3.50 per day.

Hotel Savoy: *S* $1.00 to $1.50 per day, *Sb* $1.50 to $2.50 per day.

Hotel Victoria: *S* $1.00 and $1.25 per day, *Sb* $1.25 and $1.50 per day, *D* $1.50 and $2.00 per day, *Db* $2.00 and $2.50 per day.

Hotel Kupper: *S* $1.00 and $1.50 per day, *Sb* $1.50 and $2.50 per day, *D* $2.00 and $2.50 per day, *Db* $2.50 and $4.00 per day.

Densmore Hotel: *S* $1.00 per day, *Sb* $1.50 per day, *D* $1.50 per day, *Db* $2.00 to $2.50 per day.

Hotel Edward: Rates $1.00 per day and up.

Hotel White: Rooms—running water, hot and cold, $1.00 per day; shower or tub bath, $1.50 per day; outside rooms, bath with tub, $2.00 per day.

Frank O. Hetrick, *President*,
Ottawa, Kans.
Homer C. Brown, *Recording Sec'y*,
185 East State st., Columbus, Ohio.

[At Kansas City.]

NATIONAL ASSOCIATION OF DENTAL FACULTIES.

The next annual meeting of the National Association of Dental Faculties will take place at the Hotel Baltimore, Kansas City, Mo., beginning at 10 A.M., on Friday, July 4, 1913. The Executive Committee will meet at 9 o'clock on the same morning, at the same place.

B. Holly Smith,
Chairman Exec. Com.

[At Kansas City.]

NATIONAL ASSOCIATION OF DENTAL EXAMINERS.

The thirty-first annual session of the National Association of Dental Examiners will be held at the Baltimore Hotel, Kansas City, Mo., beginning July 7th, at 10 A.M., and continuing until adjournment.

Every state board holding membership in the association is earnestly requested to have at least one representative present at this session. Members of all state boards are invited. Hotel reservations should be made immediately.

John P. Stiff, *President*,
Fredericksburg, Va.,
T. A. Broadbent, *Sec'y*,
15 E. Washington st., Chicago, Ill.

[At Kansas City.]

DELTA SIGMA DELTA FRATERNITY.

The twenty-ninth annual meeting of the Supreme Chapter of Delta Sigma Delta Fraternity will be held at the Hotel Baltimore, Kansas City, Mo., Monday, July 7, 1913, at 10 A.M.

Business of importance and initiation has been arranged for the day, to be followed by the annual banquet in the evening.

R. Hamill D. Swing, *Supreme Scribe.*

[At Kansas City.]

XI PSI PHI FRATERNITY.

There will be a meeting of the Xi Psi Phi Fraternity during the session of the National Dental Association, at Kansas City, Mo., July 8 to 11, 1913.

Headquarters for the members of the Xi Psi Phi Fraternity will be established at the Baltimore Hotel, Kansas City, Mo. Special accommodations have been made for train service from Chicago, and all members of the fraternity east of Chicago are invited to avail themselves of this service. For further information address

C. C. Markey, *Sec'y*,
1740 Greenleaf ave., Chicago, Ill.

AMERICAN SOCIETY OF ORTHODONTISTS.

The thirteenth annual meeting of the American Society of Orthodontists will be held in Chicago, Ill., June 30, July 1 and 2, 1913.

Frederick C. Kemple, *Sec'y*,
576 Fifth ave., New York City.

PACIFIC COAST ORTHODONTISTS.

Organization of Angle Graduates.

Following the three days' invitation clinic recently held in Los Angeles by Dr. Edward H. Angle for the benefit of the graduates of his school now practicing on the Pacific coast, there was organized an association to be known as the Pacific Coast Society of Graduates of the Angle School of Orthodontia, the object of this society being: (1) The promotion of knowledge in all that pertains to orthodontia, and the advancement and establishment of the science as a distinct specialty; (2) fraternal and professional association of orthodontists, and especially of graduates of the Angle School of Orthodontia; (3) mutual, cordial, and helpful relation with the Alumni Society of the Angle School of Orthodontia and other societies composed of Angle men.

The following, who were in attendance, constitute the charter membership: Wm. Bolton, Seattle; W. A. Smith, Wallace, Idaho; Robt. Dunn, San Francisco; Wellslake Morse, Los Angeles; James D. McCoy, Los Angeles; Genette Harbour, Los Angeles; John R. McCoy, Los Angeles; Wm. W. Wilson, San Diego, and Wm. C. Smith, Pasadena.

At the initial meeting officers were elected for the ensuing year, as follows: Dr. Robt. Dunn, San Francisco, president and John R. McCoy, Los Angeles, secretary-treasurer.

The next annual meeting will be held in San Francisco during February 1914.

John R. McCoy, *Secretary.*

AMERICAN MEDICAL ASSOCIATION.

Section on Stomatology.

FOLLOWING is the program of the American Medical Association, Section on Stomatology, to be held in Minneapolis, Minn., June 17 to 20, 1913:

(1) "Fields for Research in Oral Surgery." (Chairman's Address.) Virgil Loeb, St. Louis, Mo.

(2) "Social Ethics." E. M. Wooley, Winona, Minn.

(3) "Mouth Lesions." Stewart L. McCurdy, Pittsburgh, Pa.

(4) "A Safe, Efficient, Easily Administered General Anesthetic for Minor Operations." Wm. H. DeFord, DesMoines, Iowa.

(5) "The Correction of Impediments of Speech in Our Public Schools." H. F. McBeath, Milwaukee, Wis.

(6) "The Pathology of Root-findings." Vida A. Latham, Chicago, Ill.

(7) "The Responsibility of the Dentist and Physician in Regard to Mouth Infections, and Their Relation to Constitutional Effects." Thomas B. Hartzell, Minneapolis, Minn.

(8) "Bachelor of Medicine: The Need of this New Degree." Wm. C. Fisher, New York.

(9) "The Etiology of Trifacial Neuralgia or Tic Douloureux and Clinical Treatment." Nelson T. Shields, New York City.

Discussion—John A. Bodine, New York, and G. V. I. Brown, Milwaukee, Wis.

(10) "A Method of Closing a Sinus Between the Antrum of Highmore and the Mouth." L. W. Dean, Iowa City, Iowa.

(11) "Treatment of Teeth Loosening in Their Sockets Through Inflammatory Degeneration of the Gums and Alveolar Process." Joseph Head and Claude P. Brown, Philadelphia, Pa.

(12) "Bacteria of the Mouth." A. H. Levings, Milwaukee, Wis.

(13) Infective Cysts of the Jaws." F. B. Moorehead, Chicago, Ill.

(14) "Arrested Development of the Superior Maxillæ in relation to Mental and Physical Efficiency." Joseph S. Evans, Madison, Wis.

Discussion—Nelson M. Black, Milwaukee, Wis., and John S. Kirkendall, Ithaca, N. Y.

(15) "The Relation of Mouth Disease to Bodily Health." Edward H. Baker, Chicago, Ill.

(16) "The Surgical Treatment of Post-operation Lip and Palate Defects." George V. I. Brown, Milwaukee, Wis.

(17) "Interstitial Gingivitis and Pyorrhœa Alveolaris." Eugene S. Talbot, Chicago, Ill.

All those interested in the program are invited to attend the meetings and take part in the discussions.

EUGENE S. TALBOT, *Sec'y.*

DISTRICT OF COLUMBIA DENTAL SOCIETY

AND

MARYLAND STATE DENTAL ASSOCIATION.

THE sixteenth union meeting of the District of Columbia Dental Society and the Maryland State Dental Association will be held in Washington, D. C., on June 12, 13, and 14, 1913.

F. F. DREW, *Cor. Sec'y.*

TENNESSEE STATE DENTAL ASSOCIATION.

THE Tennessee State Dental Association will hold its annual meeting in Nashville, Tenn., on June 5, 6, and 7, 1913, with the following officers in charge: F. W. Meacham, president; W. C. Gillespie, first vice-president; J. L. Manire, second vice-president; C. Osborn Rhea, recording secretary; W. G. Hutchinson, treasurer; C. E. Hines, corresponding secretary.

C. OSBORN RHEA, *Sec'y.*

ALABAMA DENTAL ASSOCIATION.

THE Alabama Dental Association will meet in Birmingham, Ala., June 10, 11, and 12, 1913.

We earnestly solicit every good dentist in Alabama who is not now a member to join. It will enhance your efficiency, because in the doctrines we teach we incorporate the best of professional principles and within our ranks we encompass the best of professional men.

G. F. PETREY, *Sec'y,*
Florala, Ala.

MONTANA STATE DENTAL SOCIETY.

The next annual meeting of the Montana State Dental Society will be held in Butte, June 13 and 14, 1913.

T. T. Rider, *Sec'y*,
Missoula, Mont.

CALIFORNIA STATE DENTAL ASSOCIATION.

The next annual meeting of the California State Dental Association will be held on June 2, 3, 4, and 5, 1913, in the Hotel Oakland, at Oakland, Cal.

E. E. Evans, *Sec'y*,
Oakland, Cal.

WASHINGTON STATE DENTAL SOCIETY.

The Washington State Dental Society meets June 16, 17, and 18, 1913, in Seattle, Wash.

A. D. Remington, *Sec'y*,
Seattle, Wash.

MISSISSIPPI DENTAL ASSOCIATION.

The thirty-eighth annual session of the Mississippi Dental Association will be held at the Great Southern Hotel, Meridian, Miss., June 24, 25, and 26, 1913.

A determined effort is being put forth to make this meeting our best. There will be a fine clinic, excellent papers, a banquet, and a fine exhibit.

L. B. Price, *Sec'y*,
Corinth, Miss.

MINNESOTA STATE DENTAL ASSOCIATION.

The thirtieth annual meeting of the Minnesota State Dental Association will occur in Masonic Temple, Minneapolis, Minn., Friday and Saturday, June 13 and 14, 1913.

Every phase of dentistry will be presented by men of unquestioned ability, from Dr. Raper of Indianapolis with stereopticon lectures on treatment of root-canals, to the effect of pathological conditions of the mouth on systemic conditions, which will be presented by Dr. C. H. Mayo of Rochester, whose name is familiar wherever medicine is practiced. A large manufacturers' exhibit will round out what we expect to be an unusually large meeting of the organization.

For information, address

Benjamin Sandy, *Sec'y*,
636 Syndicate Bldg., Minneapolis, Minn.

MAINE DENTAL SOCIETY.

The forty-eighth annual meeting of the Maine Dental Society will be held at the Ottawa House, Cushing's Island, Portland Harbor, Me., on June 25, 26, and 27, 1913.

I. E. Pendleton, *Sec'y*.

FLORIDA STATE DENTAL SOCIETY.

The next meeting of the Florida State Dental Society will be held at Atlantic Beach, Fla., June 24, 25, 26, and 27, 1913. Papers and clinics of unusual merit will be presented, and it is confidently expected that this will be one of the largest and most instructive meetings ever held by the society. A most cordial invitation is extended to all ethical practitioners.

Jesse L. Williams, *Cor. Sec'y*,
Jacksonville, Fla.

SOUTHERN WISCONSIN DENTAL ASSOCIATION.

A New Departure.

The nineteenth annual meeting of the Southern Wisconsin Dental Association will be held at Hotel Highland, Delavan Lake, June 13 and 14, 1913.

Having decided to combine business with pleasure, we will hold our session in the afternoons only, consisting of a few of the best papers and clinics obtainable. The morning and evening can be spent boating, fishing, bathing, or automobiling.

Hotel Highland and Delavan Lake are seldom equaled and never surpassed as a place for such a gathering. It is our purpose to take our wives with us, and together enjoy the Lake as well as the beautiful hills and valleys surrounding Hotel Highland. Bring the young folks with you; they will enjoy the outing.

All ethical dentists are cordially invited to attend.

C. W. Collver, *Sec'y*,
Clinton, Wis.

NATIONAL DENTAL ASSOCIATION—SOUTHERN BRANCH AND VIRGINIA STATE DENTAL SOCIETY.

The fifteenth annual meeting of the Southern Branch of the National Dental Association will be held at the Chamberlin Hotel, Old Point Comfort, Va., July 22 to 25 inclusive, 1913. The Virginia State Dental Society will meet conjointly with the Southern Branch at that time.

Thos. Moore, Jr., *Cor. Sec'y, N.D.A.So.Br.*
C. B. Gilford, *Cor. Sec'y, Va. Dental Soc.*

NORTHERN OHIO DENTAL ASSOCIATION.

The fifty-sixth annual meeting of the Northern Ohio Dental Association will be held at Cleveland, Ohio, June 5, 6, and 7, 1913.

C. D. Peck, *Sec'y,*
Sandusky, Ohio.

NEW HAMPSHIRE DENTAL SOCIETY.

The New Hampshire Dental Society will hold its annual meeting at Hotel Weirs, Weirs, N. H., June 18, 19, and 20, 1913. The profession are invited to attend.

Fred F. Fisher, *Sec'y.*

SOUTH CAROLINA STATE DENTAL ASSOCIATION.

The forty-third annual meeting of the South Carolina State Dental Association will be held on the Isle of Palms, June 25, 26, and 27, 1913.

W. Busey Simmons, *Recording Sec'y,*
Piedmont, S. C.

GEORGIA STATE DENTAL SOCIETY.

The forty-fifth annual meeting of the Georgia State Dental Society will convene at Columbus, Ga., June 12, 13, and 14, 1913, beginning Thursday, June 12th, at 11 A.M. Some very interesting lectures and papers will be presented; also an elaborate clinic has been secured.

Further information will be cheerfully furnished upon request from ethical practitioners of other states contemplating a visit to the meeting, to whom we extend a cordial invitation.

M. M. Forbes, *Sec'y,*
Atlanta, Ga.

WEST VIRGINIA STATE DENTAL SOCIETY.

The seventh annual meeting of the West Virginia State Dental Society will be held in the assembly room of the Chancellor Hotel, Parkersburg, W. V., August 13, 14, and 15, 1913. Opening session 2 P.M., Wednesday, August 13th. A cordial invitation is extended to all ethical members of the profession to attend our meeting.

Frank L. Wright, *Sec'y,*
Wheeling, W. Va.

NORTHERN INDIANA DENTAL SOCIETY.

The twenty-fifth annual meeting of the Northern Indiana Dental Society will be held at the Great Steel City of Gary, September 23, 24, and 25, 1913.

W. Leroy Myer, *Sec'y,*
Rensselaer, Ind.

NEW JERSEY STATE DENTAL SOCIETY.

The forty-third annual convention of the New Jersey State Dental Society will be held in the Beach Auditorium, at Asbury Park, N. J., July 16, 17, and 18, 1913, beginning on Wednesday, July 16th, at 10 A.M.

The exhibits of modern dental appliances and the latest in office and laboratory equipment will be in charge of Dr. William H. Gelston, 40 N. Thirtieth st., Camden, N. J., who will be glad to furnish information regarding rates and space still available. Early application from those desiring to exhibit with us this year will be greatly appreciated.

The clinics will be in charge of Dr. Henry

Fowler, 114 N. Fourth st., Harrison, N. J., and will be comprehensive and of a very high order.

Further announcements will be made from time to time.

EDWIN W. HARLAN, *Sec'y*,
47 Crescent ave., Jersey City, N. J.

MICHIGAN BOARD OF EXAMINERS.

THE next regular meeting of the Michigan State Board of Dental Examiners will be held at the dental college, Ann Arbor, commencing Monday, June 16, at 8 A.M., and continuing through the 21st. For application blanks and full particulars address

F. E. SHARP, *Sec'y*,
Port Huron, Mich.

VIRGINIA BOARD OF EXAMINERS.

THE regular annual meeting of the Virginia State Board of Dental Examiners will be held in Richmond, Va., on June 10, 1913, at 9 A.M.

This meeting will be held for the examination of applicants and the routine business of the board.

For further information address

J. P. STIFF, *Sec'y*,
Fredericksburg, Va.

CONNECTICUT DENTAL COMMISSIONERS.

THE Dental Commissioners of the State of Connecticut hereby give notice that they will meet at Hartford, on Thursday, Friday, and Saturday, June 12th, 13th, and 14th, to examine applicants for license to practice dentistry, and for the transaction of any other business proper to come before them.

On receipt of application blank, filled in and sworn to and accompanied with fee of twenty-five dollars, each applicant will be sent a number, which number will represent the applicant during the examination.

The practical examination will take place at Putnam Phalanx Armory, corner Haynes and Pearl sts., on Thursday, June 12th. All prosthetic pieces should be tagged with the applicant's number, and handed to the Commissioners at nine o'clock Thursday morning. Applicants whose numbers range from 1 to 20 inclusive will be examined in operative dentistry at 9 A.M. Those whose numbers are above 20 will be examined in operative dentistry at 12 M. All applicants whose credentials are accepted shall be entitled to take both the practical and theoretical examinations. Credentials will be examined at the Hotel Heublein, Wednesday evening, June 11th, at 8.30, and at Putnam Phalanx Armory at 9 o'clock on Thursday morning.

On Friday, June 13th, the theoretical examination will be held from 9 to 11, 11.30 to 1.30 and 3.30 to 5.30. Theoretical examination will be held at the State Capitol.

By order of the Commission.

D. EVERETT TAYLOR, *Recorder*,
Willimantic, Conn.

MASSACHUSETTS BOARD OF REGISTRATION.

A MEETING of the Massachusetts Board of Registration in Dentistry, for the examination of candidates, will be held in Boston, Mass., June 4, 5, and 6, 1913.

G. E. MITCHELL, *Sec'y*,
14 Water st., Haverhill, Mass.

PENNSYLVANIA BOARD OF EXAMINERS.

THE next regular examination of the Pennsylvania State Board of Dental Examiners will be held in Philadelphia and Pittsburgh, on Wednesday, Thursday, Friday, and Saturday, June 11, 12, 13, and 14, 1913. Application blanks can be secured from the department of Public Instruction, Harrisburg.

Further information can be obtained from

ALEXANDER H. REYNOLDS, *Sec'y*,
4630 Chester ave., Philadelphia, Pa.

RHODE ISLAND BOARD OF REGISTRATION.

THE Rhode Island Board of Registration in Dentistry will meet for the examination of candidates at the State-house, Providence, R. I., Tuesday, Wednesday, and Thursday, June 24, 25, and 26, 1913.

Application blanks and particulars may be obtained from

ALBERT E. SEAL, *Sec'y*,
27 Tyler Bldg., Pawtucket, R. I.

IOWA BOARD OF EXAMINERS.

The next meeting of the Iowa State Board of Dental Examiners for the examination of candidates will be held at Iowa City, Iowa, commencing Monday, June 2, 1913. For application blanks and particulars write

J. A. West, *Sec'y*,
417 Utica Bldg., Des Moines, Iowa.

FLORIDA BOARD OF EXAMINERS.

The Florida State Board of Dental Examiners will meet in Jacksonville, June 21, 23, and 24, 1913, for the examination of applicants to practice dentitstry. Applicants for examination must be graduates of a reputable dental school. Examinations will be both practical and theoretical. The practical examination will be one gold filling, one amalgam filling in the mouth, one post crown, and upper and lower set of teeth, set up and articulated. The theoretical examination will be in all the branches taught in the dental college. Applicants must furnish all instruments for the work, except soldering appliances and articulators.

The secretary will be glad to meet all applicants at the Seminole Hotel at eight o'clock on the evening of June 20th, for the purpose of examining credentials.

W. G. Mason, *Sec'y*,
Tampa, Fla.

ALABAMA BOARD OF EXAMINERS.

The Alabama State Board of Dental Examiners convenes at the Metropolitan Hotel, Birmingham, Thursday, June 5, 1913.

Applicants must be twenty-one years of age and hold a diploma from a reputable dental college. Written examination—Operative dentistry, orthodontia, oral surgery, anatomy, physiology, chemistry, materia medica, anesthesia, pathology, therapeutics and etiology, histology, prosthetic dentistry, metallurgy, and oral hygiene. In practical work—inserting one gold and one amalgam filling, construction of bridge using first molar shell crown and canine Richmond crown as abutments; porcelain dummies 1st and 2d bicuspids, one posterior Steele facing accepted. Assembling and soldering in presence of members of the board. Inserting one approximo-occlusal gold inlay in first molar either in the mouth of the patient or on an articulator; natural tooth set in model with occluding teeth, cavity prepared in presence of board. Fee ten dollars. Address

W. E. Proctor, *Sec'y*,
Lock box 113, Sheffield, Ala.

NEBRASKA BOARD OF EXAMINERS.

The Nebraska Board of Dental Examiners will hold examination on June 16, 17, and 18, 1913, beginning at 9 A.M. on the 16th.

Address inquiries to

J. S. Pierce, *Sec'y*.

ILLINOIS BOARD OF EXAMINERS.

The semi-annual meeting of the Illinois State Board of Dental Examiners, for the examination of applicants for a license to practice dentistry in the state of Illinois, will be held at the Chicago College of Dental Surgery, corner of S. Wood and W. Harrison sts., Chicago, beginning Wednesday, June 4, 1913, at 9 A.M.

All applications, together with the fee, twenty-six dollars, must be filed with the secretary at least five days prior to date of examination. Address all communications to

T. A. Broadbent, *Sec'y*,
705 Venetian Bldg., Chicago, Ill.

CALIFORNIA BOARD OF EXAMINERS.

The next examination by the Board of Dental Examiners of California for license to practice dentistry will be held in San Francisco, Cal., beginning on June 7, 1913. This will be followed by an examination in Los Angeles, beginning on June 20th. All applications, accompanied by the fee of twenty-five dollars and the necessary credentials—a diploma or license from some other state—must be filed with the secretary of the board on the morning of the date set for examination—June 7th in San Francisco and June 20th in Los Angeles. Said application must be accompanied by a recent unmounted photograph of the applicant.

C. A. Herrick, *Sec'y*,
San Francisco, Cal.

SOUTH CAROLINA BOARD OF EXAMINERS.

The next meeting for examination of applicants for license will be held Friday, June 20, 1913, at 3 P.M., at the Isle of Palms, Hotel Charleston, S. C.

J. M. Quattlebaum, *Sec'y.*

WISCONSIN BOARD OF EXAMINERS.

The Wisconsin State Board of Dental Examiners will convene in Milwaukee, at Marquette University, on June 16, 1913, at 2 P.M., for examination of applicants to practice in Wisconsin.

High-school diploma, application, and fee of $25.00 must be filed with the secretary fifteen days prior to above date. Dental diploma to be presented in advance of examination.

F. A. Tate, *President,*
W. T. Hardy, *Sec'y,*
422 Jefferson st., Milwaukee, Wis.

VERMONT BOARD OF EXAMINERS.

The next meeting of the Vermont Board of Dental Examiners for the examination of candidates to practice in Vermont will be held at the State-house, Montpelier, Vt., continuing four days, commencing at 2 P.M., June 30, 1913.

To be eligible for examination a candidate (1) must be twenty-one years of age; (2) must be a graduate of a high school of the first class; (3) must be a graduate of a reputable dental college.

Applications must be in the hands of the secretary not later than June 20th.

For further information apply to

Geo. F. Cheney, *Sec'y,*
St. Johnsbury, Vt.

The following have been appointed as members of the Vermont Board of Dental Examiners: J. D. Bachand, St. Johnsbury, for five years; E. O. Blanchard, Randolph, for four years; G. F. Cheney, St. Johnsbury, for three years; G. O. Mitchell, St. Albans, for two years; K. L. Cleaves, Montpelier, for one year.

J. D. Bachand.

MISSISSIPPI BOARD OF EXAMINERS.

The Mississippi State Board of Dental Examiners will meet at the State Capitol, Jackson, on the third Tuesday in June, at 8.30 A.M.

All applicants must be graduates of reputable dental colleges or schools of dental surgery.

Ruel May, *Sec'y,*
Jackson, Miss.

IDAHO BOARD OF EXAMINERS.

The next meeting of the Idaho Board of Dental Examiners will be held in Boise, beginning Monday morning, July 7, 1913.

Albert A. Jessup, *Sec'y,*
Boise, Idaho.

TEXAS BOARD OF EXAMINERS.

The next regular meeting of the Texas State Board of Dental Examiners will be held in the high-school building, Houston, Texas, beginning Monday, June 23, 1913, at 9 A.M. Official application blanks and other necessary information will be furnished candidates upon application to the secretary.

All applications, accompanied by a fee of $25.00, should be in the hands of the secretary at least five days before the examination.

Address all communications to

C. M. McCauley, *Sec'y,*
Abilene, Texas.

INDIANA BOARD OF EXAMINERS.

The next regular meeting of the Indiana State Board of Dental Examiners will be held in the State-house at Indianapolis, beginning Monday, June 9th, at 9 A.M., and continuing until Saturday, June 14th. All applicants for registration in this state will be examined at this time. No other meeting will be held until November; no temporary licenses are issued.

The new law requiring annual registration will be in effect about May 15th. The first registration will take place in December of this year. For application blanks and further information apply to

F. R. Henshaw, 507-8 Pythian Bldg.,
Indianapolis, Ind.

MONTANA BOARD OF EXAMINERS.

THE Montana State Board of Dental Examiners will hold the annual session in Helena, Mont., July 14, 15, 16, 17, 1913. Address all communications to

G. A. CHEVIGNY, *Sec'y*,
Butte, Mont.

NORTH DAKOTA BOARD OF EXAMINERS.

THE next regular meeting of the North Dakota State Board of Dental Examiners will be held in Fargo, July 8, 9, 10, and 11. For further information address

F. A. BRICKER, *Sec'y*,
Fargo, N. D.

NEW JERSEY BOARD OF REGISTRATION.

THE New Jersey State Board of Registration and Examination in Dentistry will hold their semi-annual examination in the Statehouse, Trenton, N. J., beginning on Monday, June 30, and continuing Tuesday, July 1, and Wednesday, July 2, 1913.

Practical work Monday, June 30th, 8 A.M. sharp; theoretical examination Tuesday, July 1st, and Wednesday, July 2d, promptly at 8 A.M. The business meeting of the board will be held at 10 A.M., Tuesday, July 1st, and anyone having business with the board may have an audience. Applications must be in the hands of the secretary five days prior to the examination. For further information address

CHAS. A. MEEKER, *Sec'y*,
29 Fulton st., Newark, N. J.

WYOMING BOARD OF EXAMINERS.

THE Wyoming State Board of Dental Examiners will meet for examination of applicants on July 1, 2, and 3, 1913, at Cheyenne.

An examination is required of all applicants, and only holders of diplomas from reputable dental colleges are eligible to such examination. The board does not interchange with other states, nor issue any temporary permits. All applications must be completed and in the hands of the secretary fifteen days prior.

The written examination consists of anatomy, physiology, histology, bacteriology, chemistry, metallurgy, oral surgery, anesthetics, operative and prosthetic dentistry, materia medica, therapeutics, prophylactics, and orthodontia. Hand instruments for operating will be all the candidate need furnish.

For further information and application blanks, address

PETER APPEL, JR., *Sec'y*,
Cheyenne, Wyo.

ARMY DENTAL SURGEONS.

MEMORANDA OF CHANGES.

For the week ending April 19th:

First Lieut. George I. Gunckel granted ten days' leave of absence.

First Lieut. Edwin P. Tignor granted five days' leave of absence.

For the week ending April 25th:

First Lieut. John R. Ames arrived at Fort McPherson, Ga., April 19th, for duty.

For the week ending May 2d:

Lester C. Ogg, ACT.D.S., is relieved from duty at the Letterman General Hospital, Presidio of San Francisco, Cal., and will take the August 5th transport, sailing from San Francisco, Cal., for the Philippine Islands.

Charles E. Sherwood, ACT.D.S., is relieved from duty at the Presidio of Monterey, Cal., and will take the transport sailing from San Francisco, Cal., July 5th, for Hawaii, H. T.

B. C. Warfield, ACT.D.S., is relieved from duty at Madison Barracks, N. Y., and will take the transport sailing from San Francisco, Cal., about July 5th, for the Philippine Islands.

Albert R. White, ACT.D.S., is relieved from duty at Fort Des Moines, Iowa, and will take the transport sailing from San Francisco, August 5th, for Honolulu, H. T.

Arthur T. Knoderer, ACT.D.S., left Philadelphia, Pa., April 25th, *en route* to San Francisco, and will take the transport to sail from that place on or about May 5th for the Philippine Islands.

J. W. Smith, ACT.D.S., left Fort Sam Houston, Texas, April 20th for Marfa, Texas; Columbia, N. M.; Douglas, Ariz., and Fort Huachuca, Ariz.

For the week ending May 9th:

First Lieut. R. E. Ingalls arrived at his station, Fort Liscum, Alaska, April 21st.

READING (PA.) DENTAL SOCIETY—

Its Work in the Public Schools.

At a recent meeting of the Reading Dental Society a copy of the appended resolutions, passed by a committee of the teachers of the public schools, was received, and on motion the secretary was instructed to send a copy to the Dental Cosmos for publication.

Otto J. Specker, *Sec'y.*

Resolutions.

Whereas, the city of Reading and the school children of the city have been benefited beyond measure by the Reading Dental Society's gratuitous dental inspection of the children in the grades; and

Whereas, we, the teachers of the schools, knowing of the marvelous improvement in the health and physical development of these children through their magnanimity; therefore be it

Resolved, That we, the teachers of the city, in institute assembled, do express to the Reading Dental Society our sincere thanks, and in this way show our earnest appreciation and full realization of the great amount of good they have done; and be it further

Resolved, That a copy of these resolutions be sent to the secretary of the society.

[Signed] George Beggs, *Chairman,* Mary H. Mayer, Esther M. Evans, Emma C. Houder, Elizabeth Piper, Anna Fink, Josephine Murray, Carrie Lotz, Martha Goodenough, Margaret Gossler, *Committee on Resolutions.*

ORIGINAL COMMUNICATIONS.

STUDIES OF ANTERIOR AND POSTERIOR OCCLUSION OF THE TEETH, WITH SUGGESTIONS AS TO TREATMENT.

By M. H. CRYER, M.D., D.D.S., Philadelphia, Pa.,
PROFESSOR OF ORAL SURGERY, UNIVERSITY OF PENNSYLVANIA.

(Read before the Eastern Association of the Graduates of the Angle School of Orthodontia.)

IT gives me great pleasure to be with you tonight, and to have this opportunity of hearing your interesting views and discussions on various matters connected with orthodontia. If you will permit me to make a little personal reference in regard to my relations with the Angle graduates, I should like to state that, while my opinions are apt to be rather positive, and those who do not agree with me are equally firm in their convictions, there is no reason why we should not discuss these differences of opinion in a thoroughly friendly spirit with mutual benefit and good-fellowship—for the purpose of all of us is the betterment of our profession and the welfare of our patients.

Some years ago, in criticizing a paper of mine, one of your members called his article "Definite *versus* Indefinite." He may be tempted to say the same of this paper, as I fear it is a most indefinite effort. In fact, the upper and lower jaws, I find, are decidedly indefinite, as they absolutely refuse to conform to any fixed type or classification, each jaw being different from any other, and necessitating a treatment peculiar to its own anatomy.

INFINITE VARIETY IN OCCLUSION.

In making a study of any portion of the human body, especially when comparing a large number of specimens, the student is inclined to think that the particular region he is studying exhibits more variations than can be found in any other part. Thus, in looking up material for this paper, I have examined many skulls but cannot find any two occlusions alike; and I doubt if one could find, in any collection of skulls, ancient or modern, a mandible which would give the same dental occlusion if taken from its own skull and placed on another. With all the variations that we find throughout both the vegetable and the animal kingdom, there is some function or "vital instinct" which endeavors to bring these variations into harmonious relations with the whole, and usually accomplishes this design if not interfered with by disease, misalliance of parents, or traumatic disturbances. The unerupted tooth germs develop and find their proper position in the jaws through this vital instinct, the lower and upper teeth finding their normal occlusion by the same compulsion. If we accept this vital instinct of construction, we must also realize that it gives the power of repair, which the surgeon must consider and call to his aid in all his endeavors to cure disease or correct deformity.

Fig. 1.

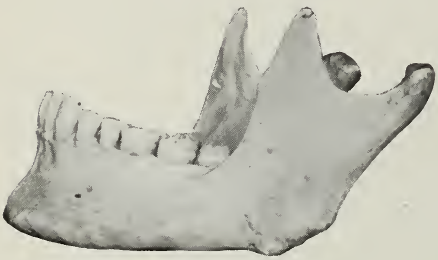

Fig. 2.

DESCRIPTION OF THE UPPER AND LOWER JAWS, AND THEIR RELATIONS TO EACH OTHER.

In order to understand the best method of diagnosing the cause of abnormal conditions of the jaws, for their treatment, it will be advisable to give a brief description of the upper and lower jaws and their relations to each other.

Lower jaw. The mandible is made up of the body, the ramus, the teeth, and their alveolar processes. At the upper and posterior end of the ramus is the condyloid process, which normally articulates in the anterior portion of the glenoid fossa of the temporal bone. The ramus joins the body at a little more than a right angle. The angle of the mandible at birth is very obtuse, in some cases being as much as 140°. As the bone increases in size, and the teeth with their alveolar processes develop and take their places, the jaws are forced apart, and the angle loses its marked obtuseness, making at full maturity an angle of about 120°, and even less in some cases of powerful jaws.

The bones throughout the body have large tuberosities, spines, ridges, etc., for the attachment of ligaments and muscles. The mandible is not an exception to this rule, there being strong attachments at or near the angle. As the muscles grow and increase in strength, that portion of bone to which they are attached also increases in size, giving the ramus a sort of square appearance, especially in strong, muscular persons, As time passes, after full maturity, the muscular action becomes less and less, and the tuberosities, etc., throughout the body become smaller. The same condition takes place at the angle of the jaw, and it becomes more obtuse as age advances. When the jaws can be kept apart with good teeth and proper, full mastication, there is not so much change in the angles. Anatomically speaking, the above description answers for ordinary purposes. The surgical consideration of the relation of the ramus to the body will be referred to farther on.

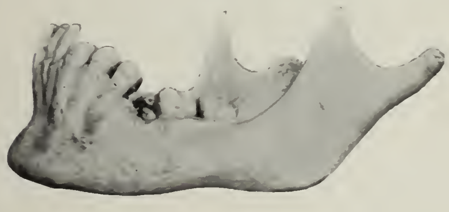
The teeth and their alveolar processes are placed on the upper portion of the body of the bone. The third molar is partially posterior to the anterior margin of the ramus, and a line can be drawn between the first and second premolars to the mental foramen. The mental process gives prominence to the chin and lower part of the face. The incisors are about normal, and having neither lingual nor labial inclination.

The above is a rather good description

of a fairly typical mandible as shown in Fig. 1, also in the skull Fig. 16.

Fig. 2 is made from a mandible of a South African negro (see Figs. 10 and 17). The body of the mandible is fairly typical, except that the angle is nearer a right angle. The prognathous features of this mandible are caused by the position of the teeth and their alveolar

FIG. 3.



processes, which are set forward on the body of the jaw. It will be noticed that the third molar is in advance of the ramus about the width of a molar, and that a line drawn downward between the premolar teeth would pass across the body of the jaw a full width of a molar tooth in advance of the mental foramen. The canine and incisor teeth are placed in front of the jaw proper, with considerable labial inclination of the incisors. The mental process is not so prominent as in Fig. 1, due in part to the carrying forward of the teeth and alveolar process.

Fig. 3 is made from a skull (see Figs. 11 and 18) showing prognathous jaws. Upon examination it will be seen that the prognathism in Figs. 2 and 3 is produced by quite different anatomical arrangements. In Fig. 2 it is evidently caused by the malposition of the teeth and their alveolar processes upon the body of the bone. In Fig. 3 the principal cause of prognathism is in the relation of the ramus to the body, which carries the body of the jaw so far forward that the mental process is much more prominent than in Fig. 2, and the anterior teeth have lingual inclination. To correct this forward protrusion would require quite a different method from the procedure illustrated in Fig. 2. Here the angle should be changed sufficiently to allow the body of the jaw with the teeth to be carried backward to a position nearer the typical.

Fig. 4 is made from the mandible of a very heavy skull with large massive teeth in excellent alignment (see Figs. 13 and 19, A), and when articulated with its skull there is fairly good occlusion. The marked feature of this mandible is the relation of the ramus to the body of the bone: its external angle is nearer a right angle than any mandible I have measured, being 103° on the right side and 100° on the left.

Fig. 5 is made from a mandible of a peculiar skull (see Figs. 12 and 22). It is a great contrast to the mandible shown in Fig. 4. The angle of the ramus with the body of the bone is 135°. Age should be taken into consideration in this comparison, as the angle usually increases as age advances. There is a difference, however, of about 6 mm. in the distance from the condyloid process to the lower portion of the symphysis in these two mandibles.

Fig. 6 is made from the mandible of a skull having a very flat face (see

FIG. 4.

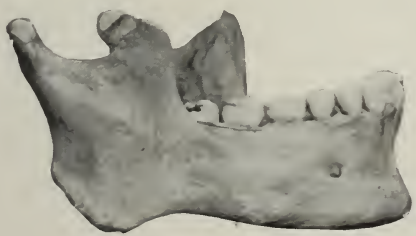


FIG. 5.

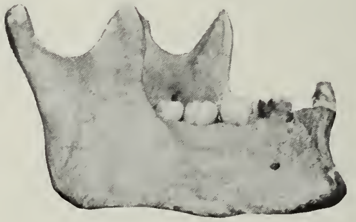
Figs. 15 and 20). There is a slight anterior occlusion. The angle of the jaw is obtuse, viz, 133°.

Fig. 6A is made from the mandible of a Chinese skull. (See Figs. 14 and 19, B.)

FIG. 6.

FIG. 6A.



The rami are rather square and unite with the body of the bone at an angle of 107°, which makes the mandible short. On the left side of the mandible there is an impacted lower third molar.

FIG. 7.

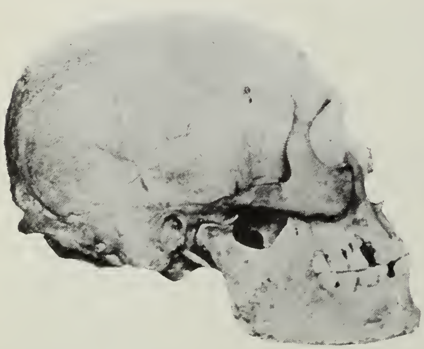


FIG. 8.

(From the collection in Peabody Museum, Cambridge, Mass.)

Taking it for granted that the upper jaw with its teeth is of normal character, the protrusion of the mandibular teeth can be traced to at least four causes. First, a comparatively normal jaw can be so situated that one or both condyles will rest upon the eminentia articularis, which throws the whole jaw forward, as shown in Figs. 7 and 8. Second, the teeth and their alveolar processes can be placed forward upon the true bone, as in Fig. 2, while the mandible in other respects is fairly typical and is normally articulated in the glenoid fossa. Third, the condyloid process may be abnormally long from the sigmoid notch to the head of the condyle, and extend more backward than usual, thus throwing the jaws forward (see Fig. 25, X-ray picture). The fourth cause of protrusion, the most common, is the abnormal shape of the mandible (see Figs. 3 and 5). When the ramus and the body form an angle that is very obtuse, the body of the mandible is bound to be carried forward in proportion to this obtuseness.

Upper jaw. From a surgical standpoint the upper jaw includes the two maxillæ and all the other facial bones except the mandible, also part of the sphenoid and ethmoid bones of the cranium.

MEASUREMENTS OF THE BASE AND THE PHARYNGEAL DOME OF SEVEN SKULLS.

In former studies of the skull I have endeavored to find a fixed point from which to make measurements or comparisons without satisfactory results. In these studies I have chosen the center of the anterior border of the foramen magnum, and we find some interesting measurements.

The first measurement is from the cutting edge of the incisor teeth to the free margin of the hard palate.

The second measurement is from the free edge of the hard palate to the anterior border of the foramen magnum.

The third measurement is from the anterior border of the foramen magnum to the vertical line at the posterior part of the skull.

Fourth, the triangle of the pharyngeal dome is obtained by lines drawn from the free edge of the hard palate (A) to the anterior border of the foramen magnum (B), from the foramen magnum to the highest part of the basilar process of the occipital bone (C), and from that point to the free border of the hard palate A, the height of the dome being from C to D.

harmony with the rest of the skull, and will be used in comparison with other illustrations of the same general character. The distance from the cutting edge of the incisors to the free border of the hard palate is 60 mm., from the hard palate to the foramen magnum 42 mm., from the foramen magnum to the vertical plane of the back part of the skull 93 mm., the total length of the skull 195 mm.

Fig. 10 is made from the most prognathous skull I have measured (see Figs. 2 and 17). It is in great contrast with the typical skull (see Figs. 9 and 16). The distance from the cutting edge of the incisor teeth to the free margin of the hard palate is 71 mm., a difference of 11 mm. between this and the typical skull; from the hard palate to the foramen magnum, 46 mm., a difference of 4 mm., from the foramen magnum to the back point of the skull, 104 mm., a difference of 11 mm. The total length of the skull is 221 mm., a difference of 26 mm.

Fig. 11 is made from a skull with a prognathous face (see Figs. 3 and 18). Its measurements are as follows: From the cutting edge of the incisor teeth to the free margin of the hard palate, 62 mm.: from the hard palate to the foramen magnum, 48 mm.: from the anterior border of the foramen magnum to the back of the skull, 95 mm.; total length of skull, 205 mm.

Fig. 9 is an illustration taken from the under surface of a typical skull. It is not necessary to go into the general description of the base of this skull other than to say that the relation of the shape, size, and position of the upper jaw is in

Fig. 12 is made from a very short skull (see Fig. 22), the distance from

Triangles Showing Height of Pharyngeal Dome and Angles of Mandible.

NOTE.—No. 9 triangle, in *heavy lines*, is made from the pharyngeal dome of skull shown in Figs. 9 and 16, which is nearly a typical skull. The others are taken from skulls that are atypical and are described under Figs. 10 to 15 inclusive. These triangles have a great deal to do with the occlusion of the teeth and the general shape of the lower part of the face, and must have their influence in modifying the whole face. The triangles in *light lines* are those of the mandibles of the same skulls.

magnum to the back of the skull, 100 mm.; total length of skull, 212 mm.

Fig. 14 is made from the base of a Chinese skull, showing a general roundness of form.

Fig. 15 is made from the under surface of a skull in which there is a slight anterior occlusion and open bite (see Fig. 20). The distance from the cutting edge of the incisor teeth to the free border of the hard palate is 56 mm.; from the hard palate to the anterior border of the foramen magnum 36 mm., from the foramen magnum to the vertical plane of the back of the skull, 105 mm.; total length of the skull, 197 mm. It is evident that in this skull the principal cause of anterior occlusion is the short distance from the cutting edge of the incisor teeth to the hard palate, and also to the foramen magnum, being only 92 mm., viz, 10 mm. shorter than typical. It will be noticed that the two second premolars—perhaps they are the first—are out of line, caused also by the smallness and shortness of the whole upper jaw. An additional cause of the anterior occlusion is that the angle of the mandible is unusually obtuse, measuring 134°. If correction were made by slowly forcing the upper premolar teeth into position, it should lengthen the arch, which would also assist in the improvement of the position of the anterior teeth. This might be all that could be accomplished in the upper jaw. The fault of the lower jaw is at the angle, and if surgery can find any safe means of changing this angle, this would be the proper procedure.

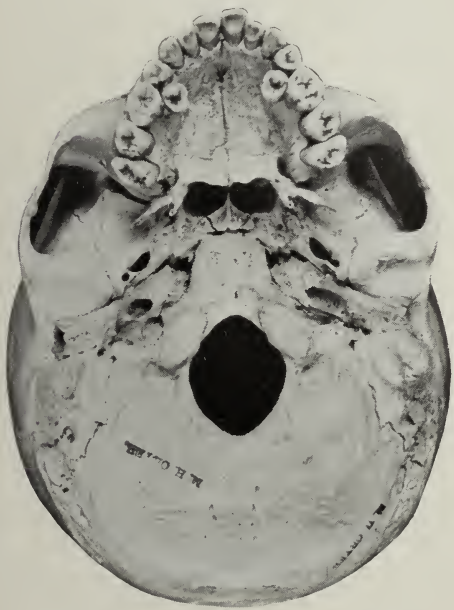
Fig. 13.

Fig. 14.

Side view of skulls. The following illustrations are taken from various side views of the skulls, shown with the mandible in position.

Fig. 16 shows a typical skull of a white person of about twenty-five years of age (see mandible in Fig. 1, and base of skull in Fig. 9) which I have taken as the foundation for nearly all my studies of the face, it having been used by Gray, Gerrish, Angle, and many others, as a generally typical skull. It is an ideal model for the surgeon to have before him when correcting irregularities, provided the patient's face and teeth possess the same characteristics and formation that we see in this skull. One of the greatest mistakes made by some orthodontists is that they are too liable

FIG. 15.



to take as models any good-looking jaws where the teeth are in regular alignment, shape, and occlusion, regardless of the fact that these regular types may not suit the special case. The teeth of this skull (Fig. 16) may be absolutely correct for an individual of about twenty-five years, but would not be so for the same individual much before that time. The surgeon should remember that both teeth-germs and teeth change position from the time they begin to develop until they are lost. Every tooth has a normal position, changing from day to day, which must be taken into consideration when changing position for better occlusion. I wish to draw special attention to the position of the condyle in the anterior portion of the glenoid fossa, and the relation of the ramus with the body of the bone,

FIG. 16.

the angle being 125°; the teeth are in typical position and occlusion.

Fig. 17 (see mandible in Fig. 2, and base of skull in Fig. 10) is of quite a different character. It is taken from the skull of one of the West African tribes,

FIG. 17.

the specimen belonging to Dr. E. T. Darby's collection. The skull would be classified by nearly all as prognathous. If, however, this man had lived until all of his teeth and their alveolar processes had been lost, it is doubtful if the jaws, especially the lower one, would then be considered prognathous. If we accept this, we must admit that this prognathous character was caused by the forward position of the teeth and their alveolar processes. The distance of 71 mm. from the cutting edge of the incisor teeth to the hard palate is greater than in any other skull I have measured.

Fig. 18 (see mandible in Fig. 3, and base of skull in Fig. 11) is made from a rather peculiar skull. From the anterior border of the foramen magnum to the vertical plane at the back of the skull it is similar to a typical Caucasian skull. The prognathous character is produced by the upper and lower jaws; the distance from the foramen magnum to the hard palate is 48 mm., 12 mm. longer than in the typical skull, so this abnormal protrusion of the upper jaw extends anteriorly from the foramen magnum. The protrusion of the lower jaw is caused by the obtuse angle of 135°, which is ten degrees greater than the typical. The teeth and alveolar processes are placed but slightly forward on the body of the bone, if we take the mental foramen as a fixed point. In this skull we have the two jaws abnormally forward of the typical position. The skull in itself is not of a prognathous character, although the basilar process of the occipital bone is longer than it should be.

Fig. 18.

It would give me much pleasure to hear the members of this society discuss the cause of the forward arrangement of the face as shown in Fig. 18. Is it the "result of mechanical stimulation"? I would also like to know how they would treat such a case. I am on record as to my method of treating the teeth and alveolar processes, if the upper jaw only were involved. (Dental Cosmos, September 1904, page 727, Fig. 22.) If the lower jaw were to be treated under similar conditions for anterior occlusion, I would change the angle from its present shape to one that would bring its anterior portion into the desired position. This I will refer to farther on.

Fig. 19, A (see mandible in Fig. 4 and base of skull in Fig. 13) is made from a heavy skull, with unusually large, strong jaws and heavy teeth, which are in fairly good occlusion, except that the left laterals are a little out of place. The extraordinary size of the jaws and the teeth produces a general appearance of prognathism, but the position of the teeth and their processes does not carry out this idea.

Fig. 19, B, is a side view of a Chinese skull, showing general roundness. On the left side there is an impacted lower third molar; in the upper jaw of the same side there is no evidence that the third molar ever developed.

We often hear that ancient skulls seem to have better teeth and belong to a more powerful race than exists to-day, but I am inclined to think that this is a mistake, as it has, thus far, been possible to duplicate almost any ancient skull I have ever seen by a modern one showing similar characteristics. Of course, I do not mean such jaws as are found in the Heidelberg or Sussex skulls, which are supposed to be anywhere from two to four hundred thousand years old.

Fig. 19, D, is made from the upper and lower jaws of an Australian aborigine, belonging to the collection of Dr. Edward C. Kirk, who kindly allowed me to use them. There is no caries in the teeth, but there is strong evidence of pyorrhea alveolaris. The arches are of good width, and more than likely the occlusion has been good, except that the bite has been about even, or edge-to-edge, especially in front.

Comparison of Fig. 19, C, made from the mandible of the modern jaw, with the aboriginal jaw, D, will show them to possess fairly similar characteristics, especially of the ramus and angle.

Many years ago Dr. Kirk discussed the change in the temporo-mandibular articulation which would be necessary to bring the teeth into occlusion, exhibiting a skull from which Fig. 21 is made.* This shows that in this deformed mouth, caused by disease and loss of teeth, it had been necessary for the left side of the mandible to move forward until the articulation was on the eminentia articularis, which permitted the few teeth remaining to come into occlusion. This action may have been partially volun-

FIG. 19.

A B C D

Fig. 20 is a side view of a skull (see base of skull in Fig. 15).

The occlusion of the six molars and the two bicuspids is fairly good, but the rest of the teeth are not in proper alignment, or occlusion, and there is an open bite. As pointed out under Fig. 15, this case should elicit an interesting discussion as to treatment.

* *Trans.* Dental Society of the State of New York, 1892, p. 111.

tary on the part of the individual, but I believe it was largely assisted by the force of vital instinct.

Another case may be interesting which will require three illustrations. Fig. 22 (and see mandible in Fig. 5, and base of skull in Fig. 12) gives a view of the right side of the skull. It will be seen that the three molars and one premolar of the upper jaw are missing. In the lower jaw, all the teeth except the lateral and central incisors have been lost.

Fig. 23 shows the interesting phase of this specimen; it gives a view of the left side of the skull, showing the upper and lower teeth in occlusion. The remarkable characteristic is the abnormally small ramus, a portion of the body of the bone being also unusually small. The condyloid process, instead of articulating in the glenoid fossa, articulated partly on the squamous portion of the temporal bone, and partly on the great wing of the sphenoid. There seem to be two ways by which this deformity could occur. One is by the lack of growth in the ramus and body of bone; the other theory is that the bone grew to its normal size, as there is evidence of its having articulated in the glenoid fossa. Some time after this an atrophied condition may have occurred which reduced the size of the ramus and part of the body; in order to keep up occlusion of

Fig. 20.

Fig. 21.

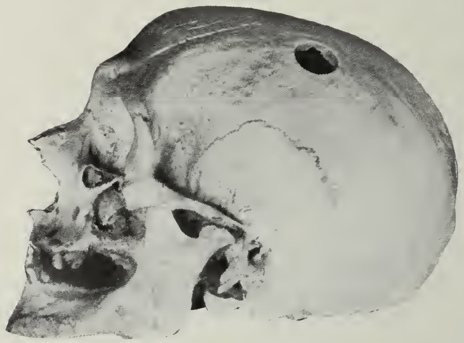


Fig. 22.

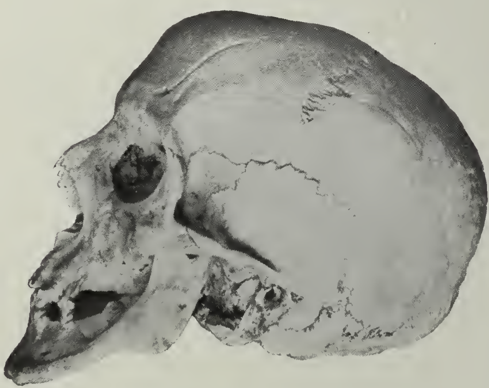
Fig. 23.



the teeth, the great vital instinct would cause the condyloid process to move forward, first articulating on the eminentia articularis, and, as the atrophy progressed, moving still forward to keep the occlusion, until the condyloid process reached the position shown in the illustration.

Fig. 24.

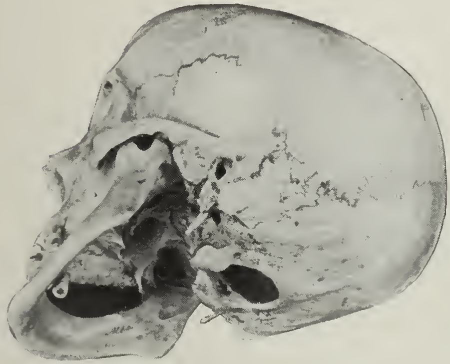


Fig. 24 gives an under view of the articulation shown in Fig. 23.

SOME OF THE CAUSES INFLUENCING PROTRUSION OR RETRUSION OF THE UPPER AND LOWER JAWS.

It is evident that the position of the upper jaw is more or less governed or influenced by the surrounding bones. For instance, the length of the basilar process of the occipital bone, the length of the body of the sphenoid bone, and the position of the pterygoid processes may cause variations in the distance of the teeth from the center of the base of the skull, or produce protrusion or retrusion of the jaws. Another influence as to position of the jaws lies in the greater or less degree of the height and curvature of the pharyngeal dome of the base of the skull. If this dome be of the height

Fig. 25.

shown in the diagram No. 9,* the face will be fairly typical.

In this diagram, No. 9, the height of dome, C to D, is about the average, viz, 21.5 mm.; in such cases the base of the dome or triangle will usually be short, in this case 42 mm., making the average typical face. (See Fig. 16.)

In diagram No. 11 the dome is but 16 mm. and the base of the triangle 48 mm., which proportion belongs to a greater or less degree to a face that is protruded. (See Fig. 18.)

Fig. 26.

The character of these pharyngeal triangles or domes will influence the lateral triangle of the mandible. These triangles are made by lines drawn from the condyloid to the angle, then to the symphysis menti and then back to the condyle.

---

* For further description of the triangles of pharyngeal dome and triangles of the mandible, see pp. 677–679.

Besides giving the lateral triangles of the mandibles of the skulls under consideration in this paper, I have incorporated those of a number of skulls of various ages commencing at eight months. (See pages 679 and 680—triangles reduced one-half—Nos. 16 to 27.)

Posterior occlusion. In posterior occlusion there are several factors that assist the orthodontist in bringing about satisfactory results. We have noticed that the vital instinct shows a strong tendency to carry the jaw, with the teeth and their alveolar processes, forward in search of occlusion. This must help greatly when force is applied to move the teeth anteriorly by bringing the jaw forward. I also believe it is possible to change the angle of the jaw, to a certain extent, by mechanical force applied to the teeth, which will allow the body of the bone to be carried forward.

Fig. 27.

Anterior occlusion. The extreme deformity of anterior occlusion is perhaps the most difficult to correct of all abnormal conditions that are likely to come to the orthodontist's notice. These variations in the lower and upper jaws should suggest the study of a skull which has that particular deformity which is to be found in the patient whom the surgeon is called upon to treat. A great many practitioners are quite satisfied to study and work from plaster casts of the mouth, which may be all that is necessary for the correction of ordinary irregularities, but I fear that it is not enough when one wishes to correct very marked anterior or posterior occlusion. Another important aid in making a diagnosis consists in obtaining a good X-ray examination, which should show the position of the condyle in the glenoid cavity, and indicate the general shape of the ramus and its relation to the body of the jaw. It will also show the relations of the teeth in both upper and lower jaws.

Fig. 28.

Fig. 25 is made from an X-ray picture of a living subject having a marked anterior occlusion. It can readily be seen that the angle of the mandible is at fault, and that the condyloid process is curved somewhat backward, naturally throwing the balance of the mandible forward.

Fig. 29.

Fig. 26 is made from an X-ray picture of the left side of a patient, showing extreme anterior occlusion.

SURGICAL OPERATION FOR ANTERIOR OCCLUSION.

In conclusion, I wish to suggest an operation for anterior occlusion which cannot be otherwise corrected by ordinary orthodontic procedure. Several cases have been reported in which a section of the bone was removed from each side of the mandible, although there was no evidence shown that the length of the body of the bone was at fault. There was also a case reported where the angle had been changed by making a straight incision at the angle. Many of the illustrations in this article show a normal condition of the condyle, as well as of the teeth and alveolar process, but digital as well as X-ray examination demonstrates that the cause of the anterior occlusion, in many cases, exists in the angle of the jaw. Wishing to experiment with a skull that had a marked anterior occlusion and an obtuse angle, and failing to find one, I selected a skull that exhibited fairly normal occlusion, and had its original capsular ligament in place. By cutting semicircular incisions through the angles of the jaw, I was able to carry the body with the teeth forward, producing anterior occlusion and open bite. Fig. 27 is made from a photograph of the right side of the skull, showing the position of the teeth. The mark of the incision at the angle is shown, with two wire sutures to hold the ramus and body together. In carrying the body of the jaw forward, the angles are increased in proportion.

FIG. 30.

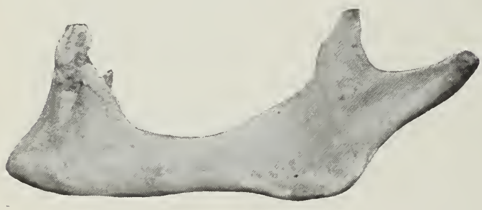

FIG. 31.

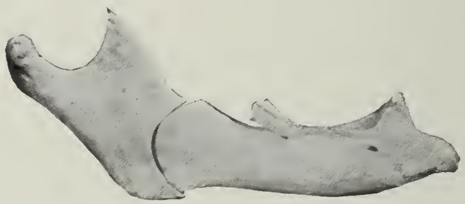

If the wire sutures be cut, the jaw can be pushed back to its original position and occlusion, as shown in Fig. 28. Fig. 29 shows the opposite side of this jaw. The advantage in using a semicircular incision instead of the straight one, consists in that it does not necessitate the removal of a V-shaped section or leave an open space (see Fig. 32). If the artificial deformity of the jaw had been natural, then the cutting of the semicircular incision, as described, would make a successful correction.

FIG. 32.

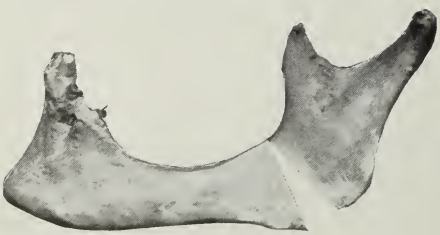

FIG. 33.

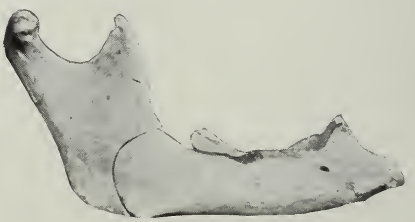

Fig. 30 shows an unusually large obtuse angle, viz, of 135°.

Fig. 31 shows a semicircular cut at the base of the ramus. By carrying the body forward, a greater obtuse angle is made.

Fig. 32 shows the same mandible as Fig. 30, showing the effect of a straight incision across the base of the ramus. The body of the bone is pushed back to lessen the angle to 110°, but it leaves an ugly V-shaped space, while in Fig. 33, showing the semicircular incision, there is no space left, and we still get the same reduction of the angle. In making this semicircular incision, I would recommend the use of a large fissure bur or a small spiral osteotome driven by the surgical engine; or it might be even better to use an ordinary cranial trephine with three-fourths of the circumference and the side cutting teeth taken away; then, by a to-and-fro motion, the bone can be cut through. In adjusting the jaw to its new position, any necessary removal of a little of the bone on either side of the incision could be made by a small spiral osteotome. It may be possible in some cases to make the incision high enough in the ramus to avoid cutting the inferior dental nerve and vessels, or, if the incision were made so that the center of the curve could come above the inferior dental foramen, the severing of the nerve might be avoided. The parts could be held together by wire sutures, assisted by a maxillo-mandibular splint, which should be made before the operation. There would be no danger of septic conditions if the operation were performed with surgical care, but when a section is removed from the body of the bone it is impossible to avoid infection.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

SYPHILITIC HYPOPLASIA OF THE TEETH.*

By JOHN BETHUNE STEIN, M.D.,

PROFESSOR OF PHYSIOLOGY AND DIRECTOR OF THE LABORATORY FOR NORMAL HISTOLOGY, NEW YORK COLLEGE OF DENTISTRY: LATE INSTRUCTOR IN GENITO-URINARY DISEASES, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA UNIVERSITY), NEW YORK.

(A synopsis of a demonstration upon "Syphilitic Hypoplasia of the Teeth," before the Academy of Stomatology of Philadelphia, at its monthly meeting, held at the College of Physicians, Philadelphia, February 24, 1913.)

HYPOPLASIA (misnamed "erosion" and "atrophy") of the teeth takes first place among the stigmata caused by heredo-syphilis. It appears in 39 to 47 per cent. of cases, according to such an authority as Fournier, who maintains that 80 per cent. of all cases of hypoplasia are caused by heredo-syphilis.

Syphilitic hypoplasia of the teeth is of great diagnostic importance, and although it has been recognized for many years, the interest in this affection seems of late to slumber in No-man's-land, concerning apparently neither physician nor dentist.

Some forms of hypoplasia of the teeth are certainly syphilitic, others may be attributed to syphilis, and others are certainly not caused by syphilis. Non-syphilitic hypoplasia of the teeth has been observed in the bull and the dog, as well as in man. The hypoplasia which affects the teeth at hazard and without method, depending upon some local accident or affection, and apparently having no significance, or a significance at present unknown, resembles in no way the marked characteristics of a syphilitic hypoplasia.

Syphilitic hypoplasia of the teeth appears to be caused not directly by the *Treponema pallidum* in the tissues of

* I am indebted to Dr. Francis Óváry for his drawings of specimens and diagrams.—J. B. S.

Fig. 1.

the embryo, fetus, or young child, but indirectly by the severe disturbance in the metabolism of the young organism brought about by the syphilitic infection —the extent of the hypoplasia depending upon the seriousness of the disturbance, which in turn is determined by the amount and duration of the infection. The syphilitic infection may be so great, and the disturbance in metabolism so severe, that the cells of the embryo, fetus, or young child are unable to resist it, and, instead of stigmata being produced, death results. Heredo-syphilis is syphilis acquired *in utero* from the mother, and is essentially the same as self-acquired syphilis.

In recognizing the syphilitic stigmata referred to in this article, and in understanding the significance of each, the reader will be assisted by his knowledge (*a*) of the development of the teeth, especially regarding their several periods of calcification (dentinification) and eruption, (*b*) of the fact that dentin always begins to form at the summits of dentinal papillæ, so that the dentin caps are formed before amelification takes place, (*c*) that, later on, dentinification and amelification proceed synchronously, and (*d*) that the process of dentinification, which is remarkably regular, proceeds from the summit of the dentinal papillæ, and gradually forms the crown, neck, and root. (See Figs. 1 to 3.)

The time of the inception of calcification of the teeth as given by Peirce is not altogether correct.

Dentinification, however, takes place much earlier than is generally supposed. According to Magitot and Legros, the dentin caps of the teeth begin to form approximately as follows:

DECIDUOUS TEETH. *Incisors and canines:* 16th to 17th week of intra-uterine life. *First and second molars:* 17th to 18th week.

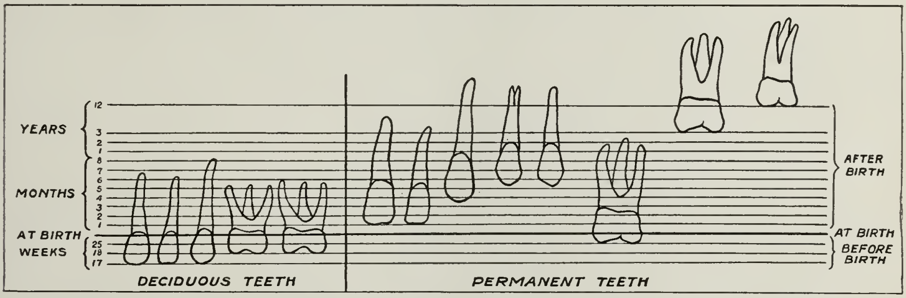
PERMANENT TEETH. *First molars:* 6th month of intra-uterine life. *Incisors :* First month after birth. *Canines:* 3d to 4th month. *Bicuspids:* 6th month. *Second molars:* 3d year. *Third molars:* 12th year.

(Black, Noyes, Hill, Redier, Zinsser, Dieulafé, Herpin, Fournier, Debrirre, Pravaz, Röse, and others have accepted as correct the chronology of Legros and Magitot.)

At birth no permanent teeth have begun to calcify except the first molars.

Fig. 4 shows the time of the inception of calcification (dentinification) of the teeth.

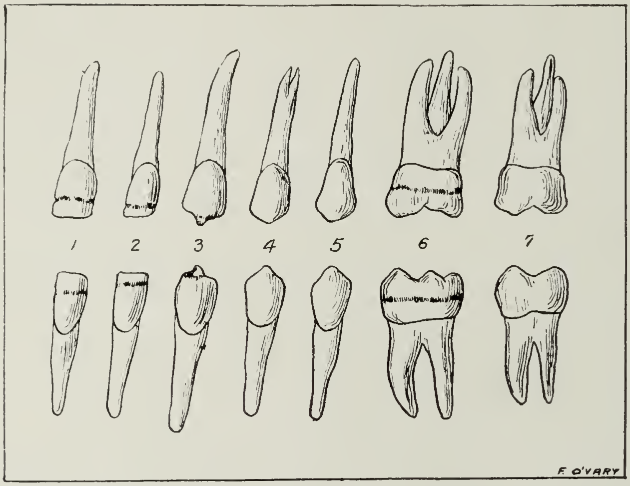
FIG. 4.



The time of the inception of calcification (dentinification) of the teeth.

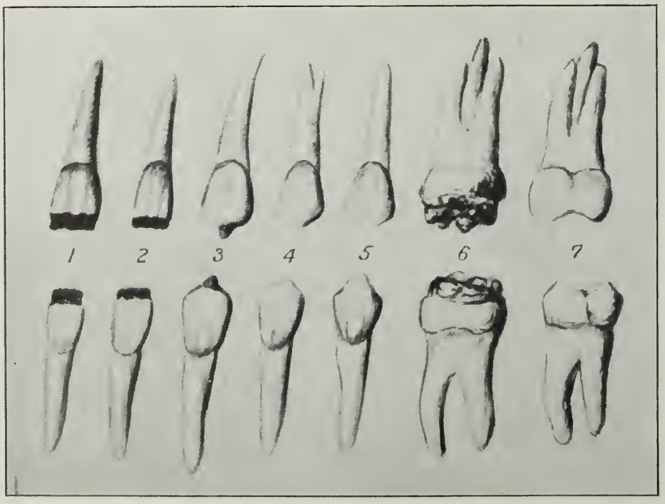
A tooth unaffected during its development by the morbid influence of syphilis erupts complete in form and structure. Syphilitic stigmata upon the teeth can be produced only during the development of the teeth, and are the result of some interruption in the process of calcification. Suspended or imperfectly performed calcification produces irreparable stigmata which may appear on any part of the tooth, from its morsal surface to its gingival margin, depending upon the time when the syphilitic infection is sufficient to produce them. If the disturbance caused by the syphilitic infection is sufficiently active at the time when dentinification is about to begin, the hypoplasia will be upon the morsal surface of the tooth; but if the syphilis is active later on, the stigma may show itself at a higher level, upon the facial, lingual, and mesial surfaces of the tooth —upon that part of the tooth which is then undergoing development. Thus it

FIG. 5.



A semi-diagrammatic representation of a systematized hypoplasia of several kinds of upper and lower teeth (incisors, canines, and molars). The general systemic disturbance which must have caused these stigmata occurred about the fourth month after birth. (The third molars have not been inserted in the drawing.)

FIG. 6.



A semi-diagrammatic representation of a systematized hypoplasia of several kinds of upper and lower teeth (incisors, canines, and molars). The general systemic disturbance which must have caused these stigmata commenced about the twenty-fifth week of intra-uterine life and continued up to about the fourth month after birth. (The third molars have been ommitted.)

is possible to tell, from stigmata on the teeth, the time when some vicious disturbing influence attacked the embryo, fetus, or newborn child.

The apparent relationship, already referred to, between the degree of syphilitic infection and the degree of syphilitic hypoplasia is indicated by the fact that the syphilitic hypoplasia of the dentin and the enamel may be slight, or, extending through various degrees, very marked. The dentin may be covered with but poorly differentiated enamel or no enamel, or the tooth, the cells of its dentinal germ having been destroyed, may not be formed at all.

Syphilitic hypoplasia of the deciduous teeth rarely occurs, because the beginning of dentinification for these teeth takes place, as we have said, from about the seventeenth to the eighteenth week of intra-uterine life, and a fetus infected with syphilis at this time usually dies. Syphilis is a potent abortionist. It is possible, when the syphilitic mother is given anti-syphilitic treatment, that the life of the fetus may be saved.

The permanent first molar, incisor, and canine teeth are the ones which show most frequently the evidences of heredo-syphilis, because the first molars are beginning to undergo dentinification during the last months of fetal life, and the incisors and canines during the first three or four months after birth. (See Figs. 4 and 6). It is at this time that the syphilitic process is most intense, frequently causing the death of the fetus or child.

Suppose the syphilitic infection, theretofore not sufficiently active to interfere with the process of calcification, is most intense at the fourth month after birth. Calcification of the deciduous teeth having already taken place, no evidences of syphilis will be seen upon them. But because, at this time, only about 1.5 to 2 mm. of the crowns of the incisors have undergone dentinification, the stigmata will, after the eruption of these teeth, be evident on them and at the same level, viz. 1.5 to 2 mm. up on the crowns. Dentinification of the canines is beginning at this period, consequently the summit (about 1 mm.) of these four teeth will be affected. The bicuspids will not yet be affected, as dentinification has not yet begun. But the first molars, at the fourth month after birth, have considerable dentin (one-half or two-thirds) formed for their crowns, consequently the lesions will appear about halfway up, or two-thirds the way up, on the crowns of these teeth. (See Fig. 5.)

The second and third molars cannot be affected, as dentinification does not occur until some years later.

The stigmata of developmental syphilitic hypoplasia are usually found upon the same class of teeth at about the same level on their crowns.

Some general morbid influence produces the hypoplasia, for a local cause would produce a more or less local result, *i.e.* a periosteitis of the left half of the mandible might interfere with the development of the teeth on that side, but not upon the other side nor with the teeth of the maxilla.

A general disturbance in metabolism occasioned by a severe general systemic syphilitic infection of the embryo, fetus, or young child, might produce—though a local cause could not produce it—the following:

(1) Multiple and disseminated stigmata of the teeth, both in the maxilla and the mandible.

(2) Symmetrical stigmata here and there upon homologous teeth.

(3) Systematized stigmata at the same level on teeth of the same kind, but at a different level on different kinds of teeth.

The most characteristic stigmata of the teeth of heredo-syphilis are—

(1) Hypoplasia of the four first molars.

(2) A systematized hypoplasia upon the several upper and lower teeth.

(3) Hutchinson's teeth.

HYPOPLASIA OF THE FOUR PERMANENT FIRST MOLARS.

The morsal surface of the four permanent first molar teeth is completely changed. In infancy and adolescence, two-thirds or three-quarters of each tooth, nearer its morsal surface, is hypoplasic, diminished in all its diameters, eaten away, and marked off from the rest of the tooth by a circular constriction so that there appears to be a small stump-like tooth—a stump of undeveloped dentin—emerging from the remaining, apparently normal, crown. This surface is extremely irregular, with rough, conical, pointed eminences, which are at times markedly anfractuous, exhibits fissures which are more or less deep and penetrate even the dentin, and has a yellow, brown, dirty gray, or black appearance. This hypoplasic stump, partially covered with enamel, is gradually worn away and crumbles to pieces, so that it finally disappears, and, with the crown of the tooth thus shortened, the morsal surface becomes flat, yellow in color, and surrounded by a zone of white enamel. This symmetrical hypoplasia of the morsal surfaces of the four permanent first molars is of the greatest importance in the diagnosis of heredo-syphilis. Later on, caries attacks the central portion of the morsal surface of these teeth, frequently destroying them. Thus, the heredo-syphilitic may have either a hypoplasia of the crowns of his first molars, or caries at the center of the remainder of the crowns of three or four of his first molars, or a loss of some or all of these through caries, or a combination of these conditions in the first molars. (See No. "6" in Fig. 6, also Figs. 8, 9, 11, and 12.)

The hypoplasia of the morsal surfaces of these first molar teeth, which must have begun at some time after the beginning of the sixth month of intra-uterine life, proves that the fetus has been attacked by some disease at this time, and syphilis appears to be the disease.

Fig. 7.

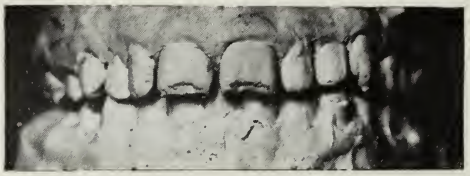


Fig. 8.

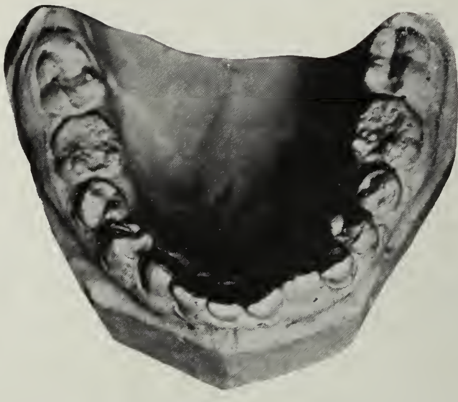
Fig. 9.



Figs. 7, 8, 9. Heredo-syphilitic, eighteen years of age, with interstitial keratitis, hypoplasia of four first molars, Hutchinson's teeth with crescents not completely formed. Delayed dentition. Supernumerary upper left lateral incisor.

The case shown in Fig. 13 is most important.

I quote from "Diseases of the Mouth" (F. Zinsser–J. B. Stein):

hypoplasia of the morsal surface. The canine and bicuspid teeth show on their surfaces slight erosions and transverse furrows.

This is the result of a condition existing

FIG. 10.

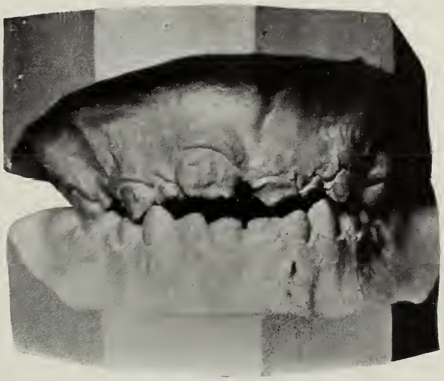


FIG. 11.

FIG. 12.

FIGS. 10, 11, 12. Teeth of an heredo-syphilitic, thirteen years old, whose father, mother, sister, and two brothers were also syphilitic, all giving a positive Wassermann reaction excepting the youngest brother (two months old). An examination of his blood was not made because the treponema pallidum was found by means of the dark-field microscope in the exudate taken from the mucous patches about his mouth. (Case of Dr. Otto Lowy.)

This case shows delayed dentition, hypoplasia of three of the first molars (the left upper first molar not having erupted), persistence of all the deciduous molars in the mandible and the second deciduous molars in the maxilla, a saw tooth, microdontism, amorphism of teeth, Hutchinson's crescents on the upper lateral incisors, and an "open bite," or absence of the "sign of the artichoke."

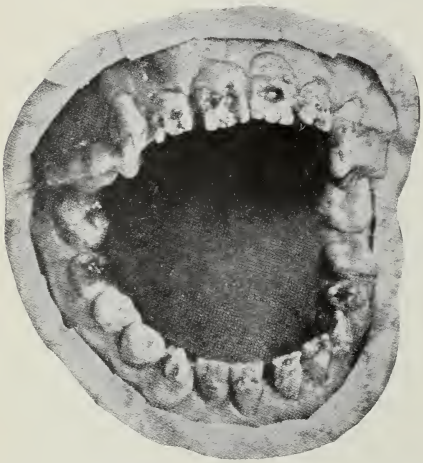
On the facial surfaces of all the upper and lower incisor and canine teeth are several furrows and cuplike erosions, and all their morsal surfaces are notched in several places. All the first molars are missing except the lower right one, in which there is a central caries, apparently following a developmental before birth and continuing to the end of the first or part of the second year of life.

The history of this case is very instructive. The patient, a boy twelve years old, had been treated a year and a half for a parenchymatous keratitis. The diagnosis of syphilis was not made, and anti-syphilitic treatment was not energetically applied because the keratitis did not react well to mercury. The Wassermann reaction was negative, there were no other symptoms of heredo-syphilis, and the condition of the teeth was attributed by me (Zinsser) at that time, to rhachitis.

A year later the boy returned with a severe syphilitic perforation of the hard palate and a positive Wassermann reaction. If the hypoplasia of the lower right first molar had been recognized as a sign of heredo-syphilis and energetic anti-syphilitic treatment resorted to, the patient would have been spared the severe disfigurement.

Although the Wassermann reaction is usually negative in heredo-syphilis,

FIG. 13.



Showing a more or less general hypoplasia of the teeth.

Noguchi and others claim that the luetin reaction of Noguchi is valuable in detecting heredo-syphilis.

SYSTEMATIZED HYPOPLASIA UPON THE SEVERAL KINDS OF UPPER AND LOWER TEETH.

This form of hypoplasia affects several kinds of teeth—the teeth of one kind at one level, and those of another kind at another level. The hypoplasia is multiple, being found as a rule on—

(1) All the incisor teeth (upper and lower).

(2) All the canines (upper and lower).

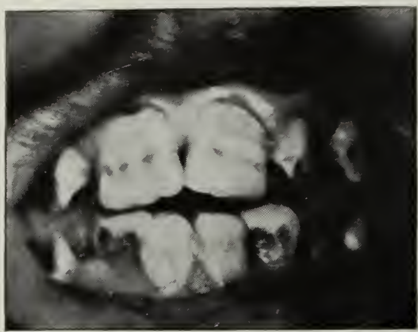
(3) All the first molars (upper and lower).

It does not seem to affect the bicuspids or second and third molars. (See Figs. 5 to 12.)

STIGMATA OF CROWNS OF TEETH IN THE FORM OF PITS AND FURROWS, AND HONEYCOMBED TEETH.

The "pits" in the teeth vary in size; they may be very small, like the depression made in soft wax with the point of

FIG. 14.



This case shows pits on the teeth, saw-teeth, hypoplasia of morsal surfaces of the upper lateral and all the lower incisors and upper left canine, and microdontism and amorphism of teeth. The patient was thirteen years of age, and but 4 ft. 1 in. in height, showing all the signs of general infantilism, and a persistence of the deciduous upper second molars, hypoplasia of the two upper and loss of the two lower first molars, and delayed dentition of three second molars, an heredo-syphilitic chorioiditis, and a positive Wassermann reaction.

a pin, or they may be large, deep, and similar to a depression made in soft wax with the head of a match. The surface of these pits is irregular, and in young teeth is white, but later becomes gray, brown, or even black. These pits, varying in depth, may be very superficial, with a slight covering of enamel, or may extend a considerable distance into the dentin. They involve by preference the incisors, especially the upper central incisors. (See Figs. 13, 14, 15, and 22.) They vary in number, and when several exist they are usually disseminated without order, but at times are arranged in a horizontal line, and more rarely in two superimposed horizontal lines separated from each other by one or two millimeters.

Stigmata in the form of "furrows" (see Fig. 15, where the pits as well as furrows are shown) are more common than pits upon the crowns of teeth. The tooth appears as if it had been scratched transversely, and the scratch, furrow, or sulcus encircles the tooth horizontally. The furrow may be so superficial that it is likely to escape notice, and resembles a line on a sheet of paper made by the pressure of one's finger-nail. This lesion, which is not very evident, gives one the impression that it is a transverse line, not a groove, crossing the tooth. The existence of the groove, however, is proved by scratching the crown of the tooth with the finger-nail. Sometimes the groove may be from one-quarter to one-half a millimeter deep, with little or no enamel covering. This form of lesion later becomes gray or black, and so more striking and evident.

Instead of the stigma taking the form of a single groove traversing the circumference of the tooth horizontally, there may be two, three, or more of them. The multiple grooves, which are superimposed horizontally on the crowns of the teeth, are located nearer the morsal surface than the gingival margin of the tooth. The grooves are separated by bands of enamel, which form light ridges between them. Such teeth have been called by the French *dents en étage, dents en escalier,* or *dents en gradin.* We might call them "graded" or "intermittently affected" teeth. The grooves, alternating with the ridges, indicate alternating periods of exacerbations and remissions of the disease. (See Fig. 15.) The morsal surface of such teeth, where the first grade or step of the hypoplasia appears, is usually thin, rough, irregular, brownish in color, and without any enamel covering. It rapidly falls to pieces and disappears, so that in adolescence or in young adult life the tooth is deprived of its morsal surface, and the shortened crown of the tooth appears as if this morsal surface had been cut off transversely. Stigmata in the form of furrows usually appear on the incisor teeth, but they may appear also upon the canines or first molars.

Sometimes a third, a half, or three-fourths of the crown of the tooth is hypoplasic, so that its surface is uneven, rough, and at times anfractuous, and appears grayish yellow, even grayish black. Fournier calls such a lesion *erosion en nappe.* Tomes calls the teeth "honeycombed." (Fig. 16.)

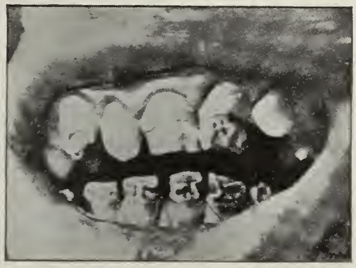
Typical syphilitic stigmata in the form of transversely arranged furrows and pits on the facial, mesial, and lingual surfaces of incisors.

Fig. 16.



Honeycombed teeth, amorphism of the teeth, microdontism, hypoplasia of upper canines. (Fournier.)

Among the numerous forms of hypoplasia of the morsal surfaces of the incisor teeth, the following are the most

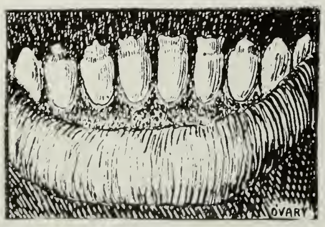
Fig. 17.

Teeth of heredo-syphilitic (?), eleven years of age. Hypoplasic flattening of the morsal surfaces of the upper central incisors, hypoplasia of canines, amorphism of teeth. Absence of upper right lateral incisor. Patient had a hypoplasia of the morsal surfaces of the first molars, more or less general venous ectasia, general infantilism, a high and contracted dental arch, adenopathy of epitrochlear lymph nodes, and had undergone two operations for adenoids.

frequent types: (1) Flattened. (2) Saw-like. (3) Stunted.

In the flattened type, the summit of the tooth is flattened on its facial and lingual surfaces, resembling somewhat a

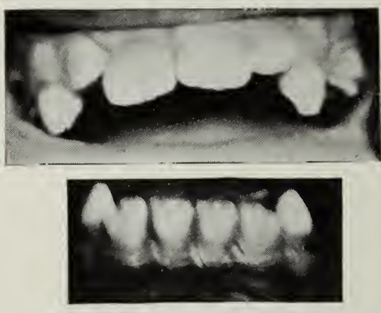
Fig. 19.



"Stunted" and "clove" teeth.

tooth which had the summit of its crown compressed on its four sides in a vise. This hypoplasic surface appears yellow, gray, or even black at some points, and is irregular, uneven, and roughened with more or less vertical furrows. (Fig. 17.) I have seen a case where this stigma extended on the crown of the tooth to the height of 3 mm. from the morsal surface. It is evident that this portion of the

Fig. 18.



Saw teeth, microdontism, and amorphism of teeth.

tooth is friable and easily falls to pieces. Fournier compares it to "a sheet of heavy paper."

The "saw teeth" have morsal surfaces which are irregular and rugged as if fine vertical incisions or little grooves had been filed on them. (Figs. 10, 13, 14, and 18.)

The teeth with "stunted" morsal surfaces have circular grooves about 2 or 3 mm. from their summits, from which emerge amorphous yellowish caps. Sometimes these caps appear like small teeth

Fig. 20.

Characteristic syphilitic hypoplasia of the morsal surfaces of two upper canine teeth. Typical Hutchinson teeth. (Fournier.)

placed upon larger ones, at other times the caps have small buds upon their summits, giving the caps the appearance of a clove. "Stunted" teeth with such caps are sometimes called "clove teeth." (Fig. 19.)

Syphilitic hypoplasia of the canine teeth occurs nearer the morsal than the gingival margin of these teeth. A circular constriction is evident near their morsal surface, the hypoplasic portion appearing somewhat like a teat upon the end of the teeth. (Figs. 5, 6, 16, 17, 19, and 20.)

HUTCHINSON'S TEETH.

Jonathan Hutchinson was the first to describe this extraordinary dental stigma and explain its pathological significance. This form of dental hypoplasia is charac-

FIG. 21.

Typical Hutchinson teeth. (Fournier.)

terized in its most typical form by a marked crescentic indentation of the morsal surfaces of the two upper central incisor teeth. (Fig. 21.) The term Hutchinson's teeth has been misapplied to any other tooth having a similar depression upon its morsal surface. This form of hypoplasia has also been seen in heredo-syphilitics upon the four lower incisor teeth, and even upon canine teeth. According to Hutchinson this term is to be applied to the upper central incisor teeth of the second dentition presenting a semilunar depression on their morsal surfaces, the teeth being "screwdriver-shaped" (wider at the neck and narrowing toward the morsal surface) and converging obliquely. Any other dental stigma, or this stigma upon any other tooth than an upper central incisor "—is not my tooth," says Hutchinson. (Figs. 7, 21, 22, 23, and 26.)

This lesion, when typical, has such an individuality that no other dental lesion can be confused with it. It can be recog-

FIG. 22.

Typical Hutchinson teeth in a patient twenty-two years of age. Here the crescents have nearly disappeared, but the beveling on the facial surface of the teeth is still evident. Notice the pits on these teeth, especially the upper left central incisor. The cause of this patient's condition, facial paralysis, was first recognized through these two upper central incisors. His blood afforded a positive Wassermann reaction, and examination of his eyes revealed an heredo-syphilitic chorioiditis.

nized at a glance. It is impossible to misunderstand it, although it varies in character with the age of the heredo-syphilitic. When the tooth erupts, the

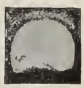
FIG. 25.



FIGS. 23, 24: An early stage of Hutchinson's teeth, showing the crescents before hypoplasic tooth structure has been wholly worn away. (Fournier.) FIG. 25: A Hutchinson's tooth at about twenty-eight or thirty years, when the crescent had disappeared entirely. (Fournier.)

characteristic semilunar indentation upon its morsal surface does not exist. The place where the future crescent is to form is filled in with hypoplasic tooth structure, either in the form of acuminate buds, points, spicules forming a sort of fine denticulation (Fig. 24), or in the form of a more or less homogeneous lobular mass (Figs. 7 and 23). This hypoplasic dentin, which is not covered with enamel, is non-resistant, friable, and rapidly crumbles and wears away, so that after a few years it entirely disappears, and in its place we have the crescentic notch.

During adolescence, the morsal surfaces of Hutchinson's teeth change, and at maturity lose their characteristic appearance. The arcs on these morsal surfaces gradually diminish, at from twenty

Fig. 26.

Hutchinson's teeth and Hutchinson's crescents on the lower incisors. (Fournier.)

to twenty-two years (Fig. 22) are noticeably effaced, and at about the twenty-fifth year the characteristic crescents disappear entirely, and the morsal surfaces become rectilinear. But at the twenty-fifth year an important characteristic of the lesion—the beveling of the inferior facial surfaces of the teeth—still persists, for the crescents of Hutchinson involve not only the morsal surface of the tooth, but also the facial surface, in that a beveling extends from above downward, slanting from the facial to the lingual surface of the teeth, and so involving more of the facial surface. These bevels which crown the crescentic notches are the last of the stigmata to be effaced through usage of the teeth, and they are the last vestiges of Hutchinson's teeth, and disappear at about the thirtieth year. (Fig. 25.) The teeth then are shorter, and have lost all their diagnostic significance.

Hutchinson's "triad," viz, Hutchinson's teeth, an interstitial keratitis, and otitis media, is pathognomonic of heredo-syphilis.

The so-called "crescentic notch" of Hutchinson may also be seen upon the following permanent teeth:

(1) The upper lateral incisors. (Fig. 10.)

(2) All the lower incisors. (Fig. 26.)

(3) Very exceptionally upon the canines.

Legros, Hutchinson, Moon, and Fournier report having seen Hutchinson's crescent upon one upper central incisor tooth, the other being perfectly normal.

The upper incisor teeth, especially the central incisors, may have a screwdriver shape, but neither converge nor have crescentic notches upon their morsal surfaces. Such teeth have not been conclusively shown to be of heredo-syphilitic origin.

DENTAL INFANTILISM.

Microdontism or persistence of the deciduous teeth may serve as a stigma of heredo-syphilis. Microdontism of all the teeth is rare, but a number of teeth—mostly the upper and lower incisors, and occasionally single teeth—exhibit this condition. (See Figs. 10, 11, 12, 17, and 18.)

The so-called *persistence of the deciduous teeth,* i.e. their non-replacement by the permanent teeth, occurs more frequently than is generally supposed—in one-third of the cases of heredo-syphilis, according to one observer, Chompret. (See Figs. 11 and 12.) Few physicians or dentists have recognized this condition in heredo-syphilis. It is a very important diagnostic sign. The deciduous teeth which remain in the mouth for a longer time than is usual are, in order of frequency, the following: (1) The second molars, (2) the first molars, (3) the canines, (4) the incisors.

The persistence of the deciduous tooth appears to be due to the absence or arrested development of the tooth which should displace it.

ABSENCE OF CERTAIN TEETH.

The absence of certain teeth is a stigma which occurs in heredo-syphilis, implying a non-formation or complete arrest in development of the dentinal germ. (See Figs. 17 and 26.)

Conditions frequently attributed to heredo-syphilis are: (1) Abnormalities in the position of teeth. (2) Amorphism of the teeth (Figs. 10, 17, and 18)—teeth with crowns somewhat resembling sharks' teeth, piano-keys, pebbles, squares, twisted teeth, pegged-shaped teeth, uni- or tri-horned teeth, or teeth with numerous small eminences upon them; and less frequently—

(1) Vulnerability of the teeth and marked liability to caries, resulting in premature edentation.

(2) The "open bite," or, as Fournier called it, the absence of "the sign of the artichoke." (Fig. 10.)

(3) Asymmetry of the superior maxillary bones. Prognathism and deformities of the palate. Supernumerary teeth. (See Figs. 7 and 8.)

What diseases are met with during intra-uterine and first months of extra-uterine life, which would profoundly affect the cells of the entire organism, and the cells of the dentinal germs in particular?

Rhachitis rarely occurs during the first six months of life, but usually in the second year. Today, variola is seldom met with. Scarlatina, measles, diphtheria, and typhoid fever are rarely observed during the first year of life. Rheumatism seldom occurs before the fifth year. Can it be said that a disturbance in metabolism occasioned by gastro-enteritis could cause hypoplasia of the morsal surface of the permanent first molar teeth?

Has an authentic case been recorded either of hypoplasia of the crowns of the four permanent first molars, or of Hutchinson's teeth, or of a systematized hypoplasia of certain kinds of teeth which was caused by any disease other than syphilis.

Heredo-syphilis is essentially a dystrophic disease, and exercises its morbid influence especially during intra-uterine life and the first months after birth, at a time when dentinification and amelification is beginning and progressing.

The diagnostic significance and economic importance of syphilitic hypoplasia of the teeth should be appreciated by all interested in dental, oral, moral, social, and mental hygiene.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

CHRONIC ALVEOLAR OSTEOMYELITIS (PYORRHEA ALVEOLARIS) —ITS TREATMENT WITH VACCINES.

By LEON S. MEDALIA, M.D., Boston, Mass.

(An address delivered before the Merrimack Valley Dental Association, at Haverhill, Mass., May 14, 1913.)

IT is indeed a great pleasure to address you this evening on this important subject. This disease, alveolar osteomyelitis or pyorrhea, cannot be discussed too much, owing to its prevalence, the hopelessness of the old method of treatment in curing it, as well as to its far-reaching sequelæ—the consequent oral sepsis and the systemic diseases.

I shall endeavor in my address this evening to give you in as simple language as possilbe a brief *résumé* of my personal work on this subject, the underlying causes of this disease, the theoretical reasons for the vaccine treatment, and a brief summary of the clinical results obtained with this new method of treatment.

Those of you who are specially interested will find a thorough discussion of the subject and a detailed description of my studies and observations of 115 cases in the article which I read before the National Dental Association last September and which was published in the DENTAL COSMOS of January and February of this year.

The bacteriological investigation of the already reported cases, together with the results obtained with the vaccine treatment, especially with autogenous vaccines, helped to establish the etiological or causal relation of the bacteria isolated from the pus to the disease "pyorrhea," and at the same time it established the value of the vaccine method of treatment in this disease.

INAPPROPRIATE NOMENCLATURE.

The large number of different misnomers by which this disease has been designated, I found, could be attributed to the prevalent erroneous anatomical description of the tissues immediately surrounding the root of the tooth and its relation to the socket. This has also been at the bottom of our incorrect conception of the etiology of this disease. Thus, for instance, while almost all authorities and text-books refer to that tissue as the periosteum or peridental membrane, Malassez showed this to be nothing but an alveolo-dental ligament, and not an enveloping membrane or periosteum, its function being that of a ligament and not of a "cushion." We thus have a circular ligament which keeps the tooth suspended in the alveolar cavity.

Between the ligament bundles emanating from the root of the tooth, and which are attached to little bony spicules in the alveolar process, there are spaces filled with loose cellular tissue or medullary tissue communicating with other neighboring medullary spaces of the spongy bone of the alveolar process. According to him, also, the alveolar process is not a bone distinct from the maxilla, but it is nothing more than the thinned-out edges of the maxillary bones and their bony offshoots, and instead of the socket being lined by a thin, smooth plate of compact bony substance, it really is an enlarged marrow space of the maxilla.

His description and plates of the anatomy of this part are so conclusive that I personally could not help but side with him.

Now, since the disease, though it begins with an inflammatory process of the gum margin, involves the alveolar bone and tooth socket, which become necrotic, this socket being an enlarged medullary space of the maxillary bones, the only name for such an affection would be an alveolar osteomyelitis. It being a chronic disease as a rule, I therefore refer to it as a chronic alveolar osteomyelitis.

ETIOLOGY.

As to the causes of this disease, I found that the mechanical causes are by far the most important ones in starting the disease, but on the whole less so in keeping it up; while the local infectious causes, on the other hand, I found more important in keeping up the disease. Among the local mechanical causes, tartar deposits and calculi are the most important. The local infectious causes comprise the group of bacteria capable of pus production which are practically always in the mouth, "laying for" a chance to attack tissues that have lost their natural resistance due to mechanical irritations, etc. The most important ones are pneumococcus (in chains), staphylococcus, streptococcus, and M. catarrhalis. They are the ones responsible for keeping up the disease.

I have emphasized in the already mentioned paper the importance of sterilizing the instruments after treating an affected tooth and before beginning the scaling or cleaning of an unaffected tooth in the same patient. This being so important, and so commonly overlooked, I feel that I cannot emphasize it too strongly. The prophylactic importance of this procedure is perfectly obvious. (The best way of sterilizing instruments during the progress of an operation is to dip them in a jar of alcohol and then burn off the alcohol. This can be readily done by bringing the alcohol-saturated instruments in contact with the flame of the alcohol lamp which is almost always found on your operating table.)

As to systemic causes, they are more in the nature of predisposing causes. By that I mean a general lowered resistance, and particularly lowered to the various organisms capable of causing infection with the formation of pus; while most of the systemic disturbances as a rule follow the local troubles and in turn may be responsible for keeping up the latter.

Having established the causes of this disease, the treatment resolves itself into —(1) Local mechanical treatment by the dentist and local antiseptic application. (2) Systemic treatment—attention to general health and correction of faulty hygiene and faulty mode of life; and finally (3) Vaccine treatment—the direct raising of the patient's blood resistance to the infecting agent by means of an active immunization.

LOCAL MECHANICAL TREATMENT.

The local mechanical treatment you are all familiar with. I have, however, noticed a difference in the mechanical treatment as done by different dentists—the difference being more a matter of the conscientious way and the time spent in cleaning and scaling. Those of you who practice among the poor or in rural districts are thoroughly familiar with the difficulty of getting a patient to appreciate a thorough conscientious cleaning. I therefore always explain to patients that the public should compensate dentists for their time, and not for the "job."

The thorough cleaning, periodically done, once every three to six months, together with the sterilization of instruments on the part of the dentist during the act of cleaning between teeth—nay, even from one root to another, especially if a root happens to be at all diseased, would go far in the prevention of this disease. Of course, each individual patient has to be looked after as to his general condition. Thus the dentist, through the condition of the gum, should be in a position to tell the patient to look for advice from his family physician, although the patient is not, as a rule, sick enough to be forced to do it of his own accord.

At times you may meet cases with marked loosening of teeth—too loose to attempt a thorough scaling. In such cases I have found that a few treatments with vaccine would help to sufficiently tighten up those very loose teeth and allow local mechanical treatment.

The local antiseptic treatment is followed up with dilute Lugol's solution (1 part to 3 parts of water) which acts as a mild antiseptic and astringent, but its more important action is an indirect one; by virtue of its staining the tartar and other deposits on the teeth, it stimulates the patients to have the proper cleaning and scaling done by their respective dentists.

I have also met patients who applied for the treatment of "pyorrhea," whose gums were perfectly healthy as to inflammation and sponginess, with no pus and no looseness of teeth, but with marked recession. The recession was so marked that it laid bare the roots of the teeth in front up to the very top. Upon a thorough investigation I found that the patients used constantly an injurious tooth-paste, one containing a high percentage of potassium chlorate. One patient in particular, whom I have in mind, not only used this injurious paste twice daily, but also used it by pasting it on the gums over night. Her gums showed very marked recession and the enamel of the teeth was grooved in ridges in places where she used the paste most. This injurious action is probably due to the free chlorin liberated from the potassium chlorate. When this ingredient is used medicinally in the form of a gargle, physicians always advise rinsing the mouth thoroughly with water because of its injurious effects on the teeth. In this connection I wish to say that the simpler the tooth-paste the better. Anything that will saponify the food-remains will do. Plain Castile soap and hot water with a clean tooth-brush will do as much good. It will at least never do harm.

SYSTEMIC TREATMENT.

The systemic treatment depends upon the condition of the patient. Each patient receives a thorough physical examination, examination of feces and urine. Whatever in the way of faulty diet, faulty hygiene, or any other abnormality is discovered during the examination, is attended to. Special attention is paid to the condition of the stomach and bowels, kidneys, and blood.

VACCINE TREATMENT.

We now come to the most important of the direct treatments of this disease —vaccine treatment. This is in reality, as said before, the production of an active immunization against the bacterium with which the patient is affected. An understanding of the principles of immunity is necessary in order to intelligently and successfully treat patients by this method.

Generally speaking, immunization is carried out therapeutically by means of biologic products, either vegetable or animal. It may be classed under two general headings: Passive immunization and active immunization.

Passive immunization. The principal treatment which falls under this heading is that of the antitoxin against diphtheria, in which case the antitoxin is prepared by means of inoculation with diphtheria toxins (poisons) in horses. The horses elaborate anti-bodies in response to these inoculations, which anti-bodies or antitoxins circulate freely in their blood and are found capable of neutralizing diphtheria toxins wherever they are met. That is, the blood serum of the horse into whose tissues diphtheria toxins have been introduced contains substances which will overcome or neutralize the diphtheria poisons when injected in the child or if mixed in a test tube.

Other therapeutic serums depending upon passive immunity have been found successful, chiefly that of tetanus.

In the case of passive immunity, therefore, the child who receives the diphtheria antitoxin takes no active part in that immunization. It is the horse, through the activity of his tissues stimulated by the inoculation of the toxins, that takes an active part in the immunity. This passive immunity is of course ideal, if we could carry it out in every one of the bacterial diseases; and, as a matter of fact, at the time diphtheria antitoxin was first discovered by Von Behring and Kitasato (1890) the medical profession hoped for a general panacea against all bacterial diseases. It was soon found, however, that only a small group of pathogenic bacteria are capable of producing free toxins when grown in bouillon—*i.e.* when the bacteria grown in the bouillon for from three to five days are then filtered out, the bacteria-free filtrate is found to contain the products of the bacteria, *i.e.* the recognized toxins. It is the latter which are necessary for the production of antitoxins.

Unfortunately, however, most of the pathogenic bacteria have been found to be incapable of producing similar free toxins when grown in bouillon, *i.e.* if the bouillon in which bacteria other than diphtheria or tetanus have been grown, and then filtered, the bacteria-free filtrate was found not to contain the poisonous products or toxins as they are to be found in the case of diphtheria and tetanus. It is therefore obvious that no antitoxins can be prepared from any of those bacteria, since the toxins are necessary to inoculate the horse which will produce the antitoxin.

No successful results have therefore been attained through the attempts at the therapeutic application of various so-called antitoxin sera—anti-pneumococcus serum, streptococcus serum, etc. It was only when the application of killed cultures or bacterial vaccines was resorted to in an attempt at the production of an active immunity, that successful results were obtained in such infections.

Active immunity. This active immunity resorted to therapeutically is distinctly in contrast to passive immunity. Here the tissues and cells of the patient take an active part in the production of his own immunity to the bacteria with which he is infected, in response to inoculations of the corresponding bacterial vaccine. The tissues of the patient thus elaborate, in a way unknown to us, inimical substances, in response to the killed bacterial vaccines, inhibitory to the growth of the living bacteria wherever they are found. This inhibitory action or immunity affects the whole body, since the blood containing these substances is distributed throughout the entire body. Thus, for instance, if in a patient suffering from staphylococcus infection, boil or carbuncle, a staphylococcus vaccine be introduced subcutaneously in the proper doses, the tissues of the patient proceed to elaborate substances—which will be found in the blood—that will prohibit the further growth of the infecting bacteria, and thus cure the boil or carbuncle. The process presumably has also an antitoxic effect, overcoming whatever poisonous products have already been elaborated by these organisms in the boil.

While the effects of the antitoxin in the case of passive immunity is greatest at the time immediately following the injection of the immune or antitoxic serum, wearing off as time goes on, in the case of active immunity, on the contrary, the immunity is actually lessened slightly for from a few hours to a day immediately following the injection of bacterial vaccine, increasing gradually after that until it reaches its height at the end of from two to three days to a week or so, then declining gradually. Repeated inoculations are therefore necessary in order to keep pushing the immunity up as long as the infection persists.

PREPARATION OF THE VACCINE AND TECHNIQUE OF INJECTION.

It is this method of active immunity by means of bacterial vaccines, first employed therapeutically by A. E. Wright, London, in 1903, which is resorted to in the treatment of chronic alveolar osteomyelitis. For the preparation of the vaccine the bacteria are first obtained from the pus of the gums, and are grown on solid culture media (glucose agar) for twenty-four hours. The growth is then washed off with sterile salt solution and placed in a sealed test tube submerged in water kept at 60° C. for one hour, which kills the bacteria. This suspension, tested culturally for its sterility, is then standardized by counting the number of bacteria present in the suspension, and diluted to the desired number, usually 200 million per cc. or 15 drops. It is then used for the treatment of pyorrhea.

The vaccine as prepared by myself is kept in 10 cc. amber-colored bottles covered with a rubber cap and sealed with paraffin. The following is the method for the administration of the vaccine:

The rubber cap is not removed. It should be washed off with a wad of absorbent cotton soaked in alcohol just before using. The hypodermic syringe is sterilized by boiling. The bottle of vaccine is shaken thoroughly. The hypodermic needle is thrust through the rubber cap—the bottle being inverted—and the requisite amount for the dose is withdrawn. Upon withdrawal of the needle the cap will reseal itself. The skin of the patient (*e.g.* of the fleshy part of the back of the upper arm) is prepared by scrubbing with a wad of absorbent cotton saturated with alcohol. The vaccine is injected subcutaneously in the deep subcutaneous tissue.

The following general rules I observe during the treatment with vaccine with reference to dose and interval of repeated injections:

I start with the minimum dose (30 to 50 million of autogenous vaccine), increasing the dose in succeeding inoculations at an interval of forty-eight hours by 12 to 25 million (to a maximum of 400 million), until the patient shows a local reaction. The local reaction is temporary and consists of an inflammatory area of swelling and redness about the size of a half-dollar at the point of the injection, with some tenderness on pressure. This usually lasts from eight to twenty-four hours, subsiding gradually without leaving any mark or sign. It does not produce the suppurative process which follows the vaccination against smallpox.

The severity of the reaction is directly related to the dose administered and is indirectly related to the state of resistance of the patient. When present it is most marked following the first injection of the vaccine, and is progressively less with succeeding doses. The treatment should not be repeated unless the reaction of the previous injection has partially or totally subsided, and if the local reaction of the previous injection was marked, the one following should never be increased, but rather decreased by 12 to 25 million. No general reaction (general malaise and fever) should ever occur. When it does it is a sign of an overdose, unless due to some other intercurrent disturbance (intestinal indigestion, etc.). The average interval between treatments is two to four days, in the beginning; later, when improvement takes place, once every five to seven days is sufficient.

"STOCK" AND "AUTOGENOUS" VACCINE.

A word as to the difference between stock and autogenous vaccines properly belongs here. "Stock" vaccines are vaccines made up from bacteria obtained from sources other than from the patient himself, and as found on the market they are supposed to be made up of pure cultures of bacteria of whatever denomination, without regard to the source (as to the disease) from which the bacteria are obtained. To the best of my knowledge they are usually obtained by the manufacturing druggists from typical infectious cases. For instance, the pneumococcus vaccine as found on the market is probably isolated from a case of pneumonia; staphylococcus aureus vaccine from a case of boils, etc., without regard to the number of strains and variety of diseases in which this pneumococcus or staphylococcus is generally found. Such a pneumococcus stock of vaccine, for instance, if used for the treatment of alveolar osteomyelitis, would not, in my opinion, yield the same results as the stock pneumococcus vaccine made up from a number of sources, including several strains from this disease. (When speaking in this paper of stock vaccine I always refer to the latter kind.)

"Autogenous" vaccines are made up from the bacteria obtained from the pus of the alveolar disease of the individual patient. This should give, theoretically, the best results. Practically, however, I found that the autogenous if mixed with the stock vaccine yields the very best results.

The reason why the autogenous alone does not at times work as well in this disease as when mixed with stock vaccine might be explained by the fact that in chronic diseases the patient becomes more or less tolerant to the infecting bacteria. The bacteria in such cases live somewhat in harmony with their host and therefore cause a chronic disease and not an acute disturbance. For that reason, too, such organisms are incapable of readily exciting an active immunity, while some of the strains in the stock vaccine presumably contain organisms capable of doing so, and therefore if mixed with the autogenous vaccine yield the better results in these chronic diseases.

In the incipient cases of alveolar osteomyelitis where no pus can be obtained, but where there is beginning recession and sponginess of the gums, I have used with good results the stock vaccines made up from a number of strains including several strains from this disease.

I have no personal knowledge of, nor have I found anything in the literature with reference to results obtained in this disease with stock vaccines, so called, as found on the market.

It might be well to say here that no animal product is mixed with the bacterial vaccines, that it is not a serum like the antitoxin of diphtheria, and that it therefore cannot produce "serum sickness" (anaphylaxis).

The data relating to the bacteriological findings in the 115 cases that I studied, and reported in the article already mentioned, would be of value in connection with choosing the particular stock vaccine to be used in those cases where for various reasons no autogenous vaccine can be obtained. The bacteriological findings were as follows:

	Times.
Pneumococcus (streptococcus lanceolatus pneumoniæ)	26
Pneumo. and staphylo.	67
" " strepto.	3
" staphylo., and strepto.	10
" and M. catarrhalis	1
Staphylo. " " "	2
" aureus	2
Strepto. and staphylo.	1
Sterile	3

Thus we find that in the majority of cases (67 out of 112) we are dealing with a pneumococcus and staphylococcus infection, while the most frequent single organism met with (107 times out of 112), either alone or mixed with other bacteria, is the pneumococcus in chains (streptococcus lanceolatus pneumoniæ). Bacteria other than these two kinds were practically of a negligible proportion. The stock vaccines, therefore, that I use most—usually either in combination with the autogenous or by themselves—are pneumococcus and staphylococcus vaccines, in both which vaccines strains obtained from chronic alveolar osteomyelitis are present.

As to the results of the treatment with vaccines in this disease, I will say that it differs according to the severity and stage of the disease. For that reason I found it expedient to classify all the cases under three headings: (1) Incipient; (2) Moderately advanced; and (3) Far advanced.

Group I, "Incipient stage"—are those cases where the gums and teeth taken as a whole are in fair condition, with two or three teeth containing pockets, with little visible, if any, pus present, and slight inflammation and recession of the gum margin with discoloration. The teeth are not loose in this stage, but the necks of the affected teeth are unclean, surrounded by food débris and tartar deposits. There is no special complaint on the part of the patient, except perhaps of bleeding and slight aching on mastication.

Group II, "Moderately advanced stage"—are those cases where the disease is much farther advanced. The gums are congested and inflamed at the margins with marked recession or sponginess. Visible pus that can be squeezed out on pressure is present in all these cases with a varying number of teeth affected. The looseness of teeth is not marked, but the discomfort and tenderness on chewing is present in all the cases of this group.

Group III, "Far advanced stage"—are those cases the symptomatic picture of which you are all familiar with. Marked looseness of teeth, deep sinus formation and marked suppuration, sponginess, or recession, necrosis and destruction of the alveolar process, and displacement of teeth. In a few cases the disease is marked by a series of acute exacerbations in individual teeth, with marked swelling and excruciating pain, coming on suddenly and continuing until the affected teeth have to be removed. Such patients have lost three to five teeth in this way before they were referred by their dentists for vaccine treatment. The majority of the cases in this group, however, are of the slow, insidious, chronic type, with little pain except on mastication. All of these cases have systemic disturbances of one form or another.

The following percentage of cures, improvement, and no improvement are the results obtained with the vaccine treatment in these groups (table A):

cavity. It is the dentist who should call the attention of the physician in charge of the case to the possible consequences of the disease in question.

To emphasize the importance of the systemic diseases that accompany alveolar osteomyelitis, I need only mention the large number of patients who suffer from various forms of infectious arthritis or "rheumatism," so called, the great number who have gastro-intestinal disturbances (50 per cent.), skin affections (14 per cent.), and the other systemic diseases. Perhaps the most common of the systemic disturbances that accompany this disease is the particular susceptibility to acute coryzas or colds, at times sufficiently severe to lay the pa-

The average duration of treatment and the number of treatments necessary will of course be of interest to you. I found them as here shown (table B).

The systemic diseases which accompany this affection are of great importance. They should be taken into consideration by the dentist because of the lack of attention at the present day paid this disease by the medical profession generally, since it is left to the dentist. This is the cause for a great many mistaken diagnoses in diseases of the oral

tient up in bed. It is quite apparent that the severity of the systemic disorders, especially those of the rheumatic disturbances, are directly related to the severity of this disease, increasing both in severity and frequency as the disease goes on. These systemic diseases have improved or have been cured side by side with the improvement or cure of the alveolar osteomyelitis. Table C gives the exact percentages of the important systemic diseases that I found accompany this disease.

To recapitulate: Pyorrhea alveolaris, so called, I have pointed out to be really a chronic alveolar osteomyelitis, because of the fact that the sockets are enlarged medullary spaces and the disease affects the bony offshoots lining the sockets and medullary spaces.

As far as the causes of the disease are concerned, I have called attention to the mechanical causes as being responsible for starting the disease, while the pus-producing bacteria are responsible for keeping it up. The most common of these are pneumococcus, staphylococcus, streptococcus, and M. catarrhalis.

The systemic diseases do not, I believe, play an important part in starting the alveolar disease. On the contrary, I believe them to be caused by it, and in turn possibly help in keeping it up. Vaccine treatment of this disease cures or relieves the systemic disturbances or symptoms.

And finally: The vaccine treatment together with local mechanical treatment yields by far the best results in chronic alveolar osteomyelitis.

THE PERFECT PORCELAIN INLAY.

By N. S. JENKINS, D.D.S., Loschwitz, Dresden.

(Read before a union meeting of the Seventh and Eighth District (N. Y.) Dental Societies, held at Rochester, N. Y., November 14, 1912.)

THE practice of dentistry, while everywhere identical in essential principles, differs in each country in its methods and in its standards. Such differences are determined not only through varieties in educational systems, but also by social conditions and temperament. It has therefore not been simply chance which has caused Europe, and in a special degree Germany, to aid so largely in the development of the perfect porcelain inlay. Permit me to refer to some points in the history of this development.

ESTHETIC NON-COHESIVE GOLD FILLINGS, AS MADE BY DR. ABBOT.

When in 1866, I first went to Europe as a young man, somewhat inflated by the belief that I knew all there was to know about making elaborate gold fillings, and half believing that this knowledge was almost all that was necessary for the practice of operative dentistry, I had still sufficient sense to ask my friend Dr. Abbot of Berlin to show me what he could of the methods of managing a European practice. This noble, generous, skilful, gifted gentleman stood at the head of his profession in northern Europe, honored and beloved to a degree which has seldom been the lot of any man. I had thought he would give me simply general information, which indeed he gave, but to my amazed delight he did much more. He insisted that I should come every day to his office and stand by his chair while he was operating, introducing me to many of his most important patients and explaining the reasons for his methods of treatment in each case. I was astonished at the pains he took to conceal his art, but I subsequently discovered that other able American and native dentists practiced with the same purpose.

Abbot was very skilful in the use of non-cohesive foils, but he took great precaution to preserve intact, as far as possible, frail labial or buccal walls, so that the gold might be invisible except as it sometimes showed through thin enamel.

Perhaps some of the older New York practitioners may remember the marvels wrought by Gunning and Dunning, and many others of the pre-cohesive gold period, in restoring shape and contour with non-cohesive foil, but I recall no instances in America where such trouble was taken to conceal the gold. Indeed, often it was quite unnecessarily in evidence, as if the operator wished his skill to be recognized by all men.

TIN AND GOLD FILLINGS, AND THEIR ADVANTAGES.

Another surprise awaited me in discovering that amalgam was prohibited in Abbot's practice, and that its place was occupied by tin and gold. This method, which never became popular in America, consisted in rolling together non-cohesive gold and tin foil No. 4, and packing it by lateral pressure in either strips or pellets, according to the preference of the operator. It was discovered by a British dentist whose name seems to have been forgotten, but the process became known to the world through Abbot and his followers. Its advantages consisted in the rapidity with which it could be worked, its comparative insusceptibility to thermal changes, the possibility of packing it securely under moisture, and the striking molecular change which occurred some time after the filling was finished. This change was caused through the acids of the mouth exciting electric action in the two metals, resulting in forming oxid of tin, which caused the filling to increase in bulk, thus pressing it more closely against the walls of the cavity. The filling also then became crystallized and formed into a seemingly homogeneous mass of great density, resembling amalgam in appearance, except that it did not discolor the teeth, and also it did not wear nor flow under the stress of mastication, as does amalgam. Its field of usefulness was very wide, and I believe no other method of filling teeth has ever had a record of such endurance.

It was largely employed for patients coming from distant lands, where at that time no dentist could be found. In such cases not only was the loss of dental tissue by caries often very great, but it was usually necessary to do many operations within a limited space of time, and with great thoroughness, since the patient could generally not return for further treatment for a series of years. It was extremely rare that such fillings were lost, or that there was evidence of secondary caries. I have seen many such fillings made in every position in the mouth, before the advent of the rubber dam, which were still perfectly preserving the teeth after a lapse of from thirty to fifty years.

REASONS FOR REVOLT AGAINST MALLETED GOLD FILLINGS.

I found Abbot also using the same care to preserve natural conditions in employing this material as he exercised in the use of gold, and at last it dawned upon me that here was a method of practice new to me, but founded in righteousness, and teaching the sacred duty of preserving the patient from unnecessary disfigurement. Presently I found that almost all dentists practicing in Europe were usually observant of this duty, and that it was encouraged and perpetuated by a *clientèle* very susceptible to départure from the harmony of nature.

About twenty years ago there occurred a revolt against the tyranny of gold fillings. It affected both dentists and patients, and arose largely from the tremendous strain of endurance necessitated by the favorite methods of that time. You remember how the brilliant Marshall Webb went down to an untimely grave under this awful strain.

There once came to me a frail American girl with a dislodged gold filling, and having compassion upon her condition, I very gently replaced it with another, which I packed by hand pressure. Upon concluding the operation, I asked the patient's mother to present my compliments to her family dentist when she again took her daughter to him, and say how much I admired his beautiful work. Thereupon the girl burst into tears, and cried, "Mother, you promised me I need never go to that man again." Then the mother told me that the nervous prostration from which her daughter was suffering was caused by a five hours' sitting for the building-up of a certain splendid gold monument which I had specially admired. Thank Heaven that through the porcelain inlay and the famous discovery of Taggart such barbarities have passed away forever!

THE ADVENT OF THE PORCELAIN INLAY.

If the influence of this revolt was felt in America, it was felt still more in Europe, where many futile efforts had been made to find some less distressing, more esthetic, and equally enduring method of filling. These efforts were chiefly expended upon various forms of gutta-percha and zinc phosphate. Their utter failure to fulfil these conditions incited the men practicing under the influence of the method popular in America to still more elaborate gold-malleted restorations, until the patience even of the most stolid clients became overstrained. It was for these reasons that the announcement of the successful making of porcelain inlays was everywhere hailed with so much enthusiasm.

In America this enthusiasm was more widely disseminated and more demonstrative than in Europe. In the former case it appears, for the most part, to have been like seed sown upon stony ground, which had no depth of root. I have been told that in America the use of porcelain has for some years steadily decreased, whereas in Europe, even during the delusive period of the silicate cements, it has held its own, and the methods have steadily improved, until at last seeming perfection has been reached.

The reasons for these dissimilar conditions are too various to be considered at length upon this occasion. Some of them, however, I may be permitted to touch upon.

PERSISTENT POPULARITY OF THE PORCELAIN INLAY IN EUROPEAN PRACTICE.

The characteristic European dentist possesses, both through temperament and education, much patience, a quality which he displays notably in trying to master the details of any new method. I remember how the late Professor Hesse of Leipzig once spent a week with me to convince himself of the value of porcelain inlays. After his return to Leipzig for a month he sat up every night until nearly morning, working at the technique of the process, until he felt that he was capable of practicing it and of teaching it to his pupils. It was in this spirit that German dentists who cared for it at all worked at the new art, and they reaped an abundant reward. I have never known a European dentist who became thoroughly capable in porcelain work who did not, by its practice, considerably increase his reputation and his income.

THE GOLD MATRIX AND ITS MANIPULATION.

Fortunately, Europe generally accepted and remained loyal to the gold matrix. It was evident that the weak point of the process was the edge of the filling; not that a defective edge always weakened the inlay materially, but it was liable to cause a dark line, which was sometimes very disfiguring. This defect was far less frequent with inlays made with gold than with platinum matrices, and many efforts were made to improve the gold matrix in consequence. To this end innumerable devices were employed, such as rubber points, burnishing over gold-beaters' skin and thin rubber dam; burnishing with agate and highly polished steel burnishers, stamping with various machines designed for the purpose, insisting upon having cements devoid of nodules, improving in cavity preparation, and securing a polished surface throughout the cavity, especially at the edges. Indeed, there was a great amount of ingenuity displayed in improving methods throughout all Europe, with the result that there is now no part of that continent and no class of society where there are to be seen such displays of disharmony in the mouth as, even after the magnificent discovery of Taggart, one finds frequently elsewhere.

DR. WEBER'S SUGGESTION OF GLASS INSTRUMENTS FOR BURNISHING THE GOLD MATRIX.

The final improvement was very simple and came with no flourish of trumpets. It was the discovery of Weber, a Swiss colleague, who is also an American graduate, and is known as one of the most ingenious and skilful dentists in Paris. Some years ago he began to use glass burnishers for the final polishing of the gold matrix, and he felt that he had reached perfection. For some two years he kept his secret to himself, testing it constantly in practice, and when convinced that the system had enduring merit he demonstrated it before the American Dental Club of Paris.

Since then, the men who have adopted this method report the same results. Given a cavity properly prepared with exact and polished edges, a gold matrix may be burnished with glass instruments, either by the direct or the indirect process, until every fold and wrinkle has been smoothed away, and a perfect matrix has been secured.

This process does not tear the gold, and greatly increases its rigidity, so that its removal from the cavity is made easier than by the old method. Moreover, the gold separates from the surface of the fused inlay with great facility, and when the inlay is placed in the cavity it is at once evident how imperfect were the former methods.

This system was immediately adopted by the Postgraduate School at Berlin. This is a government institution, attached to the Dental Institute of the University, and to it come dentists from over all northern and central Europe. Mamlok, who is at the head of the porcelain inlay department, showed me last year a considerable number of patients who had been treated by this method during a period of two years. The operations were of all classes, many of them being extremely complicated, but among them all I could not detect a single black line nor any defect of edge. When you consider that these operations had all been made by male and female dentists who were learning and practicing this beautiful art for the first time, the importance of this result is evident.

ADVANTAGES OF THE PORCELAIN INLAY.

It seems scarcely necessary to recapitulate the advantages of the porcelain inlay, but still I venture to remind you that it is not from the esthetic standpoint alone that it surpasses all others.

It is to the patient the least distressing method of restoration. It requires less loss of structure than is regarded as essential with the gold inlay, and it is exempt from the discomfort often occasioned by a large gold inlay in a vital tooth. From the moment that a porcelain inlay is set, the patient forgets that the tooth containing it was ever defective; neither heat nor cold affect it, and it can be used in eating or drinking or can be brushed with either cold or hot water with impunity. The large gold inlay, despite its film of protecting cement, remains a body which conducts caloric changes.

It is the duty of the dentist not only to restore lost tissue, together with contour and indestructible masticating surface, but also to give his patient complete exemption from subsequent discomfort. This can be permanently accomplished with porcelain alone, and, speaking from the results of wide experience, I wish to add that there is no position in the mouth in which the skilful dentist may not, if he sees fit, successfully place a porcelain inlay which will bear unimpaired the strain of mastication.

The well-made porcelain inlay also renders the tooth practically exempt from secondary caries. It does not shrink in cooling, as does the cast inlay, and has no edge to be dubiously burnished over defective cervical margins.

It may be known before setting whether a porcelain inlay fits, and if it is defective anywhere, it is better to make another rather than hazard an ultimate failure.

But it is in its esthetic aspect that the porcelain inlay is most attractive. It is a great achievement to place a mouth, ravaged by dental caries, in a comfortable and sanitary condition; but to add restoration of the original beauty of the teeth is a supreme triumph, and one worthy of the wonderful age in which we live.

In America the porcelain inlay was born; in Europe it has attained to its highest development. These facts are of much significance—for our profession is no longer provincial, but it is everywhere working upon the same problems in a generous spirit of fraternal rivalry, and for the good of all the world.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE PROGRESSIVE DENTAL CLINIC.

By WESTON A. PRICE, D.D.S., Cleveland, Ohio.

BECAUSE many of the most serious disadvantages of the ordinary dental convention clinic are quite satisfactorily overcome by the Progressive Clinic plan inaugurated by the writer at the Northern Ohio Dental Association meeting held at Cedar Point, June 1912, and because of the many inquiries asking for information regarding details for conducting such a clinic, together with the fact that the National and some other associations, when they meet in the near future, will use this plan, the following detailed outline is given. When this plan was first used, practically everyone present pronounced it a great improvement, and none were more enthusiastic than the clinicians themselves. It has since been used with the same general satisfaction in other places.

THE WRITER'S PLAN.

The plan of the Progressive Dental Clinic contemplates the greatest possible advantage and convenience to the greatest possible number, and is based upon the dividing of the audience into groups or classes of equal size, and distributing them thus equally to each of the clinicians.

At regular and pre-arranged intervals—of fifteen minutes for instance—at the sounding of a loud gong, or a series of buzzers, preceded by a one-minute signal, each class proceeds to the next clinician, there being the same number of progressions as clinicians. Each person on entering the hall is given a serial number which determines which class he shall start in. Suppose, as was the case at Cedar Point, there are thirteen star clinicians distributed, seated at small tables on slightly raised platforms, each with two rows of chairs surrounding his table, thus seating from twenty to thirty dentists. The clinics are numbered from 1 to 13. Numbered tickets with stick-pins are previously prepared, running from 1 to 13, and repeating in order. These are handed to the audience as they enter the clinic room, and their numbers will determine the clinic at which the auditors will first congregate and start. Since there are as many progressions as clinicians, every man sees every clinic from beginning to end, and each clinician has a new audience to repeat his complete clinic to. This distribution is equally as convenient if the clinicians are placed in adjoining rooms, which are provided with buzzers for signals, while outside each door is a sign with the number of the clinic. Each leader of a class can carry a standard, giving the number of his class to late-comers, and, if separate rooms are used, this class number should be left outside.

If two men wish to go together, they are given corresponding numbers, and since there is an equal number of each of the numbers from 1 to 13, it is very easy to keep the classes all of the same size.

Each class has a chairman or leader who is instructed to change the number for any man wishing to change his class to see a clinic repeated, etc. These chairmen or leaders of the classes are selected beforehand; each is instructed to keep his crowd together and progress them promptly. A copy of such an outline as this is put in the chairman's hands.

By public and program announcement, the clinicians and audience must be instructed to be in place promptly at a stated time. In order to carry out this plan successfully, all clinics should be *first-class,* and only men should be invited who are able to keep an audience for that period of time.

For large audiences with divided interests, the clinics should be divided into two or three series—say, mechanical, operative, and therapeutic—and each series should progress independently or simultaneously as desired, or have entirely different time periods for progressions.

Specially long clinics, if worthy, can have a double period accommodating two groups or classes at once, or several short clinics—such as can be grasped at sight without explanation—can be so arranged in one clinic as to use together one period of time.

At Cedar Point there was not a hitch from beginning to end, nor was there a single complaint that reached the management, and a little deluge of expressions of satisfaction came from both the audience and clinicians. The clinicians had not been notified as to the amount of time they should plan their clinics for. This should be done.

PRACTICAL ADVANTAGES.

Some of the practical advantages are:

(1) Each visitor can see each clinic from beginning to end, but only for his full share of time.

(2) Each clinician has a full audience at all times, and can tell each and every man his full story, and never repeat to a single one. He can plan his time to cover his ground, and place emphasis where he sees fit.

(3) Each clinician has an opportunity to rest for a minute or two regularly.

(4) Obtrusiveness and crowding of a popular clinic is entirely prevented.

(5) Practitioners generally get into ruts, and wish to stay there. They often do not choose or desire to see strictly educational clinics, but select only those that show short cuts to earning a dollar. With this method, men unconsciously get to see good educational clinics, and are broadened, thus being more greatly benefited than by the purely practical clinic that appeals to their narrow interest or pertains to their specialty.

(6) Argument and discussion with clinicians, and interruption, is entirely prevented.

(7) Visiting in the clinic room is practically prevented, except during progressions.

(8) Every man has an equal opportunity to see and learn everything in the entire clinic with the greatest possible convenience and comfort to the clinician and himself.

(9) This plan is a great incentive for clinicians to make a worthy preparation, and they will feel it an honor to be called upon as *star* clinicians.

SOME COMMENTS.

The accompanying letters, alphabetically arranged, give the viewpoints of the clinicians, also the viewpoint of one of the dentists in the classes, viz, Dr. Geo. H. Wilson.

These letters were sent in reply to the inquiry asking the writers' criticisms, opinions, and suggestions.

Dr. Russell W. Bunting, University of Michigan, Ann Arbor, Michigan, states:

Your letter at hand asking my opinion of the manner in which the clinics were held at the Northern Ohio meeting.

In reply would say that it was the most

successful clinic that I ever attended. From the standpoint of the clinician, the method used saved him time and energy, besides relieving him of the petty annoyance of interruptions and repetitions. He had an opportunity to tell his story, make his points clear to those who were interested, and then give the same matter to the next group. From the standpoint of those who wish to see the clinics, it must be a great relief to have the undivided attention of the clinician for a short time free from interruption.

In case this method is used in a larger meeting, I would suggest that the clinics be divided into groups as to subjects, and also as to time. Many clinics can be given in this way in five minutes, while others need fifteen. I think the scheme is an excellent one, and should be adopted wherever it is possible.

Dr. A. J. Bush, Columbus, Ohio, states:

My opinion of the progressive clinic can be briefly stated as follows: First, The clinic is indorsed as first class; second, The clinician receiving the indorsement is honored thereby, and accordingly strives to give a high-class clinic; third, The respectful attention accorded a clinician, under these circumstances, is a positive benefit and works to the advantage of all. It is the first clinic that I ever gave that someone did not try to interrupt my clinic in order to give a clinic of his own, and in thinking this over later, I came to the conclusion that perhaps someone's views had been broadened, even if my own had not. I say this to describe the complete change from former experiences.

Dr. M. H. Fletcher, Cincinnati, Ohio, states:

I am pleased to commend the progressive clinic idea. It certainly must be more gratifying to the audience than the old method. Fifteen minutes may not be as much time as some would like, yet such persons have the opportunity of returning, so everyone has a chance, which they do not have in the old way.

In the progressive plan, the clinician may not have all the time he may desire, but by proper condensation the whole story can be told in fifteen minutes. I like the plan, as a clinician, better than any I have tried.

Dr. Geo. B. Harris, Detroit, Michigan, states:

The scheme is very advantageous to the clinician. By that means it becomes possible for the clinician to go from start to finish without interruption and with the least amount of duplication.

Under the progressive method, as used at Cedar Point, I would not answer any questions until through with the clinic. I then devoted the last five minutes to answering questions and found this to be very satisfactory to all concerned. The advantage of it is that the clinician does not have to give a clinic to one or two and then repeat to twenty or thirty. It is a good idea, and should be adopted at the coming National meeting.

Dr. Wm. O. Hulick, Cincinnati, Ohio, states:

I desire to say to you that in fifteen years of clinic work in our state and many others, I have never had as satisfactory an arrangement as the one at your meeting. It gave the clinician an opportunity to do justice both to himself and to his audience, or class, as you termed it.

Dr. G. D. Laymon, Indianapolis, Ind., states:

The progressive clinic idea, as employed by the Northern Ohio Dental Association at their last meeting, impressed me very favorably. As far as disadvantages are concerned, the only one of importance is that certain clinicians must hurry through their clinics in order to finish in the allotted time, while others may have time to spare.

As to the advantages there are several: (1) The audience is so subdivided that crowding is eliminated; (2) order is maintained, which is gratifying to the clinician; (3) this arrangement permits each dentist to comfortably see and hear every clinic; (4) the interest of the clinician is maintained by the periodical change of audiences, and (5) the number of dentists attending each clinic is always constant, so that no clinician is embarrassed by having small audiences.

Dr. Andrew J. McDonagh, Toronto, Ont., states:

From a clinician's standpoint, I would say that the progressive clinic of the Northern Ohio Dental Association was a great success. It kept the clinician busy every moment, and he had the satisfaction of knowing that he was not repeating himself to the same individuals. However, all clinics in a circuit must, necessarily, require the same time to complete. Allow me to congratulate you on the success of this novel feature.

Dr. Frederic A. Peeso, New York City, states:

I think the idea one of the best that I have ever seen worked out so far, but it seems as though it might be modified in some way to make it still more satisfactory. As you know, in some of the clinics there are intricacies requiring more time in explaining or demonstrating than others which are so simple and plain that they demonstrate themselves almost at a glance. As to what changes might be made or whether any could be made to work this out, is up to you to think out, but the plan was so successful and so far ahead of anything I have ever seen, that it could be carried out as it is with great satisfaction and profit to the profession.

Dr. H. Carlton Smith, Boston, Mass., states:

I consider it the best system I ever saw used. It leaves nothing to be desired, unless possibly, in case of an all-day clinic, a recess in the middle of the forenoon might make it a little easier for the clinician.

Dr. Edward Spalding, Detroit, Mich., states:

I like the idea of limiting the number of people around the clinician, as being much pleasanter and more profitable to the clinician and the listener, but do not believe that you can make the same period of time suitable to all clinics. I think it possible to give some clinics one period of time, and others two periods, or possibly three. In my own case, I needed two periods of time, and could have used three to advantage. Then I was told by a number of men that they wished to see the same thing over.

Dr. Marcus Ward, Ann Arbor, Mich., states:

From the standpoint of a clinician I was much pleased with your progressive clinic after the first section had passed by me. Previous to this time, I was uncertain about the ground that I could cover in the time allotted to me. The first section left me almost in the middle of one section of my clinic, but the succeeding ones were handled with ease. From the standpoint of the dentists, I observed that all of them visited all the clinics. Oftentimes, a man or group will become interested in one or two clinics and will not leave them at all, to the detriment of both clinician and dentist. In your progressive clinic they *all have to see it all.*

Dr. George H. Wilson, Cleveland, Ohio, states:

I consider the clinic of the 1912 Northern Ohio Dental Association by far the most unique, successful, and gratifying of any I have ever attended. The success of that clinic should revolutionize the clinics of the entire country, and I predict it will so do. The method will create a demand for fewer and better clinicians, and everyone will have an equal opportunity to get everything presented. In a word, I consider it—CLINIC PERFECTION.

SOME REMARKS ON THE REMOVAL OF TROUBLESOME TONSILS OF INTEREST TO DENTISTS.

By HENRY GLOVER LANGWORTHY, M.D., Dubuque, Iowa.

ALTHOUGH a discussion of diseased tonsils and adenoids in their relation to mouth affections has been a common one in dental literature for a long time, there is one vital feature in connection with their surgical treatment which should be kept in mind by the dentist, and which is as applicable to his own as to other people's children. The above statement, therefore, is sufficient excuse for the creation of a special paper which has to do solely with the question of the actual removal of tonsils, and purposely omits any extended references to the causation of symptoms with which all are more or less familiar. Indeed, the entire subject of symptomatology may be briefly dismissed by saying that tonsillectomy in the main is performed for the relief of three general classes of cases: (*a*) Frequent sore throat, and the prevention of quinsy; (*b*) chronic throat catarrh where there is troublesome pocket formation in and about the tonsil causing excessive irritation, secretion, or the formation of concretions; (*c*) the ordinary run of enlarged tonsils in children which cause impediment in breathing or swallowing, and are usually associated with adenoids.

IMPERFECTIONS IN TONSILLECTOMY AS PRACTICED IN THE PAST.

In taking up the removal of tonsils it is pertinent to inquire, first, What really constitutes the removal of tonsils? and second, Have not we—meaning all departments of the medical profession—been substituting the word for the deed many times when we speak of tonsils as having been removed in all of our cases? I think it is a fair statement of fact to say that up to three or four years ago, tonsils were not taken out as thoroughly as they are at present. In other words, the situation was somewhat analogous to that of pre-appendix days, so far as knowledge and up-to-date surgical action was concerned; twenty-five years or so ago, a diagnosis of inflammation of the bowel or peritonitis and inadequate medical treatment was really the best treatment known. Somewhat the same condition, but relating to the tonsils, has been in existence not so long since. Men who were considered competent, and were, moreover, really experts in their specialties, were not always removing the tonsils when they spoke of the average case as having had the tonsils removed. Today, all such physicians not only have voluntarily changed their ideas and technique along this line, but what is more important, are this year and this week doing thorough and satisfactory work. To many of us the situation has suddenly presented somewhat the nature of the cancer picture. *Just as we expect a recurrence of cancer, so can we expect a continuance of some of the troublesome tonsil symptoms if they are not removed thoroughly—and by this I mean the entire organ as contained within the sinus tonsillaris.* When I see a throat case previously operated, with the history of the throat trouble continuing, and observe a good deal of honeycombed tonsil plastered on the lateral pharyngeal wall behind the anterior pillars, I do not and cannot honestly find fault, but tell the patients that they have had most of the tonsil removed, all at least that was thought necessary at that time, but that even the little left in their particular case is still causing trouble. This is an honest statement, and leaves us able to meet our responsibility with clear eyes.

THE WRITER'S TECHNIQUE.

Tonsillectomy or the complete removal of all of the tonsil is not an easy operation, for a great many reasons. First of all, the tonsil must be well dissected almost completely around so as to free it from the sides, or it is impossible to slip a snare over the organ and satisfactorily enucleate it. Just the past few years have brought home to the writer, who has performed this operation in over eight hundred cases, the fact that it is almost impossible to dissect the tonsil carefully and get it ready for removal without spending considerable time at this vital preliminary work. Also it is becoming more evident every day that occasionally it is most difficult to properly dissect out tonsils in young adults, and get every bit of them out even under a general anesthetic. Gagging, uncontrollable throat movements, which tightly stretch the pillars over the tonsils, excessive blood obscuring the operative field, and a flat position of the body, all conspire at times to make the tonsil operation a trying one. Personally I am finding myself doing more and more of these operations in adults, when possible under local cocain anesthesia, being careful to cocainize the regions back and under the pillars by means of angular swabs as I work along, and then following the patients for several weeks to make sure of a good operation. By spending most of the time on dissection, and taking out the tonsil only when it is ready, with scissors or a wire snare, I feel that my operative technique is materially improved. A vacuum suction apparatus which constantly sucks out saliva and blood may also be used to great advantage in patients under ether or chloroform. At present, one difficulty I have experienced with such an apparatus is that it occasionally gets out of order, but this will be remedied in a new apparatus which I am at present perfecting. Before one finishes a case, in any instance, it is highly necessary that the assistant pull the anterior pillar back, while we both make sure that the former side of the tonsil presents a clean bed showing only the lateral pharyngeal wall.

TONSILLECTOMY A MORE SERIOUS OPERATION THAN COMMONLY REGARDED.

Owing to the attention which this operation is being given, it is safe to add that, from now on, tonsils are going to be entirely taken out, no matter how much it may cost in equipment, assistant fees, etc., and no matter if it be necessary to operate a second time, if for any reason it is found unwise to complete the operation when first starting out. The day of the $25.00 tonsil operation is past. Physicians cannot do good work, especially a piece of work which often requires an assistant when done under cocain, and an etherizer and an assistant when done under a general anesthetic, without being paid a good price. The profession as a whole, both dental and medical, is going to regard the removal of tonsils as a more serious operation than formerly, and will realize then, and then only, that the results will be far superior to what they have been even in the past. The operator who cannot look back at unsatisfactory work, and has not had to repeat an operation once or twice, is one who has done little throat work. Fortunately, however, even the failures, with their evident reasons, often help us more than would marked successes.

REASONS FOR DIFFICULTIES IN TONSILLECTOMY.

Some of the chief reasons why partial decapitation or partial removal of the tonsils cannot be satisfactory in the average case are as follows:

(1) The crypts of the tonsils are little more than deep fissures, which frequently extend entirely through the organ to the outer side, or may open into large communicating spaces. Therefore anything short of complete removal still leaves crypt fissures to catch food, lodge bacteria, and cause continued irritation by the presence of septic material at the bottom.

(2) The tonsil does not completely fill its triangular bed, as there is a large space above and behind the tonsil, at the sides and, in fact, more or less all around the outside of the organ, which spaces continue to exist unless purposely eradicated.

(3) As some of the crypts open on to surface regions of the tonsil covered by such structures as the anterior pillar in front, plica tonsillaris below, palate margin above, etc., it is evident that the trouble in these places is not even touched unless attention is directed to them.

(4) As, regularly, two-thirds of the tonsil is concealed and out of sight, it is almost folly to attempt an opinion as to its possible pathogenic factor without the use of a bent probe for exploring crypts and pockets.

Lastly, if one will but consider a few of the evil results of enlarged or degenerated tonsils or adenoids from either a local or a general standpoint, also the results from badly contracting scars and lacerated pillars in the throat from poor operations, it can be easily figured out just why it is necessary to perform these operations so carefully, and to remove tonsils completely when they are removed at all.

CORRESPONDENCE.

A CORRECTION.

To the Editor of the Dental Cosmos:

Sir,—The following appears in the Dental Cosmos for May 1913 (p. 516):

> Another point in this connection: The Black followers always select bicuspids or molars to demonstrate their principle of cavity preparation on. Why? Because their preparation of a cavity in an incisor or canine would be very difficult to follow indeed, and I venture to say few of them could ever insert a perfect filling in an incisor and have it last, unless they had produced a wide separation beforehand.

The above statement is at such variance with the facts in the case that the attention of the profession is called to them, and to the following, viz:

Nineteen of the members and friends of the G. V. Black Dental Club operated at the clinic of the Fourth International Dental Congress which was held at St. Louis in 1904. These gentlemen made thirty-seven gold foil operations. But eighteen of them were reported. (See *Trans.* Fourth International Dental Congress, pp. 524-526.)

Number of gold foil operations reported	18
" " " " " made in bicuspids and molars	13
Number of gold foil operations made in other teeth	5

The following year, 1905, some of the Black Club men and their friends operated at the N. D. A. clinic which was held at Buffalo. The total number of operations made by these gentlemen was twenty. They were divided as follows:

Gold foil operations in bicuspids and molars	10
Amalgam operations in molars and bicuspids	2
Gold foil operations in other teeth	8

At the N. D. A. meeting which was held at Minneapolis in 1907, the members and friends of the Black Club made the following operations:

Total number of gold foil operations	35
Gold inlay operation	1
Gold foil operations made in molars and bicuspids	26
Gold foil operations made in other teeth	9

Summary.

Total number of operations made	76
" " " gold foil operations made in bicuspids and molars	51
Total number of gold foil operations made in other teeth	22
Total number of amalgam operations made in bicuspids and molars	2
Total number of inlay operations	1

From this summary the reader may judge for himself whether or not the men belonging to the Black Club always select molars and bicuspids in which to demonstrate their cavity preparation.

During the past sixteen years, at any and all of the annual clinics of the Black Club, there have always been clinical operations made on the incisor as well as bicuspid teeth. Beyond this, it is not necessary to say more.

E. K. Wedelstaedt.

St. Paul, Minn., May 22, 1913.

Proceedings of Societies.

SEVENTH AND EIGHTH DISTRICT DENTAL SOCIETIES OF THE STATE OF NEW YORK.

Forty-fourth Annual Union Convention.

(Continued from page 644.)

Friday—*Afternoon Session.*

The Friday afternoon session was called to order at 2 o'clock by Dr. J. Edward Line, Rochester, who presided at this meeting.

Dr. R. H. Hofheinz, on behalf of the members of the Seventh District Dental Society, presented to Dr. E. G. Link, Rochester, chairman of the Business Committee, a very handsome loving-cup in recognition of his very valuable services to the societies.

Dr. Link, in a few appropriate words, thanked the societies for their appreciation of his efforts.

Dr. Link then introduced the first essayist of the afternoon, Dr. N. S. Jenkins, Dresden, Germany, who read a paper entitled "The Perfect Porcelain Inlay."

[This paper is printed in full at page 711 of the present issue of the Cosmos.]

Discussion.

Dr. R. H. Hofheinz, Rochester. It is not difficult to discuss a subject when presented by an authority. There is no one man in the profession who is better equipped by ability and esthetic taste to present this subject than Dr. Jenkins, who was helped by the surroundings of Dresden and Meissen, a porcelain atmosphere *comme il faut.*

It is quite a revelation to hear anything said on porcelain inlays at present. In the eyes of some of the coming geniuses of dentistry, this subject needs an apologetic prelude. Not long ago I heard it stated at one of our meetings that "the porcelain era had passed out of existence." This is interesting, if amusing. A more important question arose with me, namely—Upon how many has the porcelain era ever dawned?

The very delicateness of this work, the necessary esthetic consideration, the frequent failures in producing the exact shade, the disappointment of the patient because the inlay looked different in artificial light, and last but not least, the dark line around the inlay, have made porcelain inlays not quite so popular as are rubber plates and amalgam fillings.

The principal question arises, Is this all to be charged to porcelain itself? If a man like Dr. Jenkins could devote all of his time to the making of porcelain inlays and succeed as well as many of us know he has, we must look elsewhere for the many disappointments enumerated. Dr. Jenkins in his introduction speaks of Dr. Abbot of Berlin, and his skill as a non-cohesive gold worker. It may please the essayist to know that Rochester had some of the most marvelous manipulators of this special material.

The essayist refers to the tyranny of gold fillings. It certainly was a tyrannical necessity to keep patients from two to six hours in the dental chair, but after all, the gold filling was a great maker of personality. One of my old patients for whom I made a large gold inlay recently said: "If you dentists could ever do slovenly work, you can do it now. Who knows what is under this cement?" There is certainly more truth than poetry in this statement. This fact, however, does not detract from the value of cemented fillings. I only mention it as a warning to the younger practitioner. A poorly placed gold filling soon reveals its deficiency; a cemented filling is unfortunately kinder to the unskilful and slovenly operator.

The essayist says—"In America the enthusiasm was more widely disseminated and more demonstrative than in Europe," etc. I have been told that in America the use of porcelain has steadily decreased, whereas in Europe, even during the delusive period of the silicate cements, it has held its own, and methods have steadily improved, until at last seeming perfection has been reached. Our national temperament accounts for that. We readily embrace the new and exchange it with American alacrity for something newer, frequently to our advantage, frequently to our detriment.

The example of Professor Hesse which Dr. Jenkins has cited thoroughly explains the German and, to a large degree, the general European tendency. The essayist tells us that Europe accepted and generally remained loyal to the gold matrix. I thoroughly agree with him that the dark line around the inlay was the essential cause of dissatisfaction to both patient and operator. This should not convey the idea that no perfect inlays have been made with the platinum matrix.

I have with me a broken-off crown of a lateral in which a porcelain filling had been placed some six or eight years ago, and yet it had never developed the dreaded dark line, and I know that the matrix was made of platinum. The making of a platinum matrix is an infinitely more tedious process, however, and for that reason, if for no other, the gold matrix is preferable.

The French papers take great delight in attributing the Turkish disaster to their use of the Krupp guns. It is not the gun, but the man behind it, who decides the battle. If all the dentists who attempt porcelain inlays had the wonderful patience, say nothing of skill, which I know Dr. Jenkins to possess, fewer dark lines would be visible around their inlays, even when platinum matrices were used. Let me give you an example: Some eight years ago, when the essayist was still in full practice, I called at his office in Dresden. He invited me to his chair with his customary hospitality and professional courtesy. He prepared for a woman patient a mesio-disto-incisal cavity in a central incisor. After he succeeded in making what we both called a perfect matrix, he handed it to the assistant for investment and completion. I was asked to return at 3 P.M. to see the finished product. I did not fail to appear. The inlay, though a most difficult one to make, looked perfect. In placing it into the cavity, we noticed a discrepancy at the cervico-lingual angle. Most of us would have cemented it in place, and filled the slight deficiency with gold at some other time. Not so Dr. Jenkins. With a most gracious smile he said, "Fräulein, this is not a perfect inlay; if you can come tomorrow at 10 o'clock, I will make another one for you." Ah, there's the rub! It was the wonderful personality and love for perfection that has made Dr. Jenkins such a force in dentistry.

Two years ago, when I visited the essayist in Paris, he showed me a patient's mouth, filled with porcelain inlays burnished with glass burnishers. They certainly appeared to me the most perfect I had ever seen. The greatest surprise, however, was the fact that many of them were inserted in the incisal edges of the anterior teeth, which were continually shortened by an edge-to-edge bite. They showed no signs of chipping or breaking, though they must, of necessity have been very thin.

The greatest surprise to me regarding both porcelain and gold inlays is the fact that so many do remarkable service though but little of the law of cavity preparation has been obeyed. I pass a sample of an inlay placed in a bicuspid with a very unfavorable bite, some eight years ago. Four years ago part of the lingual wall broke off. I filled it with cement and amalgam, and you now can scrutinize the lack of cavity preparation.

In enumerating the advantages of the porcelain inlay, Dr. Jenkins tells us that it requires less loss of tooth structure than the gold inlay. I do not agree with him, and unfortunately this is one of the few points in which I differ with him. An approximal cavity properly extended to the line of immunity requires as much loss of tooth structure preparatory to the insertion of a porcelain inlay as for that of a gold inlay—and there is no reason why such extension should not be made in either case. The essayist tells us that the porcelain inlay has no edge to be dubiously burnished, like the gold inlay, over defective cervical margins. The man who burnishes gold inlays over defective cervical margins is no better than the one who fills a tooth with gold and later fills the deficiency at the cervical margin with amalgam. There is no reason for a deficient edge in the gold inlay, when perfectly finished.

It can be decided with equal certainty whether a gold inlay fits the cavity. Unfortunately, the temptation with the average dentist is too great when he sees an imperfect inlay, and he relies upon cement to fill the deficiency. The man who cements a poorly fitting gold inlay would certainly not try to improve an imperfect porcelain inlay by making a new one. All other advantages I heartily second.

Some fifteen hundred years ago, the good people of Japan and Honduras put inlays of green jade nephrite into labial surfaces of front teeth. The skulls are preserved to this day, as an eloquent testimony for the lasting quality of such inlays, and these people had neither Ames nor Petroid cements.

Dr. Jenkins has spoken of the illusive period of silicate cements. I agree with him, and yet, if used with proper judgment and discretion, these cements serve a purpose which may be increased by a more thorough understanding and compatibility of the fluids of the mouth and the silicate cement.

This remains a question of evolution. If we are willing to devote more time, skill, and patience to our labor, we can all achieve what Dr. Jenkins has termed the perfect porcelain inlay, which is without a doubt the most ideal filling in the realm of dentistry.

Dr. C. K. Buell, Buffalo. When asked to discuss this paper, I readily accepted the honor, knowing that our distinguished essayist would leave little to be said upon the subject, and feeling assured that that little would be said by the gentleman preceding me in the discussion.

I wish to congratulate the essayist upon bringing before us the porcelain inlay in such a manner that we are sufficiently enthused to again take it up with renewed interest, and a determination to strive after the ideal that he has so beautifully described.

Before receiving the paper, I began to make a mental note of some of the essentials of a perfect porcelain inlay, with the following result:

The inlay must have sufficient bulk to be able to withstand the strain placed upon it during mastication. The marginal edge must be of sufficient thickness and be placed at such an angle with the line of stress that it will not fracture or chip away; also the cavo-surface angle must have the same requirements followed out in its preparation.

The cavity must, whenever possible, be so shaped that the cement alone is not depended upon for the retention of the inlay, *i.e.* labio-approximal cavities must not be saucer-shaped.

The finished inlay should fit the cavity so well that a drop of water placed in the cavity will hold the inlay in position, while, if it does not fit perfectly, the inlay drops out or becomes loose. I know of no test equal to this.

Last, but not easiest to obtain, the color should match the tooth perfectly, no matter from what direction it is viewed. Can all of these requirements be fully realized?

Almost anyone can fulfil the first two requirements mentioned—bulk, marginal thickness, and angle; but can we so prepare compound cavities in molars and bicuspids, with less destruction of tooth material than for a gold inlay, and at the same time expect the margins of the cavity and inlay to remain intact under stress? Since one of the requirements for a perfect porcelain inlay is that the cavity be perfectly prepared, I hoped that the essayist would describe his method of cavity preparation for molars and bicuspids, as these cavities seem the most difficult.

The material for a matrix, gold, and its successful adaptation to the polished cavity walls and the tooth surface, has been touched upon in such a manner that I am certain we will all be using the glass burnishers, and thus make our work more perfect. I would like the essayist to give his opinion of the direct as compared with the indirect method.

The color problem has been the most difficult for me to solve. What has helped me most have been the Jenkins' cements and their shade guide. Nevertheless I still find that color is a problem.

I would like the essayist, in closing, to tell us how he selects his shades for labial cavities that extend underneath the gum, labial cavities that do not extend underneath the gum, approximal cavities, both mesial and distal, that do not involve the incisal angle, and approximal cavities that involve the incisal angle and perhaps one-third of the incisal width.

Does he match the tooth each time perfectly, or does he allow for the change due to the refraction of light-rays by the cement? Does he allow for the size of the inlay in selecting the shade? These are some of the conditions that I find make the color of the finished product a difficult task. To mention more would only weary you.

Since we have the opportunity, let us sit at the feet of the master porcelain inlay-maker and learn, so that we too may produce porcelain inlays that shall be perfect.

Dr. B. S. Hert, Rochester, N. Y. I have read Dr. Jenkins' paper, to which we have listened with both pleasure and profit. The first portion, relating to his early experiences in Europe, the variations in the methods of practice in different countries and their causes, is informative reading.

The use of tin and gold, which was practiced so generally in Europe, was practiced in America to some extent, and its advantages were understood. I well remember when I attended the University of Pennsylvania, how much stress Professor Darby placed on the value of tin and gold as a tooth preserver, and how strongly he advocated its use, especially at the cervical margins of the posterior teeth. I used it many times before the advent of the gold inlay, and always with most satisfactory results.

In regard to the porcelain inlay, it is perhaps well to bear in mind that the essayist can almost be called the father of porcelain inlays, as he was mainly instrumental in its being used so extensively, and naturally is enthusiastic in its use. The virtues of the inlay probably loom up so large in his eyes as to throw into shadow some of its defects, and to obscure the valuable qualities of some other materials. For a number of years I used porcelain inlays very much and advocated the adoption of this method for many teeth. I used them, however, mainly in anterior teeth, and only occasionally in molars and bicuspids, and I am well pleased that I did not use them oftener in the posterior part of the mouth. "The use of porcelain is only limited by the ability of the operator," is an expression which was heard quite often a number of years ago, when porcelain had been used by many for only a short time. I have not heard it for a long time, because experience has shown that this method of filling teeth has inherent faults which no amount of skill can overcome. Only two of these will be mentioned:

First, the friability of porcelain. If the margin of the inlay is laid on the incisal edge or occlusal surface, in a large number of cases the edges will fail in a comparatively short time, the filling will become dislodged, or the tooth begin to decay again near the filling.

Then there is the cement problem, and the question, Of what consistence is it best to use cement? If it be mixed but a little too thickly, one dares not exert sufficient pressure to force out the excess, as one can with a gold inlay, for fear of breaking the porcelain or chipping the edge, and if the cement is thin enough to allow the porcelain to be perfectly seated in the cavity, it will not harden to its best strength, will dissolve out in time, and permit caries to recur around the filling. For myself, the making of porcelain inlays was the most trying class of work that I have done in dentistry, although, after becoming thoroughly familiar with the technique, the final results in approximo-labial cavities in the anterior teeth were quite satisfactory. For a number of years I have gradually done less porcelain work, and while some American dentists have experienced a "delusive period of silicate cements," as Dr. Jenkins has said of the European dentists, this, so far, has not been my lot, as this material has in my practice replaced porcelain for fillings. After several years of use of silicate cements, I am able to say that I obtain results which compare favorably with porcelain both in durability and color, with less destruction of tooth substance, much less discomfort to the patient, and greater ease for myself.

The method of making porcelain inlays as practiced by myself, as well as the majority of dentists in this country, consisted in the employment of high-fusing porcelain and platinum matrix, and I have seen fully as good results obtained by this method as by that of low-fusing bodies and the gold matrix. Some dentists who had used both low- and high-fusing bodies told me that they could obtain a better fit with the high-fusing body, and after a time entirely discarded the low-fusing.

It may be that, with the use of the glass burnishers mentioned by Dr. Jenkins and invented by Dr. Weber, a perfect fit can always be secured with the gold matrix and low-fusing body, and, if this is so, it should prove a boon to those dentists who are still using porcelain, the number of whom, even in America, is still quite large.

Dr. Jenkins says that cavity preparation for a porcelain inlay requires less destruction of tooth substance than that for a gold inlay. I cannot see why this should be so, and am satisfied that sometimes the contrary is true. As for conducting thermal changes: If caries has not progressed to the pulp, and the pulp is properly protected with cement before the inlay is made, or the inlay is made hollow, usually no trouble will ensue from that source. If durability be the paramount quality desired in a filling, gold is still the first of all the materials used for filling teeth. No single filling material, however, is best for all the various cavities which are to be filled, and the dentist should use his best judgment and select that material which is best fitted for each operation as he performs it.

Dr. A. E. Sager, Rochester. Like Dr. Hert, I have used porcelain a great deal, and with success. I had the pleasure of seeing two inlays the other day made eight years ago, which are still doing good work, but like many of my *confrères* I have abandoned the use of porcelain inlays. I never used the gold matrix, but now, with the enthusiasm inspired by Dr. Jenkins, I shall look into the gold matrix idea, and see if I cannot resume this work where I left off.

Dr. H. L. Belcher, Seneca Falls, N. Y. I would like to ask Dr. Jenkins to tell us something in regard to the selection of the proper color of the cement to be used with the porcelain inlay. I took up porcelain work a year ago, but the great trouble we beginners find is that, after we have a perfect match of porcelain, the color will change when the inlay is cemented in. I am in the habit of using Ames' pure white cement, and I find that this produces less change in the inlay than any other cement. In fact, there is practically no change in the shade of the inlay, and if the color of the inlay has been properly matched to begin with, it will still be perfect after cementing. I should like to have an expression of opinion from Dr. Jenkins in that respect. I have obtained the best results by using the Ames pure white cement with all inlays, regardless of color or shade.

Dr. A. McAlpin, Bradford, Pa. While not wishing to depreciate the value of the artistic qualities of the porcelain filling, it may not be out of place to say a word in defense of silicate cements.

There is no question of the esthetic effect of the porcelain filling, but the average practitioner is probably incapable of obtaining the same average of high quality work with porcelain as with silicate cement. Personally, I have had experience with both, and while I recognize the value of a perfect porcelain inlay, I have great respect for the esthetic effect and all the other good features of the silicate cements as perfected within the last few years. In order to offset in a measure the effect that the depreciation of silicate cements might have on the minds of some who are not familiar with their use, I would say that the silicate cements have qualities that appeal to the average practitioner and insure him better average success than the attempt to perform operations with porcelain inlays exclusively. There is no question, however, that the porcelain inlay has its place, and if inserted by a competent operator, answers all the requirements of a filling, but there are limitations to porcelain, and some of the better silicate cements really are a very good substitute for porcelain.

Dr. D. H. Squire, Buffalo, N. Y. I have felt, like many others, that the porcelain inlay is not the most desirable filling, as its technique is so difficult. The examination of many porcelain inlays made by European dentists has convinced me that when this work is well done, it is the most beautiful of all tooth restorations.

Perhaps it is because of our faulty technique and lack of practice in this art that we do not obtain the same good results as the dentists abroad. There is no question, with all due respect to gold, that an acceptable porcelain filling gives us the keenest satisfaction.

I wish to thank Dr. Jenkins for stimulating us once more to renewed effort in this work.

Dr. C. S. Butler, Buffalo. There is one phase of the subject of inlays about which I have thought much. In the past few years porcelain has been developed to a high degree of efficiency, but I doubt whether the development of the cements or the cementing media has advanced in the same relative proportion, and I feel that in the near future the cementing media must receive more attention from practical men. If we could interest the practical man in the development of the cement, just as Dr. Jenkins has been interested in the development of porcelain, I apprehend that some of the difficulties that confront the profession today would be largely eliminated. In the first place, we must have not only a medium that will withstand stress, but it must also be sterile or germicidal in character. It seems to me that if we are to attain the degree of efficiency and permanence that has already been attained with porcelain, efforts must be made in the direction of improving the cementing media.

Dr. Henry H. Tompkins, Utica. We have all listened with a great deal of interest to the paper which has been presented by Dr. Jenkins, and to the discussion which has followed. I feel, however, that many of us would like to have a little more light thrown on this topic. The essayist seems to assume that we understand how to make a perfect porcelain inlay. Yet there is something more to the making of perfect porcelain inlays than the mere use of glass burnishers, which Dr. Jenkins mentions. I should therefore like to hear more of the details of construction. For instance, does Dr. Jenkins still use asbestos investment material? My observation leads me to believe that this has a great tendency to shrinkage, as has porcelain itself. I know that many of us would be very glad to have Dr. Jenkins in his closing remarks go into all the details which enable him to produce a perfect porcelain inlay.

Dr. Jenkins (closing the discussion). I am very grateful to the gentlemen who have done me the honor of discussing this paper in such a kindly manner.

I was much interested that Dr. Hofheinz referred to, or rather took exception to, my assertion that less sacrifice of tooth substance is necessary in porcelain than in gold-inlay work. I have not, however, expressed myself quite accurately in that respect. In many instances it is necessary, in making porcelain inlays, to observe the general rules with which we are all familiar in the formation of cavities for gold inlays; but there are cases where, by reason of the physical quality of the porcelain, less extension for prevention may be allowed with the porcelain inlay, partly because the surface is so smooth that it can be kept perfectly clean, and partly because a porcelain inlay in a vital tooth is more readily brushed without discomfort of any kind. All of you have had instances, sufficiently numerous, in which it has been difficult to induce patients to keep large gold fillings or gold inlays clean because of the sensitiveness of the teeth to thermal changes; and that danger is eliminated in the case of the porcelain inlay. It is also true that, by using the direct method, one is able to preserve here and there some important portion of the tooth, which, with the indirect method, or with the method of making a wax model and casting a gold inlay, one is often obliged to sacrifice. There are many such instances of sufficient importance to deserve mention.

As for the question of the indirect method, I may say, I believe that in all cases where, without too great sacrifice of substance, one can obtain a perfect model of the cavity with wax, this method is to be preferred, because it is much easier for the patient and for the operator. A perfect impression of the cavity may be put into the hands of a laboratorian who does that work, and a model may be made—I may say that personally I much prefer the cement model—into which the gold matrix may be burnished at one's convenience. One can be absolutely certain, befoie embedding that matrix, that it is an exact duplication of the cavity. Under all circumstances, every matrix for porcelain inlays should, in my opinion, be embedded.

One of the gentlemen has asked for some information about the technique. I may say that there is nothing relative to this work which has not been the subject or occasion of a great deal of thought and experiment. It is essential that the matrix should be embedded in asbestos or some other material which will neither expand nor shrink. The returning of the nearly finished porcelain to the cavity for additional burnishing is something which I believe to be under all circumstances pernicious or unnecessary, and therefore to be avoided. The embedding of the matrix in the platinum or nickel cup is of great importance. The mere mixing of the asbestos requires a little care and skill, if the ideal consistence is to be obtained, and unhappily there are a great many kinds of asbestos which either contract or expand through the process of removing the moisture. For years I have been endeavoring to discover the source of a certain asbestos, which I believe to be in the island of Sicily. It is with great difficulty that any considerable quantity can be obtained from the dealers, but this asbestos, like some others we find in Europe, will neither contract nor expand. When the matrix is placed in an investment of this asbestos, and the moisture is removed by heat, no change whatever in the size or shape of the investment or the matrix occurs during the process of fusing.

As to the question of adapting the color of the cement to that of the inlay, I am very glad that one of the gentlemen said he used in his own practice only one kind of cement. I may say that my experience is quite the same as his. I find no reason whatever for using a multitude of different colors. In the perfectly prepared porcelain inlay, except at certain points, it is necessary to have only a thin film of cement, and whenever the color of the inlay has been properly selected, and when it has been baked true to color, it looks all right when put into the cavity for trial, but after that, when the rubber dam is put on and the tooth is bleached through dryness, the inlay is not exactly the color of the tooth, and the setting with cement appears to increase still more that disharmony of color. After a short time, however, the tooth comes back to its normal condition, and the inlay then assumes its proper color again, which thereafter it never loses.

I was also very much pleased to hear what good success some of you have had in the use of silicate cements. That is also largely a question of skill and temperament. The objections which we have found in Germany to the use of silicate cement, except for temporary purposes, are its structure, which is not sufficiently resistant; its lack of adhesion to the cavity—often accompanied by shrinking—and its tendency to discolor and become rough on the surface. The porcelain inlay—and I hope this will prove to be the case with the gold inlay also—is, so far, the only kind of filling which continually improves in the mouth. If it is once properly placed in position and has no serious defects, it becomes constantly firmer as the years pass by.

Dr. HOFHEINZ. To what do you attribute this. To the physical property of the porcelain itself?

Dr. JENKINS. To the continued hardening of the cement, not to the porcelain, for the cement, being protected from moisture, finally assumes a hardness as great as that of the porcelain itself. I have had occasion to remove a few porcelain fillings, made many years before, because I was discontented with the color, and it has been one of the most difficult tasks I have ever performed to remove the porcelain and then cut out the cement beneath it. One can cut ordinary porcelain with greater ease than this cement.

It is quite true that the inlay must have sufficient bulk to be able to withstand the stress placed upon it by mastication. That goes without saying, and there are cases where one sometimes deliberately runs a little risk; but one fact I have established to my own satisfaction is that, under favorable conditions, if one has two millimeters of thickness of a good low-fusing porcelain, such bulk is sufficient to endure the strain of mastication. Of course, one ordinarily takes as much bulk as one can get, but in many delicate cases I am convinced that two millimeters' thickness is sufficient for the integrity of the properly fused porcelain inlay. I should also like to add that there is far less danger of spoiling a low-fusing porcelain than a high-fusing one, even though one has an excellent furnace and an accurate pyrometer; for one can far more easily control the low than the high temperature, and at high temperatures sudden changes very quickly occur. I will say also that one great advantage of using the low-fusing porcelain, in my opinion, is that it may be more rapidly fused and more rapidly cooled. Moreover, the rapid cooling of low-fusing porcelain in the open air never seems to injure its texture or cause it to be more fragile.

One of the gentlemen emphasized that the cavity must, whenever possible, be so shaped that the cement will not be depended upon for retention; that is, that labial cavities must not be saucer-shaped. Of course they must not be. All cavities, as far as possible, must have parallel walls. The ideal cavity we can never form—at least almost never; but when the cavity has sufficient depth and some strong parallel walls, a step is never necessary for the security of a porcelain inlay.

Color is something that one learns chiefly by experience. There are places where one has to modify the color, and not have the exact color of the tooth itself. For instance, in labial cavities the tint of the tooth should be preserved, but the color should be slightly darker than in an approximal cavity. An approximal inlay in the incisors may be made distinctly lighter than the tooth itself.

Dr. BUELL. Mesial or distal cavities?

Dr. JENKINS. Either.

Dr. BUELL. The same degree of lightness in both cases?

Dr. JENKINS. Not always the same. In distal cavities the color may be lighter than in mesial cavities.

I hope I have answered all the questions asked. I thank you very much for your courteous consideration of my paper.

The meeting then adjourned until Saturday afternoon.

(To be continued.)

EASTERN ASSOCIATION OF GRADUATES OF THE ANGLE SCHOOL OF ORTHODONTIA.

Monthly Meeting, held at Philadelphia, March 29, 1913.

The regular monthly meeting of the Eastern Association of Graduates of the Angle School of Orthodontia was called to order by the president, Dr. Milo Hellman, New York, in the assembly room of the Hotel Stenton, Philadelphia, on Saturday evening, March 29th, at 8 o'clock.

The first item on the program was the reading of a paper by Dr. M. H. Cryer, Philadelphia, entitled "Studies of Anterior and Posterior Occlusion of the Teeth, with Suggestions as to Treatment."

[This paper is printed in full at page 673 of the present issue of the Cosmos.]

Discussion.

Dr. H. C. Ferris, New York. I wish to ask Dr. Cryer if he will not help us in clarifying one point; that is, the relation between the first measurements that he gave of the skull and the angle of the mandible. Has he made any comparison between these two measurements?

Dr. Cryer. Yes.*

Dr. Ferris. I note in a number of the essayist's illustrations that he rather treats these skulls as if they were finished products in normal development, but they are abnormal. In a few, lack of function is noted rather than normal function in occlusion during the developmental period. The change of the angle of the ramus, according to my interpretation of the slides, had a great influence upon the development of the maxilla, and that is one point that I believe would be of great assistance to us, if we could gain some idea of the normal in different types. We have heretofore failed to compare the angle of the ramus with the length of the first measurement mentioned by the essayist. I believe this would help us in our work, by giving us some idea of the normal development of the maxilla.

The essayist's suggestion for the surgical treatment and the subsequent movement of the jaw is intensely interesting, and I believe that this operation could be performed by skilful operators. This also explains to my mind the puzzling condition which I have encountered in many cases of that particular type. I believe that the angle of the ramus is subject to influence, and that I have modified this angle by moving the molars distally. I have a case of class II, division 1, at the present time, where I am convinced, after observation, that I have brought about normal mesio-distal relation, but there is a prominence in the chin which indicates that I have not altered the mandible in its angle. It is in such a case that the relation between the essayist's first measurement in the angle of the ramus would be of assistance in the diagnosis as well as the treatment of our cases.

Dr. Cryer. The object of this paper is to bring out discussion. I am here to learn, and want to study these conditions with you who are constantly dealing with the changing of the positions of the teeth and the jaws. In the first place, however, Dr. Ferris has misunderstood me in regard to the normality of the skulls. I only give one figure as being fairly typical. (See Figs. 6, 9, and 16.) The other illustrations are all of abnormal character in one form or another.

* [Details regarding these measurements have been inserted in the body of Dr. Cryer's paper.—Ed.]

Dr. Ferris. You noted that you had made comparison between that first measurement and the angle of the ramus?

Dr. Cryer. Yes. In the skull which I call the "mixed skull" (Fig. 11), we have the measurements of 62 and 48, making the great length of 110 from the cutting edge of the teeth to the foramen magnum; in connection with this we have one of the most obtuse angles. 135°. We can obtain these relations between the angle of the jaw and the length of the skull in the living subject to a certain extent. We can judge where the foramen magnum is by its relation to the pharyngeal wall, and, with the aid of a straight probe, can approximate the distance from the incisors to the foramen magnum, and with the aid of X-ray and digital examination we can tell the character of the angle.

Speaking of the surgical treatment of the angle, I have not done this operation, but shall probably do so, and would recommend it to a competent surgeon. The one point to keep in mind is to avoid disturbing the inferior dental nerve, if possible, and I believe that with proper instruments the circular incision can be made in such a way that it will not injure the nerve. Nevertheless the operation would be justifiable under any circumstances, as the collateral circulation will take care of the tissues, and the nerve would more than likely re-unite in a short time, if it should be severed accidentally.

Dr. J. Lowe Young, New York. I do not propose to discuss skulls with Dr. Cryer, because it would be absurd for me to attempt such a discussion with a man who has made such a close study of skulls as he has. It seems to me, however, that the difference in what he has presented to us tonight and our work, is that our work is principally done on children, whereas he has shown skulls principally of adults, and, as Dr. Ferris says, many of them have undoubtedly developed abnormally. The problem of greatest interest to the orthodontist is the development of the organism, and regarding this I would like to ask one or two questions. First, is the shape of the temporo-mandibular articulation in the child at five and six years of age the same as in the adult? To make myself clear, is it possible for a child of this age to voluntarily or involuntarily slip the mandible distally in order to get the teeth in better occlusion? According to the vital instinct, the child wishes to masticate food as much as possible, and if for some reason the upper dental arch has not widened sufficiently to accommodate the lower teeth, can the child's mandible be slipped back so as to get these teeth in such a position that he can masticate better? If that is true, then does it not follow that, if the child is allowed to go on in that condition until adult life, he would have abnormal development of the temporo-mandibular articulation of the bones surrounding the teeth and in both the upper and lower arches.

Dr. Cryer. In regard to the teeth of children coming into occlusion, I believe that the vital instinct will place the mandible backward or forward to a certain extent to allow the child to obtain the best position for mastication, because good chewing and insalivation are necessary to life and health. The change of the temporo-mandibular articulation during childhood is very great. At birth, the glenoid fossa is rather flat or shallow; posteriorly the external auditory fossa is not formed, there being only a ring with its external tympanic membrane stretched on it; anteriorly the eminentia articularis is very slight. The condyles are round and short. As the auditory process and the eminentia articularis develop, the glenoid fossa becomes deeper until near adult life. Therefore the mandible is more at liberty to change its position in early life. If changed to a forward position, there is little danger of doing harm, but if it be carried backward, either by the vital instinct or by mechanical means, there is great danger to the organ of hearing. Does that answer your question?

Dr. Young. That is what I was after.

Dr. Cryer. You will find in the Transactions of the American Society of Orthodontia for 1908 several illustrations showing the glenoid fossa at various ages.

Dr. Young. You spoke about changing the shape of the mandible where it forms an obtuse angle. With your knowledge of the anatomy, do you believe that it is possible for the orthodontist with any mechanical appliance to really change the angle of the mandible?

Dr. Cryer. You can surgically do so.

Dr. Young. No, but by mechanical pressure applied for a long period of time?

Dr. Cryer. I believe the angle can be made more obtuse, but bringing it nearer a right angle would be rather difficult.

Dr. Young. You spoke of the obtuse angle or straight mandible, and asked whether the orthodontist could make that mandible more of a right angle.

Dr. Cryer. I do not think he could, but do not want to dispute that point, and hope that some of you will show it.

Dr. Young. I do not think anybody will ever show it.

Dr. C. A. Hawley, Washington, D. C. Would there not be quite a different result, so far as the auditory canal is concerned, if this vital instinct were allowed to exert itself gradually over a period of three or four years? Is it not true that there would be no danger then, because of the fact that all of the tissues would change in conformity to the new relationship of the parts?

Dr. Cryer. If the vital instinct, or if mechanical appliances were allowed to force the mandible backward, it would come into contact with the auditory process which forms the anterior wall of the external auditory canal. This wall has often become resorbed by the pressure of the condyloid process against it. This would interfere with hearing. Of course the ear cannot change its position to accommodate any movement of the mandible posteriorly. Illustrations of these conditions are given in the Transactions spoken of in answer to Dr. Young.

I believe, as I did years ago, that bone can be bent, and with the ingenuity that you orthodontists show, I believe you can bend the angle, especially in the direction of which I speak. This can be done because none of the tissues are absolutely solid. It was argued recently in a paper, as though it were a new discovery, that bone is pliable. Of course this is possible; even the rocks of the mountains are pliable. Every tissue is subject to change, and is to a certain extent pliable. If constant force is applied to it, the mandible can be bent, but I should not like to see it forced back on the auditory canal; that must always be avoided.*

Dr. H. E. Kelsey, Baltimore. This discussion reminds me of a case which indicates effectively to my mind that the bones of the mandible can be bent.

No doubt many of you have seen the report of this case published in the January 1913 Cosmos,† and will remember that the deformity of the jaw which required treatment was caused by an appliance which had been used previously in the treatment of spondylitis.

A leather strap or sling had been worn under the mandible and carried up on each side of the head, to be attached to a support above which projected upward from a plaster frame which rested upon the shoulders. The purpose of this appliance was to elevate the chin and keep the neck straight.

The result on the patient's jaw was to compress it laterally and bring it into lingual and distal occlusion, while the anterior portion of the upper arch was much protruded.

If this very great alteration in the shape of the mandible of an adult could occur as the result of wearing a mechanical appliance, it seems to me that,

* Since reading the paper on March 29th, I have had a patient referred to me whose mandible has apparently changed in shape in the last few years by the action of the hyoid group of muscles. In the anterior portion of the mouth, the occlusion is gradually opening. This was first noticed by the patient when she lost the power of biting a thread. So far, there is no other explanation than the fact that the muscular action is opening the bite. The patient has been examined and studied by many eminent men without any other cause being found—M. H. C.

† "Deformity of the Jaws Caused by the Extension Bandage in the Treatment of Spondylitis." By G. Lind, Dental Cosmos, January 1913, p. 13.

on the same principle, force when properly applied to a deformed jaw might bring about desirable changes, such as bending it at the angle, and thus reducing its protrusion. That we will ever be able to apply sufficient force to do that I do not contend, but I believe that if sufficient force is applied, the bone will respond, and changes will take place, and I have no doubt that the angle can be made obtuse or acute; but whether this will ever be a practical procedure, I do not know as yet.

The dangers which Dr. Cryer points out might make such an effort inadvisable, but the illustrations of the article that I speak of are very convincing as to the alteration which could take place in the jaw.

Further than that, I saw a similar condition in which a sling had been passed around the jaw somewhat like the Angle chin-cap, and pressure applied backward and upward, and the lower jaw of this patient was forced back perhaps half an inch distally to the upper.

The relations of the incisal region of the upper and lower jaws at least indicate that much change, and though I have not yet had an opportunity to make a careful examination of this case, there can be no doubt that, in two years' time, the jaw has been considerably altered in shape and possibly displaced by this pressure. What took place I do not know, but if I have an opportunity to take X-ray pictures of it I shall do so, and study the effects of the appliance upon the jaw. It will be interesting to know just what changes have occurred.

Dr. W. B. Weinburger, New York. I have examined a case of class II, the patient being one of seventeen or eighteen years, who seems to be normal in profile, the incisors having normal inclination and the lips also being normal. The question which interests me in this case in regard to the angles of the condyles is—Were the angles in the same position at the age of fourteen, or have the jaws shifted since then?

Dr. Cryer (showing slide Fig. 17). The angle of this mandible is nearer a right angle than usual, especially when belonging to a skull with so much protrusion of the teeth. The angle is 118°, while in the typical skull it is 125°. It is interesting to note how the mandibular teeth were carried forward to form occlusion with those of the upper jaw, which were placed so far forward of the foramen magnum. The vital instinct carried the mandibular teeth and their processes forward the width of a molar, which also gave the anterior teeth a labial inclination.

Dr. Hawley. Was the first skull an inherited type?

Dr. Cryer. I think it was an inherited type, as it is supposed to be the skull of a cannibal of the West African Fan tribe.

Dr. Strang. Can we not say that this is just as much a normal skull for that race as the Caucasian skull was for that race?

Dr. Cryer. I should say so. Yes, I think it is a normal West African skull.

Dr. Strang. Then would it be necessary to treat that case?

Dr. Cryer. Not this particular case. It was shown only for the purpose of studying such a conformation, which might be found in a more modified degree in some abnormal case. We have, in this country more than in any other of the world, the mixing or blending of different types.

Dr. Stanton. What would result from breeding the orthognathous with the prognathous type?

Dr. Cryer. Unfortunately, I have not tried it.

Dr. Stanton. Do we not have this on all sides when we see the black and white races mixing?

Dr. Cryer. No, hundreds of negro skulls can be produced, showing no two alike. Hundreds of negros are to be found who are not prognathous, while, on the other hand, many of the white race have protruding jaws.

Dr. F. L. Stanton, New York. If it is true that a child may inherit jaws in which the disharmony of size and form is produced by the intermarriage of different types, would it not be possible to examine the jaws of the father and mother, and ascertain the relation of the types of the father and mother to the deformity in the child? The bone of contention is whether or not the intermarriage of races with different facial angles can produce deformities of the jaws. I was reading today in the DENTAL COSMOS of November 1906* a quotation from one of the essayist's articles: "The intermarriage of German, Italian, and Hebrew races will in time produce a distinct type. At first the offspring of such unions may possess some of the characteristics of the father and some of the mother. These may not always harmonize with each other, with the result that the teeth are not in harmony with the face, or the mandible with the maxilla." From this I would infer that the essayist thinks it possible for the child to inherit the mandible of one parent and the maxilla of the other. I want to suggest that it would be more convincing if he would present models of the jaws of the father and the mother after he has seen a child with these deformities, rather than assume that disharmonies of the jaws and teeth may be produced by the intermarriage of different types.

Dr. CRYER. We can perhaps obtain measurements for one or two generations, but if a man today is going to breed a racehorse, he may have a horse and mare that have great racing ability, but no thoroughbred breeder will attempt to breed a racehorse unless he goes back many years and through many generations. We can readily see animals modified by great-great-great-grandparents, and we have to go back that length of time, because peculiarities are inherited from ancestors all the way back. I cannot give up the idea that these characteristics are reproduced in the offspring of animals, of human beings, and of plants, and, if there is a misalliance, there results in the offspring a mixture, to a certain extent, of attributes that do not harmonize with each other, as the teeth may not harmonize with the face, or the mandible with the maxillæ, though I would not call these attributes deformities.

Dr. DESNOES. Would we not have a blending rather than a mixture?

Dr. CRYER. There is quite a difference between blending and mixing in animals and plants. The color of the offspring of a union of the black and white human races is usually a blending of the two, as a mulatto; the features may be of a mixed type. In breeding the white hog with the black one, however, there is seldom a blending of color, the litter consisting generally of pure white and pure black, excepting little white patches on the face or the feet, as in the case of the Berkshire hog, and occasionally a black-and-white is produced, though not often, as a result of the first crossing.

Dr. F. T. MURLLESS, Jr., Hartford, Conn. In discussing this matter, it may be interesting to refer to the fact that it has been found that the atmosphere of personal freedom and education which is characteristic of our national life has changed the cranial dimensions of the descendants of our immigrants. It is said that the Sicilians with long heads have changed in one generation, and in occasional instances this is true of children born on the other side and brought to this country at an early age, the dolichocephalic type becoming mesocephalic. Also, at the same time, under this favorable environment, the Slavonic types, with their brachycephalic crania, show in their descendants the mesocephalic type. That has naturally led to the conclusion that, at least in a general way, cranial proportions depend upon mentality, food supply, and physiological influences, and that the best of these tend to produce mesocephalic crania.

In the slide shown by Dr. Cryer, in which the mandible has slipped forward, the jaw rests at but two points, upon a few of the anterior teeth and upon the condyle, and the pull of the masticatory muscles is abnormal. This would no doubt produce special tension in the region of the insertion of the masseter muscle, and tend to make the angle of the lower jaw progressively more obtuse.

The question of correcting the angle would really depend very largely upon the points where the force could be

---

* See DENTAL COSMOS for November 1906, vol. xlviii, p. 1074.

applied, and because of the very uncertain base upon which such an experiment could be conducted it would probably be impossible to reduce the angle. The abnormal stress of the masseter muscle upon the bone has tended to thicken it at the point of insertion, and has perhaps contributed to the apparent obtuseness of the angle, and its continued use would doubtless interfere greatly with any correction which one might undertake at that point.

Dr. CRYER. I fully agree with Dr. Murlless as to the modifying effects of environment. Improved conditions and education will change cranial dimensions. This condition we notice particularly in our immigrant class and their descendants. The stand taken by Dr. Murlless in regard to the action of the masseter muscles having influence in modifying the angle of the mandible is certainly worthy of consideration, and I wish to thank him for his remarks.

Dr. I. B. STILSON, Providence, R. I. If I understood Dr. Cryer correctly, he spoke of the teeth in the mandible adjusting themselves so to meet the teeth of the upper jaw as to improve the occlusion. The question which arises in my mind in this connection is—Are the upper teeth placed in their position more constantly, and earlier, and do the lower teeth meet them? or, Do not, as I had supposed, the lower teeth erupt first and form the mold over which the upper teeth are formed?

Dr. CRYER. That is a debatable point, as a rule, but I think you can quote me as saying that the mandible is the frame upon which the upper teeth are placed in position—I believe you will find a statement to that effect somewhere in my writings. The upper teeth and jaws are fixed, in one sense. The upper jaw is not made up only of the two maxillary bones, but of all the bones of the face excepting the mandible, including a part of the sphenoid and the ethmoid of the cranium. It is the articulations with these bones that help to fix the upper jaw and make it comparatively firm, barring a spring in the bones by some mechanical or muscular action. The lower jaw can be pushed forward, but the upper one stays comparatively still, because it is braced there. If you will recall, I showed in Fig. 9 and other figures the manner in which the jaw is braced, not only by its own articulation, but at the sides, by the articulation of other bones.

Dr. STILSON. Would not the facts that the lower jaw-bone can move, and that the teeth are not embedded in bone but in the process, indicate that the lower teeth and the process of the lower jaw move less, and the upper more?

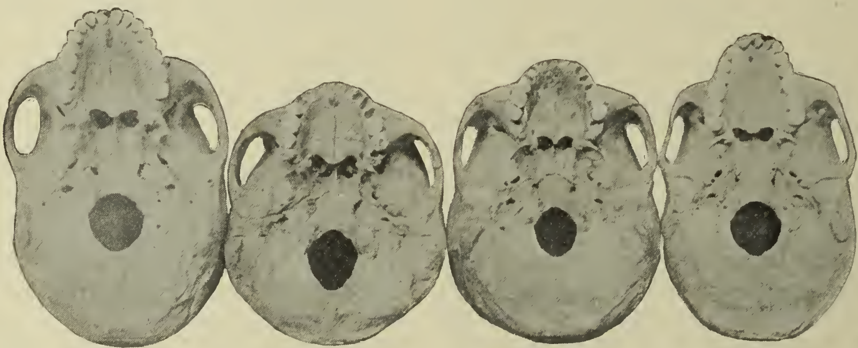
Dr. CRYER. I do not quite understand.

Dr. STILSON. The upper jaw-bone being fixed and the lower movable, would not, in adapting themselves in their relationship, the process and teeth of the upper change more than the process and teeth of the lower?

Dr. CRYER. I do not think so, judging from my experience and from the skulls I exhibited tonight. The lower teeth are, as a rule, not so firmly situated as the upper. The lower teeth extend down into the cancellated bone, and are but little associated with the cortical bone, while the upper teeth are, to a very great extent, closely associated with the cortical bone, which is comparatively solid.

Dr. MILO HELLMAN, New York, N. Y. It seems to me that this evening's paper has not been quite in harmony with the sentiment of the meeting, or *vice versa*. I wish to say first, that orthodontia of today is essentially based upon a knowledge of normal development, and secondly, that the modern practice of this specialty depends upon the recognition of any deviation from the normal. Furthermore, as orthodontic procedures necessarily involve the correction of certain maldevelopments, it is imperative, in diagnosis, to recognize any disturbance of those forces which, by their harmonious co-operation, govern the normal.

If we examine the specimens presented by the essayist, it would be well-nigh impossible to answer his question pertaining to the treatment of this or that abnormal skull, simply because the conditions present could only be diagnosed by assumptions. On the other hand, Dr. Cryer has shown us a prognathous skull belonging to the African Fan tribe, and asked how it would be treated. In my estimation that skull would require no treatment, as the condition is normal for that type. It is singular that we are still inclined to consider a prognathous type as an abnormality; some authors even designating it as "bimaxillary protrusion." It is as normal for the type mentioned above as the so-called orthognathous skull is for the European type, both depending on the inclination of the alveolar process in relation to the face and head.



Negro. Mexican Indian. Thibetan. Australian.
—*Osburn.*

Although anthropologists classify the gnathic index as prognathous, orthognathous, and opistognathous, all races are in fact prognathous (Topinard), the difference being in the degree of the inclination of the alveolar process. This difference, however, is not ascertained in the manner described by the essayist, but by the construction of a triangle, employing as the three points the nasal spine, the incisal point, and the center of the external auditory meatus.

The application of the method advanced this evening involves an increase in the source of error, for there is but one dimension that is resorted to, the horizontal, while in the architectural construction of the head three dimensions are covered. The maxillary portion of the head may vary in its relative position to the foramen magnum in any of those dimensions, diminishing the horizontal distance, and yet remaining prognathous. Again, if these skulls in the illustration from Osburn be observed, it will be seen how the form and position of the foramen magnum may vary in different skulls. In addition to this, the level of the foramen magnum is so different in individuals that it may be on the horizontal plane in one, as in the skull shown by Dr. Cryer, or at an angle of 45° in another, which of course will change the measurement as presented, though not the index.

In conclusion, I wish to thank Dr. Cryer for his highly instructive paper.

Dr. CRYER (closing the discussion). I do not quite understand Dr. Hellman's contention. I ask how would you treat the abnormality in skull No. 18, and Dr. Hellman says it would be impossible to treat this skull, because we cannot get at the deviations of the normal, but must only study normal skulls in order to base conclusions thereupon. I disagree entirely with this view, as in my opinion one must be familiar with as many variations from the normal as possible in order to understand the causes of an abnormality, and to treat it intelligently. I do not ask how one could treat the skull of the African Fan negro, as you will see by referring to Fig. 17 in my paper. It is in regard to Fig. 18 that I ask your opinion, as it represents a type which you may have to deal with and treat.

I wish to say in closing that I appreciate very much the invitation of this society, because there are many questions in regard to this subject that I have wanted to consider with orthodontists.

The meeting then adjourned.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held February 25, 1913.

The regular monthly meeting of the Academy of Stomatology of Philadelphia was called to order by the president, Dr. Joseph Huggins, in the lecture hall of the College of Physicians and Surgeons, Tuesday evening, February 25, 1913, at 8 o'clock.

The President introduced Dr. J. Bethune Stein, New York, N. Y., who read the paper of the evening, entitled "Syphilitic Hypoplasia of the Teeth."

[This paper is printed in full at page 691 of the present issue of the Cosmos.]

Discussion.

Dr. Otto E. Inglis. The studies permitting the placing before us of such evidence as has been given this evening have no doubt been the result of arduous labor, and too much praise cannot be bestowed upon an investigator who has gone to the facts for his knowledge of the subject. It is really wonderful how a few demonstrated facts relegate to the mortuary a great mass of theory based upon clinical evidence alone.

Though syphilographers of wide practical experience have related certain sequelæ of almost constant attendance upon known primary lesions of syphilis—for example, such secondary lesions as eruptions upon the skin and oral mucous membranes and the mucous patch and sore throat resulting therefrom, and such tertiary lesions as the gummata, etc.—and while they were all but certain of its exact etiology, it seems that not until the discovery of the spirochæta pallida or treponema pallidum as a constant and exclusive accompaniment of syphilitic lesions could they fix upon the contagion which passed from individual to individual. This led others to trace the germ into the placenta and embryo and other organs, and also into the subject of hereditary syphilis. A most satisfactory and in many respects conclusive *résumé* of this part of the subject was given by Cavallaro in an article in the Dental Cosmos, running from November 1908 to February 1909 inclusive, entitled "Syphilis in Its Relation to Dentition." This writer showed that the fetus can be contaminated by the spermatic fluid, the ovum, or by way of the placenta from a mother infected extragenitally.

Cavallaro further called attention to the fact that the clinical evidence of syphilis may appear in the newborn child within a few days or weeks, within a few years, or as tertiary lesions at about the age of puberty. Whether the clinical manifestations be mild or severe is beside the question, for it is now evident that the treponema is transmitted, and the child really has syphilis and its manifestations.

As to the relations of syphilis to dental embryology, the clinical evidence in hypoplasic teeth has, from the time of Jonathan Hutchinson, Sr., in 1868, been a disputed question. It has always been an open question whether syphilis or malnutrition or eclampsia, or, most important, the various exanthemata produce the stigmata of pits or grooves or other hypoplasic evidence of permanent character upon the teeth. This is a question which could only be settled in the way in which the more characteristic lesions of syphilis have been related to the primary infection, namely, by finding the treponema in the child, or, better, in the developmental organs of the teeth. The discovery of the presence of the treponema in the dental organs is credited by Cavallaro to Pasini of Florence, Italy, and he claims to have himself found them there in quantity. From his studies of interrupted hypoplasias, or as he terms them, dystrophies, he deduces that the effect of the treponema upon the developmental tissues is to destroy them or cause atrophy, so that constrictions in the organs exist corresponding with the defects in the teeth. He deduces that, when sound tissue is found between the stigmata, the treponema has been active in the individual at different periods. This destructive or atrophic action can readily be comprehended when we regard the dental organs as of dermal origin, and, as such, readily affected by any germ that would produce skin eruptions.

Cavallaro also pointed out clearly the fact that syphilitic lesions of the teeth occur upon the same level of homologous teeth; he also noted the predilection of the attack upon special groups, as the incisors, particularly the upper—Hutchinson's teeth—and the cuspal portions of the first molars—Fournier's teeth—these being the teeth in process of calcification at their tips in the early period at which the clinical evidence of hereditary syphilis is most manifest. The molar tip is calcified first, and therefore when Hutchinson's teeth are found, Fournier's teeth are also found. He also points out that the infection of the fetus may produce dystrophies in the deciduous teeth, and that many other defects of the maxillæ and palate may be attributed to syphilis.

Dr. Stein in his lecture showed dystrophies in the lower teeth of a Frank attributed to about 400 A.D. Considering that it could not be syphilis, though in another case illustrated, of known syphilitic origin, an almost identical dystrophy of lower teeth is shown, Dr. Stein accordingly attributes some of these cases to syphilis, while he states that others are not due to that affection.

It is just at this point that I seem to lose clear vision of the cause of these various dental stigmata—*i.e.* whether they are of syphilitic or exanthematous origin. Which of them presenting in an adolescent patient may be due to syphilis? The true Hutchinson's notch is seldom seen.

If the treponema can exist at any age, why could it not have produced the dystrophy? A positive Wassermann reaction would of course be some proof, but a negative one might merely mean the absence of the treponema after the damage was done.

Dr. Stein also seemed to give the impression that the enamel is formed in the first year. True, its deposition is begun, but it would seem to continue much longer than even the second year in the permanent tooth, and many of these hypoplasias have some deposit of enamel next the dentin while that which should be external to it is lacking. This means a disturbance at a later period, that at which the enamel is first deposited.

So instructive are Cavallaro's statistics relative to the associated signs of hereditary syphilis that I cannot resist quoting his offering of six hundred cases of known hereditary syphilis observed by Sidler-Huguenin and the Fourniers, of which approximately fifty per cent. had some ocular disease, from forty to forty-five per cent. dental dystrophies, and from fourteen to eighteen per cent. auricular lesions. Hutchinson's triad of dental dystrophy, disease of the middle ear, and interstitial keratitis has been modified to some extent by additional ocular and auricular symptoms, which Cavallaro epitomizes in his article.

In a case of my own, Hutchinson's teeth, interstitial keratitis, and nasal catarrh with sunken nasal bridge in a boy of twelve could well be taken as evidences of tardy hereditary syphilis.

In all these cases presenting in dental practice, the practitioner is in a peculiar position, and, as the exact condition of the patient may not be known, either secretions from present associated lesions may be examined by the now known methods for the presence of the treponema, or the Wassermann test may be made. G. V. I. Brown quotes Baum as stating that this reaction occurs also in scarlatina, pellagra, Hodgkin's disease, and leprosy, and does not always occur in syphilis. It should preferably be performed by one accustomed to frequently perform the test. If the finding is positive, one should consult the family physician, as the treatment will fall into his province, and family peace must always have the utmost consideration.

As it is not certain to what extent natural vitality may have overcome the treponema, strict sterilization is a wise precaution after dental operations upon patients exhibiting these dystrophies.

Dr. G. M. Dorrance. This has been a very interesting and instructive lecture. While there are a number of minor points with which I take issue, I agree in the main with the essayist. I was impressed very much by his remark that the teeth are only one diagnostic factor, and that we should always look for other signs.

In regard to oral symptoms of syphilis, one should be very careful to remember that hypoplasia of the teeth can be due to other causes. The differential diagnosis of syphilis of the mouth from early leucoplakia, malignancy, etc., is frequently very difficult, and many complications are likely to arise from a careless diagnosis. In malignancy, for instance, the best time for treatment is lost by delay.

How is one to determine whether a lesion is due to syphilis or not? Clinical experience usually directs us, but in the borderline cases we frequently fail, and this is where the Wassermann test and examination of the tissue for spirochetes are very valuable. There are a certain number of conditions in which the Wassermann reaction will not be of much value. First, the test is usually negative in the primary stage; second, the patient may have taken mercury or other medicine which will interfere with the reaction; third, some authorities claim that large quantities of alcohol cause differentiation in the test.

It is very difficult to obtain a history of the infection, and it is almost impossible to secure a history of congenital lues.

The changes that have been described tonight as occurring in the teeth are undoubtedly due to changes of nutrition of the entire body, and not to any local action of the spirochete. The same changes, in a modified form, can be found in the bones. They may be due to conditions other than syphilis, such as tuberculosis, etc., but in most cases, syphilis is the cause. Children may become infected with the spirochete at any time before or after birth, the date of the infection, of course, producing a different type of syphilitic teeth.

The question of treatment was not included in the lecture, but a few remarks along this line may be interesting. The newer remedies of salvarsan and neosalvarsan have improved our methods of treatment; nevertheless most men are still using mercury and the iodids in combination with these arsenical preparations. The indications for continued treatment are controlled by the results of the Wassermann test.

More important than the cure of syphilis is the prevention, which is a very easy matter. First, let us clearly understand that there are three distinct stages of syphilis and that all are infectious. I know, personally, of six cases in which the victims had become accidently infected. You will all remember the series of infections from a kissing game, in which one boy, not knowing that he had a mucous patch, took part, thereby infecting six or seven people.* There are many other similar instances, including that of a very prominent dentist in this city, who contracted syphilis from one of his patients. He was under the false impression that it was not infectious in the tertiary stage.

The method of preventing infection by the spirochete consists in the use of rubber gloves and twenty per cent. calomel ointment. The ointment is applied before putting on the gloves, and when finished with the operation the gloves are removed, the hands scrubbed, and again the calomel ointment is applied.

A Member. Do you leave it on the hands?

Dr. Dorrance. Yes, it does no harm to leave it on. This method has been thoroughly tried out by rubbing the skin

* See "An Epidemic of Chancres of the Lip from Kissing." By Dr. J. F. Schamberg, Dental Cosmos, January 1912, p. 123.

of a monkey with the calomel ointment, and then trying to infect him with syphilis.

In regard to the question of the Wassermann test, I would say that if the patient can be absolutely prevented from taking mercury, iodids, or other patent remedies for syphilis, then the Wassermann findings can be relied upon.

Syphilis is now curable, but one can become reinfected.

Dr. Robert H. Ivy. With regard to Profeta's and Colles's laws, I think the Wassermann reaction rather explains these laws than disproves the fact that the mother can be infected by a syphilitic child and *vice versa.* A positive reaction in the child of a syphilitic mother shows that it has syphilis in a latent form, and therefore the child cannot be infected by the mother. Wassermann's reaction in scarlet fever, as Dr. Inglis said, has been found positive in a few cases, but only during the febrile stage, so that there is no confusion in those cases. It seems to me that the whole question as to whether dental stigmata should be ascribed chiefly to syphilis depends on which theory we accept as to the period of time occupied by calcification of the teeth. If calcification only proceeds or is complete in the first few months after birth, then syphilis is undoubtedly the cause of a great majority of these defects. If, however, we are a little more conservative, and regard calcification as proceeding for two or three years after birth, then a great many of the other eruptive fevers, such as scarlet fever and measles, must play a more important part in these lesions. If calcification occupies only the first few months, then syphilis must be practically in all cases the cause of the hypoplasic lesions, because calcification is complete at the age when other diseases are common. It is by no means certain, however, that the enamel is thoroughly calcified at this early age.

Dr. Pickerill, in his new book on stomatology, in opposition to the theory that syphilis is the common cause of dental hypoplasia, cites the fact that in New Zealand, where hereditary syphilis is comparatively infrequent, these dental defects are rather common. The results of the Wassermann tests that he has been making have supported his view.

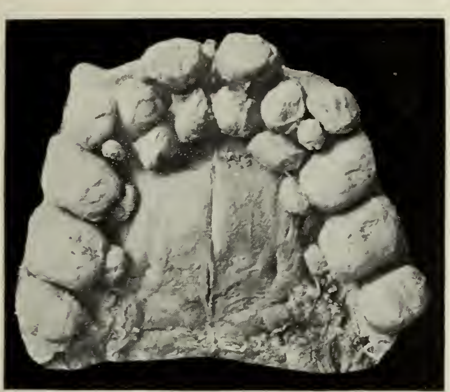
Today I saw a girl nine years of age with typical honeycombed hypoplasia of the permanent incisors, with central caries and poor development of the cusps of the first molars, but who gave no history of syphilis. I questioned the mother in regard to miscarriages, etc., but could get nothing from the history suggestive of syphilis. I took the blood for the Wassermann reaction, but unfortunately will not be able to find out the result until tomorrow. It will be interesting to note whether this case shows a positive reaction to the Wassermann test. If so, the chain of evidence will be complete that this is a case of hereditary syphilis. A negative test may not be of great importance, because these defects may simply be the results of syphilis, and not mean that the disease is active at present.

Cavallaro, who has already been referred to, claims that he can make a diagnosis of syphilis on the dental lesions alone, and that they are of sufficient importance to warrant putting the patient on anti-syphilitic treatment. Whether his views have been modified by our experience with the Wassermann reaction, I do not know.

Dr. I. N. Broomell. One surprising phase of this discussion is that any question should be raised as to the time at which calcification of the teeth begins, and how long this process continues. Dr. Ivy, particularly, has dwelled on this, evidently treating it as though there were some doubt as to whether calcification is a continuous process, or whether it is complete in a short period. It is quite a simple matter to make dissections and find out the extent to which calcification has taken place at a certain time, either before or after birth. By request I brought some slides showing dissections, which may add something to the argument as showing the manner of calcification.

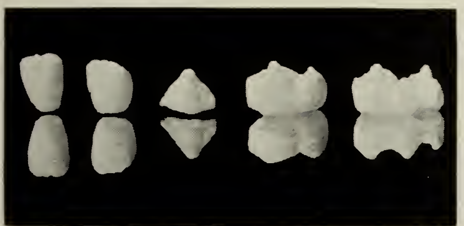
The first slide (Fig. 1) shows a dissection recently made, and similar to one made years ago, the mucous membrane and the periosteum having been dissected away from the hard palate of a child one month after birth. By turning the soft tissue over, we expose to view, as shown in the illustration, the dental follicles, not only those for the deciduous teeth but also those for ten of the permanent teeth. The study can be very easily con-

Fig. 1.



tinued by opening up the follicles (Fig. 2), and noting the extent of calcification as it appears at about birth, or perhaps one month after birth. This illustration shows the incisors, in which almost the entire crowns have calcified; scarcely one-half of the canine, but a large proportion

Fig. 2.



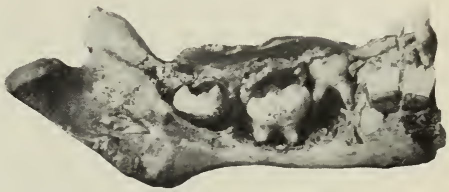
(Reflected picture.)

of the crowns of the first and second deciduous molars have undergone calcification.

Fig. 3 shows a similar dissection on the lingual side of the mandible, made a little later on. Here we can see evidences of the two incisors being almost fully erupted, and we can consider this child to have been about six months old.

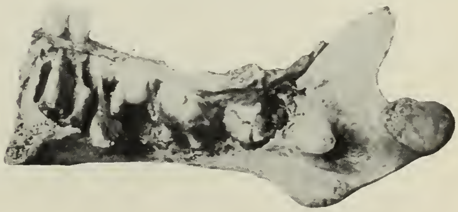
We can note here the various teeth in their follicular coverings. The sacs containing the permanent incisors are

Fig. 3.



shown, giving evidence of the extent of calcification of these teeth at this time. The lateral incisor has developed almost to the same extent, while the canine,

Fig. 4.



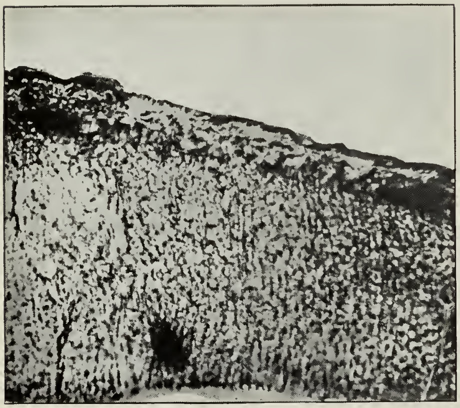
which rests close to the base of the bone, shows one-third of its crown calcified. Nestled between the roots of the deciduous molar we have a sac containing the

Fig. 5.

bicuspid, and at another point the beginning of the second bicuspid.

In the next slide (Fig. 4) we have the follicles open. There is no question as to the age of this child, the two central incisors being almost fully erupted. We see the permanent incisors calcified to about two-thirds of the length of the

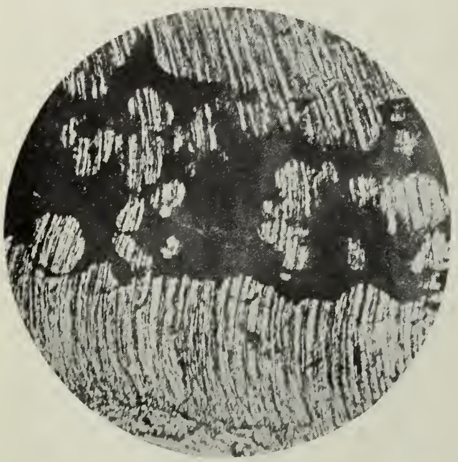
Fig. 6.



crowns, as are also the first and second deciduous molars.

Attention should be called to the defective development of the second molar. It will be noted that while there is no

Fig. 7.



defect in the enamel of the first molar, there is a decided defect in the enamel development of the second molar, showing that there has been some pathological disturbance, resulting in hypoplasia of the tissue.

A Member. What age is that?

Dr. Broomell. About six months.

A Member. What would be the stage of the enamel development at that time?

Dr. Broomell. The enamel would not be complete so long as the tooth is unerupted. It does not rupture the enamel organ until it breaks through the epithelial layer of the mucous membrane.

A Member. Would not that have something to do with the question of hypoplasia?

Dr. Broomell. It certainly would. That is what I am trying to get at, the possibilities of these teeth becoming affected before they are erupted.

The next illustration (Fig. 5) shows two deciduous molars under a higher magnification. The first molar is perfect, the second defective so far as the enamel development is concerned. It is possible that the pathological condition which caused the death of the child is responsible for the defects in the enamel. Had the child recovered, these defects might have been repaired by a secondary deposit of enamel, and we would have had that peculiar pigmentation effect frequently noticed in enamel.

To carry out this study farther, two or three other slides were made. These showed a disarrangement of the enamel rods and a peculiar pigmentation, as well as a disarrangement of the dentin.

Fig. 6 is another specimen under higher magnification, which is quite typical of the effect of hypoplasia of the enamel. There is no definite arrangement between the enamel rods, a complex tissue with no definite structural arrangement. There has evidently been a discontinuance of development at this point [demonstrating]. Here and there are breaks in the structure which show an attempt at repair which has not been carried out.

Fig. 7 shows a microscopic section of the dentin of these teeth, exhibiting the characteristic so-called interglobular spaces usually present in that structure when hypoplasia is present.

Dr. Nathaniel Gildersleeve. The important point in connection with this whole subject lies not only in the diagnosis of syphilis itself, but in the differential diagnosis from other conditions as manifested in the oral cavity, as well as in different parts of the body.

Today in the laboratories we are relying to a great extent upon the Wassermann reaction, but we are paying altogether too little attention to the use of the staining methods for determining the presence of the treponema pallidum, and to the use of the dark-field illuminator. When the dark-field illuminators were first put on the market, they were extremely unsatisfactory, and, as a matter of fact, we obtained better results from some of the old paraboloid condensers made by Beck in London and Zentmeyer in Philadelphia, but the later types of the dark-field illuminators are very satisfactory, if one has the proper light and knows how to manipulate them. It requires, however, not a little experience to handle one of these devices properly to get the best results, and some experience is needed in taking material from the lesions so as to be sure that the material contains the organisms.

It is important to bear in mind that there are conditions other than syphilis which will cause inhibition in the development of the fetus *in utero*, and many other dystrophies besides a dystrophic condition of the teeth, and that other pathologic conditions in the mother may affect the fetus.

There are a good many cases that have been diagnosed as syphilis through examination of the teeth without taking into consideration the fact that the condition of these teeth may have been due to some other pathological condition.

Dr. Stein (closing the discussion). Several points which are of interest have been brought out in the discussion.

Syphilis is such a broad subject that it has been said that—"If a fourth-year megalo-cephalic medical student knew syphilis, he would not have much trouble in carrying the rest of medicine in his head."

Syphilitic hypoplasia of the teeth is usually symmetrical, affecting certain types of teeth at a given time, and, as I have said, is due to a disturbance of metabolism in the cells of the tooth germ caused by the syphilitic infection. The mere presence of the treponema pallidum in a tooth germ would not be likely to cause such symmetrical lesions on the same kinds of teeth in both the maxilla and the mandible.

Scarlatina may give a positive Wassermann reaction, but the differential diagnosis of syphilis and scarlatina is easy.

The Wassermann reaction may be positive in certain tropical diseases and in tuberculosis—in the latter about 1 per cent. of cases. How do we know that the patient is not suffering from both tuberculosis and syphilis?

I have no knowledge of the special diseases in New Zealand which cause a positive Wassermann reaction. I do not know what kind of diseases they have in New Zealand.

The Wassermann reaction is not always positive in heredo or latent syphilis. Some of the worst cases, that never get well and where neither mercury, iodin, or salvarsan seem to have any effect, give a negative reaction. In such cases the syphilitic probably possesses no syphilitic anti-bodies. The Wassermann reaction, nevertheless, is of great worth in the detection of syphilis.

A positive Wassermann reaction is a valuable symptom of syphilis; a negative reaction is only of value at the time when it is obtained. The Wassermann reaction is not only of use in detecting syphilis, but helps to determine the degree of the syphilitic infection at a given time. I had ample opportunity of studying the effect of anti-syphilitic treatment upon the positive Wassermann reaction at the sero-diagnostic station at Finger's Clinic in Vienna, which was conducted by Dr. Rudolph Müller, under whom I served, and up to the time I left Vienna in September 1911, over 36,000 suspected cases of syphilis and controls had been examined.

The dark-field microscope is of great use in the diagnosis of a chancre or mucous patches; for after having found the treponema pallidum in the exudate from one of these lesions, we can place the patient at once under treatment and heal these lesions, which are very infectious.

It is important to know where to look for the treponema pallidum in the chancre, as it is rarely found upon the surface of the lesion, but beneath the surface at the side of the erosion. The chancre should be washed with saline solution, and its edge scraped with some sharp instrument until the serum exudes. After the lesion has been squeezed, some of this exudate is to be taken for examination. One man may search for the treponema pallidum in a lesion and never find it, while another may find it at once.

Prof. R. W. Taylor, under whom I served for twelve years in the department of genito-urinary diseases at the College of Physicians and Surgeons, Columbia University, New York, was in the habit of saying that lying was a symptom of syphilis.

I am glad to hear what has been said at this meeting regarding salvarsan, for it has received some hard knocks, but it is mostly from those who have had no experience with it, and have read the writings of prejudiced individuals. The discovery of salvarsan is one of the greatest discoveries in medicine.

Incidentally I might mention the fact, as proved by Gerber, that salvarsan is the only disinfectant that kills all the spirochetes in the mouth.

The statement has been made that there is much syphilis in our midst. I remember Prof. Herman Knapp, the ophthalmologist, making the statement that—"Many persons have syphilis; never believe a patient who you think has syphilis when he denies having the disease." Lesser says, if I remember correctly, that 14 per cent. of the population of Berlin have syphilis.

The treponema pallidum has been found in the ovocyte, but infection *ab ovo* has not been proved.

The treponema pallidum has not been found in either the spermatozoa or the semen of syphilitics, but the semen of syphilitics in the secondary period of the disease has been proved infectious, because it produced a chancre upon apes which were inoculated with it.

I have attempted to show that hypoplasia of certain teeth is simply one point in the diagnosis of syphilis. We should keep in mind that the triad of Hutchinson—viz, Hutchinson's teeth, otitis media, and interstitial keratitis—is diagnostic of heredo-syphilis.

As I stated before, the stigmata upon the teeth are at times the only signs of the disease.

The meeting then adjourned.

EDITORIAL DEPARTMENT.

SCIENTIFIC RESEARCH.

FROM all directions, generally speaking, come the expressions of a desire for more results in the way of research into the unsolved problems that confront us as a profession, a demand for more knowledge of underlying conditions upon which to base a more rational system of practice. The demand is not new, for ever since Miller demonstrated what might be accomplished in a practical way by systematic scientific research the illuminating effect of his example and the brilliancy of the results which he attained have acted as a sort of intellectual ferment in the creation of the general desire for more light, and a recognition of the fact that the light may be had if it be properly and persistently sought.

It is only within comparatively recent years that scientific research work has had any recognizable standing in the court of dental professional opinion. The self-styled "practical man," who sneered at the scientific laboratory worker as a dreamer and theorist, held the center of the stage and proclaimed the superiority of his empirical methods as the only type of practicality worthy of serious consideration. But the dental profession, under the convincing logic of demonstration after demonstration, is re-defining the term "practical," and is beginning to use with more and more discretion and precision of application and meaning such terms as "practical," "scientific," "theory," "hypothesis," and other terms expressive of relative orders of thought and phenomena. We are realizing more and more that science is knowledge, or ascertained truth, organized into systematic order; that "scientific" is descriptive of a precise method of thinking or doing, and that a "theory" is, within its proper meaning, one of the most practical conceptions with which humanity, by and large, is enabled to conduct its most practical affairs.

The growing recognition of the importance of all these things has brought about with marked insistence the demand for scientific research into unsolved dental questions during the past several years. Nearly everybody wants somebody to take up scientific research and find out something useful about things concerning which we now know but little or nothing. Funds are being collected—indeed, have been collected—for the purpose of "endowing scientific research," or "establishing a chair of scientific research," or paying someone to "carry on" or "carry out" "original re-research." Besides the encouraging recognition of the value of scientific research upon the part of the general dental profession which these tendencies manifest, there are certain other implied characteristics of this movement that need to be taken into thoughtful consideration if the most fruitful results are to be attained thereby. First, it may be seriously questioned whether, in its best expression, scientific research is something that can be bought at all, or that the true scientific worker is one whose work can really be subsidized upon a commercial basis, any more than it is possible to buy a wife. Scientific work is a labor which must be performed *con amore*, and the man who sells his services to science deludes not only himself but his public into believing that the output of his labor is veritable science rather than a commercial imitation thereof. Moreover, the very attempt to subsidize the scientific worker involves another fundamental misconception—viz, the idea that fitness for scientific research is a divine endowment given only to the especially favored few; that the scientist is somehow a special creation different to ordinary or unscientific humanity because of his fitness to unravel the mysteries of nature and interpret the language of the unknown into terms of the known.

We have already called attention to the meaning of the terms "science" and "scientific" as representing in the first place organized knowledge or truth, and in the second place a mode or method of dealing with truth and knowledge—the vital essence of the mode or method being precision and accuracy, resulting in the elimination of error. If the foregoing view may be accepted as fairly correct in principle, then the scientific method of research, as reduced to its lowest terms, becomes simply the accurate and precise method of thinking and doing with respect to any given category of phenomena. It is a matter of common knowledge that untrained human testimony upon any subject or with respect to any phenomena is, generally speaking, wholly untrustworthy. It is the purpose and object of the scientific method to eliminate the factor of observational error by developing the ability to observe and report with accuracy. Is not this type of culture—with the discovery of truth as its objective purpose—a worthy and noble goal of self-education?

It is clearly recognized that certain types of mind are by natural endowment and educational training pre-eminently fitted for original research work. Such individuals are, however, comparatively rare; Huxley placed their number, as related to society in general, at about the ratio of one in four hundred thousand. Moreover, researchers of this particular type are their own justification; they need no external stimuli to insure their productiveness, and our present contention, therefore, does not apply to their case. The purpose of this article is to emphasize the fact that the average practitioner of dentistry must, in order to keep abreast of the advances of his professional work, devote some of his time to study and self-education; and therefore, to the degree that he brings to bear upon the study of his problems habits of accurate observation, logical thinking, and precise reasoning, he is not only cultivating scientific methods of thought, but is in no small degree contributing to the accumulation of professional knowledge as an original researcher.

If, then, scientific research is but the result of precise observation and reasoning upon the part of the trained worker, it is evidently within the capacity of each of us to contribute a quota to the sum-total of our professional knowledge, and the sooner we let go of the fetish that to see the truth and correctly reason about it is a special divine endowment, and arrive at a belief that these things are our common human heritage, to be cultivated by systematic training, we shall have more scientific researchers, more seekers for the truth among us, and less need to buy the services of the few than we shall then have to applaud the attainments of the many.

REVIEW OF CURRENT DENTAL LITERATURE.

[*Lancet*, London, March 15, 1913.]

THE ABUSE OF HYPNOTIC DRUGS IN AMERICA. ANNOTATIONS.

The increase in the habit of self-drugging is going on in many parts of the civilized world. It is perhaps less marked in the British colonies, where people live more natural lives, and is probably most pronounced in America. In England, and more successfully on the continent of Europe, it is kept in check by the proper administration of the several poison laws. In the United States, in every state, the sale of poisons is the subject of legislation, some of which is very drastic on paper, but is not properly enforced. The United States Public Health Service has recently issued an official publication (*Public Health Bulletin* No. 56) in which figures are given to show the extent to which the drug habit has grown in America. This report shows that since 1860, when the various forms of opium and its alkaloids were separately enumerated in the tariff schedules, there has been 351 per cent. increase in the importation and consumption of all forms of opium as against 133 per cent. increase in population. During the last ten years there has been an annual importation and consumption in America of over 400,000 lbs. of opium, and it is stated that fully 75 per cent. of this is manufactured into morphin, 80 per cent. of which, it is estimated, is used by victims of the drug habit. The report goes on to say that—"In addition to the tremendous amount of opium unnecessarily consumed annually in the United States, it has been estimated that 150,000 oz. of cocain are illegitimately used each year"; and further—"Hundreds of pounds, probably tons, of chloral and other hypnotic drugs are consumed annually by the people of this country, who, it has been asserted, are rapidly becoming hopelessly addicted to the habitual use of narcotic drugs of various kinds." The remedy for this abuse is not easy to find, but it is possible that much good might be effected by a greater uniformity in the poison legislation of the several states, and by a more careful administration of it. The report also deals with other forms of legislation designed to protect the public health. The laws relating to the misbranding of drugs and foods are of comparatively recent origin, and the differences in the requirements with regard to the labeling of foods and drugs suggest the need for greater uniformity in the several state laws.

so as to provide for the ample protection of the public, and yet avoid as much as possible unnecessary requirements that tend to hamper trade, increase the cost of production, and greatly enhance the cost of food and drugs to the consumer.

SYMPOSIUM ON THE RELATIONS OF DENTAL AND ORAL HYGIENE TO HEALTH.

THE TEETH AND THEIR RELATION TO THE BODY. BY G. H. WRIGHT, BOSTON.

ORAL PROPHYLAXIS. BY H. W. ADAMS.

SCHOOL INSPECTION AND DENTAL CARIES. BY W. J. GALLIVAN, BOSTON.

THE PURPOSE OF THE FORSYTH DENTAL INFIRMARY. BY T. LEARY, BOSTON.

A WORD ON THE SCIENTIFIC, ECONOMIC, AND SOCIAL PROGRAM OF THE FORSYTH DENTAL INFIRMARY. BY H. DEW. CROSS.

The dental papers published in this issue of the *Journal* call renewed attention to the public importance of oral hygiene and instruction for children, and to the approaching completion of the Forsyth Dental Infirmary, which will make possible the realization of some of our ideals in dental care and prophylaxis. The infirmary, whose beautiful marble building is an architectural as well as a sociological adornment, has recently issued a pamphlet, prepared for the International Congress of Hygiene and Demography at Washington, in which are outlined not only the plans for the institution, but the nature of the work which it will have to do and the spirit in which the work is to be undertaken.

"The acute dental needs of the children have never been fully recognized outside of the profession; their importance has never been acknowledged. Until municipalities recognize these needs and their obligation to meet them, the work must be carried on by independent foundations. The Forsyth Dental Infirmary represents the first attempt on an adequate scale to satisfy the requirements. This is a plea for recognition of the right to develop children physically as well as mentally at the public expense. The private dental clinic would eventually obtain public support in freely giving expert advice and dental treatment to pupils in the schools. It is an aim that should be encouraged to the extent of providing for children in poverty whose parents cannot pay for the treatment needed. Public support and all charity support should stop here."

The work is indeed of great importance, and rightly administered should be capable of accomplishing immense good in the community.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, February and April 1913.]

WHICH IS THE BEST METHOD OF CLEANSING THE ORAL CAVITY? BY PROF. KUESTER AND W. WEISBACH.

THE MECHANICAL CLEANSING OF THE ORAL CAVITY. BY J. GOLDHAMMER.

After most painstaking and elaborate investigations into the cleansing and bactericidal effects of a great many of the dentifrices and mouth-washes popular abroad and in the United States, Kuester and Weisbach come to the conclusion that disinfection of the oral cavity by rinsing with the solutions usually employed seems an impossibility. Cleansing with tooth-brushes and all sorts of chemical compounds that are not detrimental to the organism, never reduces the oral flora more than 50 per cent. The same reduction in the oral flora can be obtained by the employment of ordinary white clay in conjunction with physiological salt solution. This common table salt solution, which is isotonic, is the most indifferent mouth-wash, that is not in the least irritating, while white clay is an excellent mechanical cleanser and a good therapeutic agent in case of angina, diphtheria, etc. From the standpoint of popular hygiene the cleansing of the mouth with these agents is recommended for economic reasons.

Goldhammer also strongly indorses the use of white clay and physiological salt solution, but objects to the taste, which, in his opinion will not tend to popularize these simple preparations. He therefore proposes the substitution of argilla for white clay, which is frequently impure and unduly hard. In combination with catechu, which is astringent, it gives a cheap, fine aromatic tooth-powder, which has been recommended by the International Commission for Public Oral Hygiene in 1912.

[*L'Odontologie,* Paris, March 30, 1913.]

APPLIANCE FOR REGULATING SEVERAL ROTATED TEETH AT ONCE. By L. Ruppe, Paris.

Frequently, after a successfully completed regulating operation for the widening of the dental arch, the teeth are still in malposition toward one another, and require more or less rotation upon their axes. For this operation bands with spurs or tension screws are usually employed. The writer suggests the following simple appliance for this purpose: A plaster impression of the widened arch is taken, and, before the model is poured, a pin is placed in the long axis of each tooth. After pouring the model, each tooth is sawed off without disturbing the pin, and the plaster teeth are replaced on their respective pins in the positions which they are to occupy after the regulation, and fastened on the model with sticky-wax. One lingual and one facial splint are then swaged or cast, and the portions in the interdental spaces are reinforced and notched with a fine round file. The splints are then polished, their edges rounded off, and are fixed in place with strong Angle ligatures, which are tightly twisted on the labial side. The teeth are thus put in a sort of vise, which should be tightened as often as feasible.

[*Deutsche Monatsschrift fuer Zahnheilkunde,* Berlin, February 1913.]

EXPERIMENTAL INVESTIGATIONS REGARDING THE CAUSE OF DEATH OF THE DENTAL PULP UNDER SILICATE CEMENTS, WITH THEORETICAL AND PRACTICAL STUDIES ON CEMENTS AND OTHER FILLING MATERIAL. By Dr. Proell, Koenigsberg.

Proell has subjected a great many cements and other plastic filling materials to very accurate tests under a great variety of different conditions, the results of which he summarizes as follows: Death of the dental pulp under zinc phosphate and silicate cement fillings is more of an infectious than a chemicotoxic character, resembling in its clinical aspect gangrene with subsequent osteitis and purulent pericementitis in case of hidden caries. The cause of infection is not to be attributed to the lack of antiseptic action of cements, for freshly mixed cements possess at least an inhibiting action upon the growth of bacteria, nor must it be attributed to the perviousness to bacteria of the cements commonly in use. Doubtless a considerable quantity of liquid penetrates dental cements, but their permeability by water and ether has so far not been proved experimentally. Many silicate and zinc phosphate cements exhibit considerable changes in volume in the oral secretions at body temperature—generally a contraction which impairs marginal adaptation. This volumetric change is the most probable cause of gangrene of the pulp under cement fillings. In the air, fresh as well as old silicate cement fillings dry out quickly and contract. The changes in volume observed in silicate cements render the application of these cements impractical in anterior teeth, especially in places that are not continually flooded by the oral secretions. In every case the cavity must be carefully prepared for a silicate cement filling, and by the aid of a very tenacious agglutinant a firm union of the silicate cement with the cavity walls must be obtained so that marginal adaptation is preserved despite contraction. The drying of fresh or old silicate cement fillings after setting must be carefully avoided. The absolute advantage of the customary two methods of varnishing the cavity interior or inserting a zinc phosphate lining cannot be proved experimentally. The silicate cements employed in dentistry exhibit physical properties similar to those of Portland cement as employed in building operations, while chemically they are perhaps nearer to the zinc phosphate cements. In order to arrive at final criteria for the quality of cements, the author urges further scientific tests and the establishment of definite, simple and expedient methods enabling the practitioner to decide upon the merits or shortcomings of a cement.

Periscope.

Sharpening Pyorrhea Instruments.—In sharpening pyorrhea instruments, the corners should be rounded off to avoid cutting any grooves in the roots of the teeth.—*Dental Review.*

Contra-indications to Antipyrin.—Antipyrin is contra-indicated in persons with cardiac trouble, owing to the depressing effect of this drug upon the heart with subsequent circulatory disturbances.—*La Odontología Colombiana.*

Treatment of Hypertrophied Gingivæ.—The following remedy can be highly recommended for combating hypertrophy of the gingivæ so common in pregnant women: Zinc chlorid, 2 parts; peppermint water, 250 parts.—*Anales de la Soc. Dental de Habana.*

Desensitizing Sensitive Dentin.—Hypersensitive dentin at the cervical margin is best treated with a concentrated solution of sodium bicarbonate in glycerin, thus avoiding discoloration as produced by silver nitrate.—*Odont. Tidskrift*, per *Oesterreich. Zeitschr. f. Stomatologie.*

Seventy per cent. Alcohol Best for Disinfection.—According to the investigations of Beyer, as published in the *Muenchener Med. Wochenschrift*, 1912, p. 1408, the maximum disinfectant powder of alcohol is at 70 per cent., while absolute alcohol is a weaker disinfectant.—*Deutsche Monatsschr. f. Zahnheilkunde.*

Preventing Nausea in Taking an Impression.—If the patient has a tendency to nausea, a little of the following solution should be painted on the soft palate: Cocain hydrochlorid, 0.25; menthol, 0.10; phenol, 1.00; distilled water, 50.00; alcohol enough to make a 90 per cent. solution.—*Revista Odont. Paulista.*

Vinegar for Softening Plaster.—Vinegar is a very good means for removing hardened plaster of Paris from the hands, or from flasks. Plaster models can be easily removed from an articulator by pouring a little vinegar upon the portion where the bow is embedded in plaster.—*Oesterreich. Zeitschr. f. Stomatologie.*

Preparing a Gold Inlay Wax Pattern for Investment.—When the wax model for a gold inlay has been trimmed to correct form, and the surface has been carefully gone over with a very small quantity of oil of cajuput, it is carefully washed off in water and gone over with liquid soap and water. Besides giving a beautiful finish to the wax, it will be found that this treatment enables the operator to paint the investment on the wax much more readily.—E. S. Best, *Dental Review.*

Removing Nickel-plating. — Before replating nickel-plated articles it is often necessary first to remove the remains of the old plating. This is sometimes done by means of a so-called stripping bath. The results of this method are not always satisfactory. The *Keystone* recommends its mechanical removal by means of a polishing wheel and an abrasive powder whenever it can be done. This leaves the surface in better condition to receive the new deposit.—*Dental Brief.*

Disinfection by Iodin Before Extractions.—In order to prevent infectious matter from being carried by the forceps from the neck of the tooth into the alveolus, thus frequently setting up post-operative infection, the neck and surface of the tooth or root to be extracted should be carefully cleansed with a cotton wad dipped in iodin. This method of disinfection of the field of operation is very simple and efficient, and insures freedom from infectious sequelæ.—*Deutsche Zahnaerztliche Wochenschrift.*

Nitrous Oxid and Oxygen Analgesia.—The technique required to produce and maintain the analgesic stage with nitrous oxid and oxygen is not difficult to acquire, but unless it is perfectly mastered, good results will not be obtained. Most operators make the great mistake of keeping their patients too far under the anesthetic, and then trying to work upon them during the excitable or second stage of anesthesia. This stage is entirely too deep and unsatisfactory, both to the dentist and the patient. The latter must not be carried to the unconscious stage, but must be left in control of his mental faculties at all times.—A. E. Smith, *Oral Hygiene.*

Means for Determining Vitality of the Pulp.—A useful test for determining the vitality of a pulp is the temperature test. For it, a small instrument is heated and applied to the crown of the tooth, or to a metal filling if one be present. If the pulp is vital, momentary pain will be felt on applying the heat. Cold may be applied by dipping a tightly rolled pledget of wool into some very volatile substance, like ether or ethyl chlorid, and applying to the crown of the tooth. A positive result is conclusive, but a negative one is not.—*Journ. Laryng., Rhin., and Otology*, per *N. Y. Med. Journal.*

Removing Broken Burs and Broaches from a Root-canal.—The following method has proved very efficient: A small pellet of cotton saturated in sulfuric acid is laid over the broken instrument, and carefully sealed with gutta-percha and left in the cavity for several days. The pellet is then removed, the cavity flushed with water, and an attempt is made to pass a barbed broach between the root-canal wall and the instrument, and to lift out the latter. If this is unsuccessful, the sulfuric acid application is repeated. Usually the instrument can be removed on second trial. The root-canal is then cleaned and bleached with pyrozone, and the filling inserted.—*Arch. für Zahnheilkunde.*

Liquid Celluloid and Its Uses.—Liquid celluloid is obtained simply by dissolving small pieces of clear celluloid, such as is used for covering photographs, pictures, etc., in acetone, making a varnish of more or less thick consistence. This varnish is very suitable for assembling plaster impressions or mending broken plaster casts. A thin solution of celluloid is excellent for varnishing the plaster model, also the upper half of the flask after separating and boiling out the wax in vulcanite plate work, thereby insuring a smooth and brilliant surface to the plate. To exhibition models this solution imparts a glossy, beautiful appearance, and greater durability. It is preferable to keep a thin solution, and if desirable apply several coats. The celluloid solution may also be used for lining cavities.—*La Odontologia*, per *Journ. Zahnheilk. u. Zahntechnik.*

Care of the Operator's Hands.—In surgical cases, the operator's hands and arms are brushed thoroughly with hot water and tincture of green soap. Particular attention is given to the nails, which are pared and cleansed with a nail-file and orange-wood stick. The hands are then rinsed in sterile water, bathed in alcohol, and immersed for some time in a sublimate solution. If rubber gloves are worn, the hands are dried in a sterile towel and powdered with sterile talcum powder, and the sterile gloves are put on. If there are any cuts or abrasions upon the fingers, these are painted with a coat of collodion. In daily dental practice the thorough brushing of the hands and fingers with a good soap and hot water is sufficient. If an operator is treating a syphilitic patient and should injure the skin, the immediate and very thorough massage of the wound with $33\frac{1}{3}$ per cent. calomel ointment is a prophylactic measure against infection. The hands must always be very thoroughly dried before going out, to prevent chapping.—W. J. LEDERER, *Dental Digest.*

Exercise for the Deciduous Teeth.—Emphasis is to be laid upon the importance of efficient mastication during early childhood for the proper development of the jaws and accessory parts, as well as for the prevention of dental disease in later life. The deciduous teeth should be exercised by chewing. In addition to a diet made up largely of milk, such articles as a smooth-ended chop or chicken bone should be given the child to chew. Dry crusts, toast, or rusk, well buttered, may also be given. Unable to swallow these in the dry state, the child chews them, thus exercising the jaws and causing a sufficient secretion of saliva. The milk is given separately. This method is vastly preferable to giving the child food sodden in milk or gravy, such as soft porridge deluged with milk.—*Journ. Laryng., Rhin., and Otol.*, per *N. Y. Med. Journal.*

Treatment of Alveolar Abscess.—In all alveolar abscesses evacuation of the pus and extraction of the offending tooth, if too badly decayed to be preserved, should be carried out early; delay in these cases is dangerous. After opening such an abscess, or extraction of the tooth, the use of hydrogen dioxid to wash out the cavity should be avoided. This remedy has very frequently been the direct cause of extensive destruction of bone. If, in spite of this treatment, the infection progresses, the further care of the case depends on the course of the disease. In the early stages the application of an ice-cap to the affected side of the face, together with pressure by a gauze pad and bandage, will tend to reduce pain and swelling, and possibly limit the extent of the infection. When there are indications that pus is present, it should be evacuated, through the mouth if possible, and if not, by as small an external opening as is necessary to give thorough drainage.—R. H. IVY, *Dental Brief.*

Hints, Queries, and Comments.

HEATING ALCOHOL: DR. FISCHLER'S REPLY TO HIS CRITICS.

To the Editor of the Dental Cosmos:

Sir,—In answer to the criticism in your June issue of my suggestion for warming alcohol (printed in the April issue) I would like to state as follows:

Passing the saturated cotton over the flame and letting it burn for one second does not heat the alcohol sufficiently. It has to burn a good deal longer than that—with the result that most of the alcohol on the surface of the cotton is consumed.

By holding the heated thimble containing the alcohol close to the patient's mouth, the distance one has to carry the saturated cotton is so short that it will not cool off. The cotton is thoroughly saturated with warm alcohol, and when touched to the cavity flushes it effectively. A pellet of dry cotton is introduced immediately afterward.

I believe that my method, although it takes a few seconds longer, is more effective.

Bernard Fischler.

Brooklyn, N. Y.

GOLD FILLINGS IN ARTIFICIAL TEETH.

To the Editor of the Dental Cosmos:

Sir,—I notice that in the May issue of the Cosmos, page 528, a clinic is reported in which the clinician demonstrates a method of putting gold fillings in artificial teeth by means of grooves and cement. I think the following procedure, which I have been using for certainly ten years, to be much better for the purpose.

Grind a small depression where the gold filling is to be placed; cover this with Jenkins' inlay body mixed to a thin cream. Press in the piece of crystal gold, the size of the depression, and fuse in an electric furnace. When cold, more gold can be malleted to the gold base, using the same care as with a gold filling. I have never yet seen one of these fillings come away from the tooth. I trust this will interest your readers.

C. Every Brown, L.D.S.

Dundee, Scotland.

Obituary.

DR. DRURY J. McMILLEN.

Died, at his home, Kansas City, Mo., on April 2, 1913, Drury J. McMillen, M.D., D.D.S., of heart disease, in his sixty-eighth year.

The passing of Dr. McMillen, dean of the Western Dental College of Kansas City, Mo., closes the career of one of the most noted dentists in the West and Southwest. Both as a dental teacher and as an indefatigable worker in dental society matters, the deceased won for himself the love and admiration of many student generations, and notably appreciated was his conservative and considerate attitude as a member of the National Association of Dental Faculties—so as to render his demise a severe loss to the dental profession.

Dr. McMillen was born in Bracken county, Kentucky, in 1846. At the age of fifteen he moved to Chillicothe, Mo., during the early days of the civil war, and during that most critical period was made deputy sheriff, in which capacity he saw much active service and took part in many exciting and dangerous events, being once severely wounded by a gunshot. Following the close of the war, although he had not yet reached his majority, the deceased was appointed collector of internal revenue by the government, and again exhibited that courage and energy that characterized his activity during manhood.

In 1868, Dr. McMillen married Miss Sallie Poindexter, and a few years afterward he took up the study of dentistry under the preceptorship of Dr. J. W. Greene of Chillicothe. After practicing dentistry for a time in Brunswick, Mo.—from 1874 on—he felt the need of perfecting himself in his profession, and subsequently attended the Missouri Dental College in St. Louis. Following his graduation from this college in 1877, he returned to Brunswick, Mo., where for seven years he conducted a very lucrative practice. In 1882, Dr. McMillen moved to Kansas City, Mo., and quickly succeeded in establishing a good practice. He was materially interested in the organization of the Western Dental College in 1890, being elected to the deanship, to which office he devoted his undivided energy after retiring from active practice in 1896. He held the chair of operative dentistry throughout his connection with the college, and, in 1895, had the degree of M.D. conferred upon him by the University Medical College of Kansas City, Mo.

Dr. McMillen was a progressive in every field of dentistry, and his early demonstrations of bridge work as well as his mastery of continuous gum work and non-cohesive gold technique eminently fitted him for his teaching position, and made his presence at dental meetings an ever-welcome event.

The deceased was a member of the Kansas City Dental Society, the Missouri State Dental Society, and at one time president thereof, also a member and late president of the National Association of Dental Faculties, an active member of the National Dental Association, and an honorary member of many state and district societies.

As a loving father of his own immediate family, and a devoted friend and generous adviser of generations of students, Dr. McMillen set a high example, and, though it seemingly terminated before his life's work was fully crowned, his career was one of genuine usefulness and lofty inspiration.

DR. JAMES A. HALL.

Dr. James A. Hall died at Collinsville, Ala., July 24, 1912. He was born in Oneida county, N. Y., January 15, 1841.

Dr. Hall had reached a little more than threescore and ten years of life. He received his early training in the public schools, from which he went to Rome, N. Y.; later to Gloversdale Seminary. He taught school three years, and then renewed his studies in New York City, choosing dentistry as his vocation. He practiced there about six years, when his health failed, and he moved South, in 1867. In order to build up his health he went into the railroad business, in which he continued for nine years. December 29, 1874, he married Miss Josie C. Nicholson. Seven children survive from this union.

In the year 1876 Dr. Hall settled in Collinsville, Ala., and resumed the practice of dentistry, in which he was most successful. He early identified himself with the Alabama Dental Association, of which he was a lifelong active and progressive member. It was the rarest thing that he failed to attend its meetings, and although suffering from ill health was present at the last meeting in June, just a few weeks before the end. In 1894 he was elected a member of the Alabama Board of Dental Examiners. A few years later he was chosen president of that body, which position he filled until his death. His work on the board was epoch-making. He instituted the practical phase in the examinations. Being a man who kept abreast with the times, in addition to his affiliation with his state societies he was a member of the National Dental Association and the National Association of Dental Examiners, also a member of the Southern Branch of the National Dental Association. It was his custom to represent the Alabama board at the annual meetings of the National Board of Dental Examiners, and a few years ago he was elected vice-president of that body. He was elected honorary vice-president of the Fourth International Dental Congress, held at St. Louis in 1904. He represented the state of Alabama at the Lewis and Clark Dental Congress, and was one of its vice-presidents.

The death of Dr. Hall removes one of the most conspicuous and remarkable characters of the dental profession. He was not an ordinary man, and cannot be judged by the standards of ordinary men. He was aggressive in all things, and fearless of consequences in the prosecution of his endeavors. Criticism was to him a stimulus to renewed activity, failure a thing which did not enter into his calculations as a possibility. His chief ambition was the advancement of dentistry.

Brief Necrology.

Dr. JOSIAH OXFORD KELLER of Chicago, Ill., on April 9, 1913.

Dr. ARTHUR W. MINAKER of San Francisco, Cal., on April 16, 1913.

Dr. WILLIAM R. WATTERSON of Pittsburgh, Pa., on April 21, 1913. Deceased was a graduate of the School of Dentistry, University of Pittsburgh.

Dr. M. ORDWAY DALY of Boston, Mass., on April 7, 1913, in his forty-seventh year. Deceased was a graduate of the Tufts College Dental School.

Dr. CHARLES EDWARD MOORE of Brooklyn, N. Y., on April 6, 1913, of acute kidney trouble, in his fifty-fourth year. Deceased was a graduate of the New York College of Dentistry, and a member of the New York Dental Society.

Dr. J. AUSTIN DUNN of Chicago, Ill., on April 10, 1913, of acute indigestion, in his sixty-second year. Deceased was a graduate of the Chicago College of Dental Surgery, and a member of the Chicago Dental Society, the Illinois State Dental Society, the National Dental Association, and a past president of the Odontographic Society.

DENTAL COLLEGE COMMENCEMENTS.

LINCOLN DENTAL COLLEGE.

THE fifteenth annual commencement exercises of Lincoln Dental College were held in University Temple, Lincoln, Nebr., on May 15, 1913.

The doctorate address was delivered by Dr. J. S. Leonhardt.

The degree of Doctor of Dental Surgery was conferred by the dean, Dr. Clyde Davis, on the following graduates:

Stephen C. Adkins	Raleigh A. Gibson	Harry T. Olson
Clarence M. Brookman	Robert V. Nicholson	Walter H. Thomas

UNIVERSITY OF SOUTHERN CALIFORNIA, COLLEGE OF DENTISTRY.

THE thirtieth annual commencement exercises of the University of Southern California, College of Dentistry, were held in Los Angeles, Cal., on June 12, 1913.

The commencement address was delivered by Robert J. Burdette, D.D., of Pasadena.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Harold Anderson	Lawrence F. Haseltine	Robert W. Norris	Hugh M. Swift
Earl R. Andrews	Jerry V. Holcombe	Herbert L. Noxon	Almon D. Siewert
Milton F. Bailey	Clement W. James	Albert H. Osborne	Francis F. Tanaka
Wilbur E. Bedford	Emmett C. Kesling	Chas. H. Pool	Herman G. Thomas
Chas. E. Bokay	John F. Lynch	Geo. G. Powers	Samuel H. Thompson
Frank W. Chandler	Percy H. F. McKay	Fred A. Ross	Harvey E. Walter
Duane S. Coffin	Hubert B. Nall	Harry E. Senseney	Roy B. Wells
Chas. LeR. DeCou	Ulysses H. Nicholson	Carrick W. Symmes	John W. Witly
Nathan Hale			

BARNES DENTAL COLLEGE.

The annual commencement exercises of Barnes Dental College were held on Monday, June 2, 1913, at St. Louis, Mo.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Lucien Duguay	Missouri
Anton A. Gitchoff	Macedonia
William N. McAtee	Illinois
Paul D. Saum	Missouri
Ernst L. Steward	Missouri
William A. Tevis	Illinois
Robert L. Turley	Missouri

KANSAS CITY DENTAL COLLEGE.

The thirty-second annual commencement exercises of the Kansas City Dental College were held in the First Presbyterian Church, Kansas City, Mo., on May 17, 1913.

An address was delivered by Rev. Frank S. Arnold.

The degree of Doctor of Dental Surgery was conferred by the president, Dr. John Deans Patterson, on the following graduates:

James M. Alley
Audy G. Ames
Ray H. Barnes
William E. Beard
Oscar O. Beattie
Raoul L. Beland
Sidney S. Block
Wilton W. Cogswell
Clyde F. Davidson
Otto R. Docekal
George L. Dodson
Forrest D. Fischer
Charles A. Furrow
Grover C. George
Albert R. Harold
William T. Hope
John S. Ingram
Clifford S. Kile
Forrest Kutz
Samuel J. Lamoreaux
Roy A. Long
Leonard F. McGrath
Francis P. Meyer
John R. Moore
Frederick R. Muller
Warren E. Need
Elmer H. Neighbors
Clifford J. Palmer
Nelson C. Paro
Jesse A. Ringold
Clarence W. Roberts
Peter W. Schwartz
Hugh H. Scott
Homer M. Shelden
Paul G. Spencer
Joseph E. Stark
Ray E. Tibbetts
Francis S. Williams
James H. Wilson
Edward A. Wohlgemuth
Sylvester J. Wooldridge

LAVAL UNIVERSITY DENTAL SCHOOL.

At the annual commencement exercises of Laval University Dental School, held in Montreal, Que., the degree of Doctor of Dental Surgery was conferred on the following graduates:

T. Asselin	Pr. Quebec
E. Bourgeois	Pr. Quebec
A. Comeau	Pr. Quebec
M. Dérome	Pr. Quebec
A. Deshênes	Pr. Quebec
A. Dionne	Pr. Quebec
R. Doucet	Pr. Quebec
M. Fleury	Pr. Quebec
A. Girard	Pr. Quebec
P. E. Kieffer	Pr. Quebec
J. Lantier	Pr. Quebec
L. LaRocque	Pr. Quebec
A. Lavigne	Pr. Quebec
T. Lavoie	Pr. Quebec
A. Lebrun	Pr. Quebec
T. Lefort	Pr. Quebec
L. Plante	Pr. Quebec
P. E. Poitras	Pr. Quebec
O. Rajotte	Pr. Quebec
W. Saint-Pierre	Pr. Quebec
A. Voisard	Pr. Quebec

The degree of Bachelor of Dental Surgery was conferred on the following graduates:

J. De Montigny
E. Desroches
M. Durand
E. Farrell
P. Fleury
J. H. Fontaine
P. Hamel
E. Hébert
E. Jobin
J. Labrecque
L. Lafond
A. L'Archevêque
A. Melady
F. Rhéaume
V. Rondeau
E. Turgeon

VANDERBILT UNIVERSITY, DEPARTMENT OF DENTISTRY.

The annual commencement exercises of Vanderbilt University, Department of Dentistry, were held in Nashville, Tenn., on May 26, 1913.

An address was delivered by John Stewart French, D.D.

The degree of Doctor of Dental Surgery was conferred by the vice-chancellor, Wilbur F. Tillett, A.M., D.D., LL.D., on the following graduates:

Hayden G. Austin	Tennessee
George A. Braly	Tennessee
Young M. Brown	South Carolina
Lee W. Bryant	Tennessee
Jesse M. Buddin	South Carolina
Samuel F. Call	Texas
Ewing B. Connell	Tennessee
Henry L. Crow	Tennessee
Sidney A. Crumbley, Jr.	Georgia
Thomas W. Gillis	Mississippi
Landis L. Graham	Tennessee
Edmund B. Hammond	South Carolina
Claude C. Harris	Tennessee
Thomas C. Harris	Tennessee
Robert L. Houston	Alabama
William F. Jones	North Carolina
Henry G. Kennedy	Tennessee
George P. Kumpe	Alabama
Elvis O. Mansker	Louisiana
Herman F. Martin	Tennessee
Johnson G. McDowell	Texas
Robert L. Morris	Tennessee
Jake H. Park	Tennessee
William P. Rea	Tennessee
Walter E. Reeves	Mississippi
William A. Spence	Mississippi
William C. Steele	Tennessee
Ralph E. Stevenson	South Carolina
James C. Taylor	Tennessee
Garland V. Taylor	Tennessee
George F. Tenison	Tennessee
Mitchell Thomas	Tennessee
William O. Thomas	Tennessee
Joseph H. Turner	Arkansas
James J. Vaughn	Tennessee
George Wheeler	Alabama
Levert E. Wilson	Alabama

Society Notes and Announcements.

DENTAL SOCIETY MEETINGS:

July, August, and September.

JULY.

American Society of Orthodontists. Chicago, Ill. June 30th to July 2d.

Delta Sigma Delta Fraternity. Kansas City, Mo. [During N. D. A. meeting.]

National Association of Dental Examiners. Kansas City, Mo. July 7th.

National Association of Dental Faculties. Kansas City, Mo. July 4th.

National Dental Association. Kansas City, Mo. Four days: July 8th to 11th.

National Dental Association—Southern Branch, and Virginia State Dental Society. Old Point Comfort, Va. Four days: July 22d to 25th.

New Jersey State Dental Society. Asbury Park. Three days: July 16th to 18th.

Rhode Island Dental Society. Providence, July 24th.

Xi Psi Phi Fraternity. Kansas City, Mo. [During N. D. A. meeting.]

Virginia State Dental Society and National Dental Association, Southern Branch. Old Point Comfort, Va. Three days: July 22d to 24th.

AUGUST.

West Virginia State Dental Society. Parkersburg. August 13th to 15th.

SEPTEMBER.

Northern Indiana Dental Society. Gary. September 23d to 25th.

Examiners' Meetings.

Idaho Board of Examiners. Boise. July 17th.

Montana Board of Examiners. Helena. July 14th to 17th.

New Jersey Board of Registration. Trenton. June 30th to July 2d.

North Dakota Board of Examiners. Fargo. July 8th to 11th.

South Dakota Board of Examiners. Sioux Falls. July 8th.

Vermont Board of Examiners. Montpelier. June 30th to July 3d.

Wyoming Board of Examiners. Cheyenne. July 1st to 3d.

NATIONAL DENTAL ASSOCIATION—SOUTHERN BRANCH AND VIRGINIA STATE DENTAL SOCIETY.

The fifteenth annual meeting of the Southern Branch of the National Dental Association will be held at the Chamberlin Hotel, Old Point Comfort, Va., July 22 to 25 inclusive, 1913. The Virginia State Dental Society will meet conjointly with the Southern Branch at that time.

Thos. Moore, Jr., *Cor. Sec'y, N.D.A.So.Br.*
C. B. Gilford, *Cor. Sec'y, Va. Dental Soc.*

[At Kansas City.]

NATIONAL ASSOCIATION OF DENTAL EXAMINERS.

The thirty-first annual session of the National Association of Dental Examiners will be held at the Baltimore Hotel, Kansas City, Mo., beginning July 7th, at 10 A.M., and continuing until adjournment.

Every state board holding membership in the association is earnestly requested to have at least one representative present at this session. Members of all state boards are invited. Hotel reservations should be made immediately.

John P. Stiff, *President*,
Fredericksburg, Va.,
T. A. Broadbent, *Sec'y*,
15 E. Washington st., Chicago, Ill.

N. D. A. Meeting at Kansas City.

Seventeenth Annual Session—July 8 to 11, 1913.

THE 1913 Session of the National Dental Association will be held in Kansas City, Mo., July 8 to 11, 1913. The reorganization of the association should make this the most important meeting in its history. Every state society that has met since the new constitution and by-laws were adopted—at the Washington meeting—has voted to become a constituent society, and we can all appreciate the influence of such an organization if all the state societies take similar action.

CONVENTION HALL, KANSAS CITY—MEETING-PLACE OF N. D. A.

The officers and committees have been active in preparing an exceptionally interesting program. It is impossible to incorporate the clinical program in the journal announcements; however, the Clinic Committee does not expect to present the number of clinics which have been listed for the past few years, but have planned to present a smaller number, which are classified so that they will be most interesting.

Program.

Dr. Frank O. Hetrick, Ottawa, Kansas: President's Address.

Dr. Weston A. Price, Cleveland, Ohio: "Scientific Foundation Fund."

Dr. Roscoe A. Day, San Francisco, Cal.; "Orthodontia and Its Relation to Dentistry."

Dr. J. L. Howell, Denver, Colo.: "Crown and Bridge Work."

Dr. Gail W. Hamilton, Council Bluffs, Iowa: "The Missing Steps in Platework."

Dr. Percy R. Howe, Boston, Mass.: "The Saliva."

Dr. Marcus L. Ward, Ann Arbor, Mich.: "Conflicting Opinions Concerning the Manufacture and Use of Alloys for Dental Amalgams."

Dr. Hermann Prinz, St. Louis, Mo.: "A Preliminary Report on Action of As_2O_3."

Dr. Carl G. Parsons, M.D., Denver, Colo.: "Physiological Action of Nitrous Oxid-Oxygen Analgesia and Anesthesia."

Dr. Arthur D. Black, Chicago, Ill.: "Something of the Etiology and Early Pathology of Diseases of the Peridental Membrane, with Suggestions as to Treatment."

Dr. Howard R. Raper, Indianapolis, Ind.: "The Value of the Radiograph in the Practice of Modern Dentistry."

Dr. G. S. Junkerman, Cincinnati, Ohio.: "Dental Educational Harmony."

Dr. Burton Lee Thorpe, St. Louis, Mo.: "Prophylaxis: Illustrated with Lantern Slides."

Dr. H. B. Tileston, Louisville, Ky.: "The Application in Practice of What is Known Concerning the Diagnosis and Treatment of Diseases of the Dental Pulp."

Dr. Edward D. Coolidge, Chicago, Ill.: "The Etiology and Progress of Dental Caries."

Dr. Clarence J. Grieves, Baltimore, Md.: "Periapical Infection."

All reputable practitioners of dentistry and medicine are cordially invited to attend this meeting.

Railroads.

The Central passenger association, the Western passenger association and the Southwestern passenger association have granted an open rate of two cents per mile in each direction in their territory, with a minimum excursion fare of $1.00. Tickets on sale from the 5th to the 8th of July, and good returning up to July 20th. The Trunk-line association has declined to make any concessions.

Information regarding transportation from any point may be secured from any local railroad agent, as they have full information with reference to all rates granted by various passenger associations in their particular territory.

Hotels.

The Local Committee of Arrangements are providing ample facilities for a large meeting, and have selected the Baltimore Hotel as headquarters. Those desiring to make hotel reservations in advance should address the Baltimore Hotel, or the chairman of the Local Committee of Arrangements, Dr. Charles C. Allen, 507 Rialto Bldg., Kansas City, Mo.

Below is given a list of the principal hotels, with their rates:

S = Single, without bath. *Sb* = Single, with bath.
D = Double, " " *Db* = Double, " "

Hotel Baltimore: *S* $1.50 and $3.00 per day, *Sb* $2.50 and $6.00 per day, *D* $2.50 and $3.00 per day, *Db* $4.00 and $7.00 per day.

Sexton Hotel: *S* $1.00 per day and up. *Sb* $2.00 per day and up.

The Coats House: *S* $1.00 to $2.00 per day, *Sb* $1.50 to $3.50 per day.

Hotel Savoy: *S* $1.00 to $1.50 per day, *Sb* $1.50 to $2.50 per day.

Hotel Victoria: *S* $1.00 and $1.25 per day, *Sb* $1.25 and $1.50 per day, *D* $1.50 and $2.00 per day, *Db* $2.00 and $2.50 per day.

Hotel Kupper: *S* $1.00 and $1.50 per day, *Sb* $1.50 and $2.50 per day, *D* $2.00 and $2.50 per day, *Db* $2.50 and $4.00 per day.

Densmore Hotel: *S* $1.00 per day, *Sb* $1.50 per day, *D* $1.50 per day, *Db* $2.00 to $2.50 per day.

Hotel Edward: Rates $1.00 per day and up.

Hotel White: Rooms—running water, hot and cold, $1.00 per day; shower or tub bath, $1.50 per day; outside rooms, bath with tub, $2.00 per day.

FRANK O. HETRICK, *President*,
Ottawa, Kans.

HOMER C. BROWN, *Recording Sec'y*,
185 East State st., Columbus, Ohio.

[AT KANSAS CITY.]

XI PSI PHI FRATERNITY.

THERE will be a meeting of the Xi Psi Phi Fraternity during the session of the National Dental Association, at Kansas City, Mo., July 8 to 11, 1913.

Headquarters for the members of the Xi Psi Phi Fraternity will be established at the Baltimore Hotel, Kansas City, Mo. Special accommodations have been made for train service from Chicago, and all members of the fraternity east of Chicago are invited to avail themselves of this service. For further information address

C. C. MARKEY, *Sec'y*.
1740 Greenleaf ave., Chicago, Ill.

[At Kansas City.]

NATIONAL ASSOCIATION OF DENTAL FACULTIES.

The next annual meeting of the National Association of Dental Faculties will take place at the Hotel Baltimore, Kansas City, Mo., beginning at 10 A.M., on Friday, July 4, 1913. The Executive Committee will meet at 9 o'clock on the same morning, at the same place.

B. Holly Smith,
Chairman Exec. Com.

[At Kansas City.]

DELTA SIGMA DELTA FRATERNITY.

The twenty-ninth annual meeting of the Supreme Chapter of Delta Sigma Delta Fraternity will be held at the Hotel Baltimore, Kansas City, Mo., Monday, July 7, 1913, at 10 A.M.

Business of importance and initiation has been arranged for the day, to be followed by the annual banquet in the evening.

R. Hamill D. Swing, *Supreme Scribe.*

[At Kansas City.]

NATIONAL MOUTH HYGIENE ASSOCIATION.

Second Annual Meeting.

The second annual meeting of the National Mouth Hygiene Association will be held in Kansas City, Mo., July 9–12, 1913.

The board of governors will meet at the Hotel Baltimore at 9 A.M. on July 9th, 10th, and 11th, to consider questions to be presented to the general body. These meetings are open to members of the association, and those having matters which they wish to present to the association for consideration must present them to the board at one of these meetings.

The regular meeting of the association consists of three sessions (open to the general public): Friday, 1.30 P.M. and 8.00 P.M.; Saturday, 9.00 A.M. A very interesting and instructive literary program is to be presented.

The association has charge of the Mouth Hygiene Section of the Fourth International Congress on School Hygiene, and the board of governors' plan is to have, in so far as possible, the program duplicated at both the National meeting and the Congress.

The most important subject to be presented to the association will be the question of "Ways and Means for Conducting the Campaign of the Association in Its General Presentation of Mouth Hygiene to the Public." A complete, practical, economic and co-operative plan, which will permit every section of the country to begin an active appeal to the general public, will be presented for consideration. It is desirable that every member be present when this important subject is presented for discussion.

W. G. Ebersole, *Sec'y-Treas.*,
800 Schofield Bldg., Cleveland, Ohio.

FOURTH INTERNATIONAL CONGRESS ON SCHOOL HYGIENE.

The most important Health conference that has ever been held in this country is the Fourth International Congress on School Hygiene, which will take place in Buffalo, August 25–30, 1913.

This congress will deal with every phase of school hygiene, and will be attended by the leading hygiene and educational people throughout the world. An entire section has been devoted to Mouth Hygiene, with a large amount of floor and wall space set aside for an exhibit dealing with the same subject. The organization of both the literary program and the exhibit has been placed under the supervision of the National Mouth Hygiene Association. This is the greatest opportunity that has ever been accorded the dental profession to present in an effective manner the important relation that mouth hygiene bears to the general hygiene of the body.

To make a showing in keeping with the importance of this subject it is vital that the members of the organized dental profession throughout the country do their duty both as members of the various organizations and as individuals. A few individuals cannot make an impressive showing. It is therefore imperative that, in addition to a literary program and the presentation of an exhibit, a large number of dentists unite with the congress and attend the meeting, thus establishing the dental profession's interest in and right to participate in the hygiene conferences of the world.

An elaborate literary program has been prepared and an extensive exhibit is being arranged, committees having been appointed representing each state in the Union.

W. G. Ebersole, *Ch'man, Div. Mouth Hyg.*, 200 Schofield Bldg., Cleveland, Ohio.

AMERICAN SOCIETY OF ORTHODONTISTS.

The thirteenth annual meeting of the American Society of Orthodontists will be held in Chicago, Ill., June 30, July 1 and 2, 1913.

Frederick C. Kemple, *Sec'y*, 576 Fifth ave., New York City.

RHODE ISLAND DENTAL SOCIETY.

The Rhode Island Dental Society are arranging for their summer meeting, which will be held at the Pomham Club, Providence, R. I., Thursday, July 25, 1913. The meeting will be a combination of outing, field-day, and business meeting. The feature of the day will be a famous Rhode Island shore dinner. The Pomham Club is one of the most beautifully located clubs in New England, situated high above the picturesque Narragansett Bay. The Executive Committee in charge of the affair consist of Dr. C. N. Williams of Providence, chairman, Dr. Frank P. Duffy of River Point, and Dr. A. L. Midgley of Providence.

NEW JERSEY STATE DENTAL SOCIETY.

The forty-third annual convention of the New Jersey State Dental Society will be held in the Beach Auditorium, at Asbury Park, N. J., July 16, 17, and 18, 1913, beginning on Wednesday, July 16th, at 10 a.m.

The exhibits of modern dental appliances and the latest in office and laboratory equipment will be in charge of Dr. William H. Gelston, 40 N. Thirtieth st., Camden, N. J., who will be glad to furnish information regarding rates and space still available. Early application from those desiring to exhibit with us this year will be greatly appreciated.

The clinics will be in charge of Dr. Henry Fowler, 114 N. Fourth st., Harrison, N. J., and will be comprehensive and of a very high order.

Oral hygiene and prophylaxis will be made a special feature. There will be essays on nitrous oxid and oxygen anesthesia and analgesia and extraction of teeth. These essays will be illustrated with moving pictures and stereopticon slides, and will be further exemplified in the clinics.

All ethical practitioners of dentistry and medicine will be accorded a hearty welcome.

The programs will be ready July 1st, and will be mailed to all those sending their names and addresses to the secretary.

Edwin W. Harlan, *Sec'y*, 47 Crescent ave., Jersey City, N. J.

WEST VIRGINIA STATE DENTAL SOCIETY.

The seventh annual meeting of the West Virginia State Dental Society will be held in the assembly room of the Chancellor Hotel, Parkersburg, W. Va., August 13, 14, and 15, 1913. Opening session 2 p.m., Wednesday, August 13th. A cordial invitation is extended to all ethical members of the profession to attend our meeting.

Frank L. Wright, *Sec'y*, Wheeling, W. Va.

NORTHERN INDIANA DENTAL SOCIETY.

The twenty-fifth annual meeting of the Northern Indiana Dental Society will be held at the great Steel City of Gary, September 23, 24, and 25, 1913.

W. Leroy Myers, *Sec'y*, Rensselaer, Ind.

ILLINOIS STATE DENTAL SOCIETY.

The Illinois State Dental Society held its forty-ninth annual meeting at Peoria, Ill., May 13 to 16, 1913. The following officers were elected for the ensuing year: Wm. H. G. Logan, Chicago, president; W. A. Hoover, Gibson City, vice-president; H. L. Whipple, Quincy, secretary; T. P. Donelan, Springfield, treasurer; I. B. Johnson, Onarga, librarian.

The 1914 meeting will be the golden jubilee of the society, to be celebrated in Chicago. Date to be announced.

Henry L. Whipple, *Sec'y*, Quincy, Ill.

EASTERN DENTAL SOCIETY OF THE CITY OF NEW YORK.

The thirteenth annual meeting of the Eastern Dental Society of the City of New York was held on Thursday, May 1, 1913.

The following officers for 1913-14 were unanimously elected: A. G. Hindes, president; Henry Schwartz, vice-president; Victor Ettinger, treasurer; A. LeWitter, general secretary.

A paper, entitled "Orthodontia and Facial Orthopedia," was read by Prof. Victor H. Jackson, M.D., D.D.S.

On Friday, May 2nd, at 2 P.M., four clinics were held by the society, viz: (1) The preparation of cavities for inlays, Dr. S. W. A. Franken. (2) The treatment of pyorrhea alveolaris, Dr. W. F. Spies. (3) Dental radiographic exhibit, Prof. Geo. Miller Mackee, M.D. (4) Oral surgery clinic, Dr. Wm. J. Lederer.

An elaborate banquet was given to members and guests in the evening at Café Boulevard. Dr. R. Ottolengui, Dr. Alfred R. Starr, and Dr. George Evans were among the guests present.

A. LeWitter, *Sec'y.*

IDAHO BOARD OF EXAMINERS.

The next meeting of the Idaho Board of Dental Examiners will be held in Boise, beginning Monday morning, July 7, 1913.

Albert A. Jessup, *Sec'y,*
Boise, Idaho.

NEW JERSEY BOARD OF REGISTRATION.

The New Jersey State Board of Registration and Examination in Dentistry will hold their semi-annual examination in the Statehouse, Trenton, N. J., beginning on Monday, June 30, and continuing Tuesday, July 1, and Wednesday, July 2, 1913.

Practical work Monday, June 30th, 8 A.M. sharp; theoretical examination Tuesday, July 1st, and Wednesday, July 2d, promptly at 8 A.M. The business meeting of the board will be held at 10 A.M., Tuesday, July 1st, and anyone having business with the board may have an audience. Applications must be in the hands of the secretary five days prior to the examination. For further information address

Chas. A. Meeker, *Sec'y,*
29 Fulton st., Newark, N. J.

MONTANA BOARD OF EXAMINERS.

The Montana State Board of Dental Examiners will hold the annual session in Helena, Mont., July 14, 15, 16, 17, 1913. Address all communications to

G. A. Chevigny, *Sec'y,*
Butte, Mont.

NORTH DAKOTA BOARD OF EXAMINERS.

The next regular meeting of the North Dakota State Board of Dental Examiners will be held in Fargo, July 8, 9, 10, and 11, 1913. For further information address

F. A. Bricker, *Sec'y,*
Fargo, N. D.

SOUTH DAKOTA BOARD OF EXAMINERS.

The South Dakota State Board of Dental Examiners will meet at Sioux Falls, S. D., Tuesday, July 8, 1913, at 1.30 P.M. For application blanks and further information apply to

A. L. Revell, *Sec'y,*
Lead, S. D.

WYOMING BOARD OF EXAMINERS.

The Wyoming State Board of Dental Examiners will meet for examination of applicants on July 1, 2, and 3, 1913, at Cheyenne.

An examination is required of all applicants, and only holders of diplomas from reputable dental colleges are eligible to such examination. The board does not interchange with other states, nor issue any temporary permits. All applications must be completed and in the hands of the secretary fifteen days prior.

The written examination consists of anatomy, physiology, histology, bacteriology, chemistry, metallurgy, oral surgery, anesthetics, operative and prosthetic dentistry, materia medica, therapeutics, prophylactics, and orthodontia. Hand instruments for operating will be all the candidate need furnish.

For further information and application blanks, address

Peter Appel, Jr., *Sec'y,*
Cheyenne, Wyo.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending May 17, 1913:

First Lieut. F. L. K. LaFlamme arrived at Fort Hamilton, N. Y., May 9th, for duty (from leave, by way of Europe).

Harry M. Deiber, act.d.s., will proceed to Fort Thomas, Ky., for duty.

Lowell B. Wright, act.d.s., will proceed to Fort Porter, N. Y., for duty.

James G. Morningstar, act.d.s., will proceed to the Letterman General Hospital, Presidio of San Francisco, Cal., for duty.

Claude G. Baker, act.d.s., will proceed to Fort Oglethorpe, Ga., for duty.

Eugene Milburn, act.d.s., will proceed to Columbus Barracks, Ohio, for duty.

For the week ending May 23d:

E. Milburn, act.d.s., reported for duty at Columbus Barracks, Ohio, May 15th.

First Lieut. George D. Graham is relieved from duty in Hawaii, and will sail on the steamer leaving the Philippines about September 15th for the United States via Honolulu, for San Francisco, Cal.

For the week ending May 31st:

C. G. Baker, act.d.s., arrived at Fort Oglethorpe, Ga., May 21st.

H. M. Deiber, act.d.s., arrived at Fort Thomas, Ky., May 23d.

For the week ending June 7th:

J. G. Morningstar, act.d.s., joined station, Letterman General Hospital, San Francisco, Cal., May 26th.

L. B. Wright, act.d.s., is relieved from duty at Fort Porter, N. Y., and will proceed to Madison Barracks, N. Y., and report in person to the commanding officer of the latter post for duty, and by letter to the commanding general, Eastern department.

L. B. Wright, act.d.s., left Fort Porter, June 1st, for Madison Barracks, for duty; arrived June 2d.

Albert R. White, act.d.s., is relieved from further duty with the Second Division, Texas City, Texas, and will return to his proper station, Fort Des Moines, Iowa.

ORIGINAL COMMUNICATIONS.

SOME STUDIES OF THE JAWS IN HEALTH AND DISEASE.

By A. HOPEWELL-SMITH, L.R.C.P.Lond., M.R.C.S.Eng., L.D.S.Eng., London.

(Report of a lecture delivered before the union meeting of the Seventh and Eighth District Dental Societies of the State of New York, Rochester, N. Y., November 16, 1912.)

INTRODUCTORY.*

THE study of disease of the jaws is a very important one, especially in relation to "pyorrhea alveolaris." In the treatment of any special disorder one has to know something of the pathology of disease, and in order to know something of this, one must know something of the anatomy of the parts. I am bound to say that I am not yet satisfied with my own knowledge of the anatomy of the parts concerned with "pyorrhea alveolaris," and the parts of the jaws known as the gingival region of the alveolar process. That is perhaps a sweeping statement, but personally I am a great skeptic about many other things. I regard it from the point of view of trying to find the truth—believing that we are still students and anxious to gain more knowledge of the principles of pathology and many facts of vital importance. So the first thing I studied was the anatomy of the parts with which we are dealing in connection with the gingival tissues,

* [This lantern lecture was intended (1) to explain the importance of ascertaining the anatomical characteristics of the sockets of the teeth of man, and of comparing them with those of the higher mammals, thereby demonstrating that absorption of the margins of the alveolar processes of the jaws is a normal condition, even in children; and (2) to point out that the prognosis with regard to the saving of teeth affected by "pyorrhea alveolaris" is greatly affected by the persistence or otherwise of the *lamina dura*, or *linea dura*, as revealed by the use of Roentgen-ray photography. It included descriptions of the anatomy of the bone of the alveolar processes of the jaws of the higher mammals and of man in childhood, adolescence, and middle age; the anatomy of the soft parts adjacent to the cervical regions of the teeth; the nature of the gingival trough and its contents; the physiological, as apart from the pathological, absorption of bone, "pyorrhea alveolaris" being a symptom, not in itself a disease: and was illustrated by numerous photographs, radiographs, and photomicrographs of various conditions—the conclusion being that treatment should be based on anatomical and pathological and surgical considerations, and not on clinical symptoms alone.]

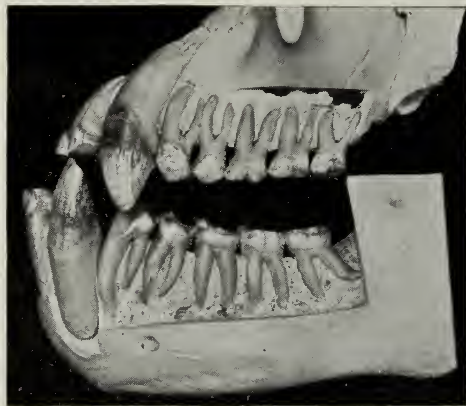
and I went to the lower animals, the carnivora and the anthropoid apes, to find out, in the first instance, the structure of the jaws of animals like the lion, the bear, the hyena, and the orang-utan, in normal circumstances. I studied the polar bear which eats fish, and the orang-utan which mainly eats fruit, and the hyena, which has possibly the best teeth of all and the strongest of alveolar processes—because, as you know, the hyena eats anything. He has a special protection (the cingulum) around the necks of the teeth to prevent injury to the gums when biting bones, etc. (See Fig. 3, c, c.)

FIG. 1.

COMPARATIVE ANATOMY.

I will begin the demonstration of these unique lantern slides by showing the jaws of the lion, a specimen in which the external alveolar plate has been chiseled away, displaying the nature of the bone in which the teeth are developed and fixed in their anatomical articulations. This shows the alveolar process and the gingival margin. The bony tissues are very cancellous in the upper jaw (Fig. 1, A), and almost equally so in the lower jaw. The same thing occurs in the case of the polar bear. One can easily tell the difference in the teeth by the presence of the human-like molar in this animal. Here is cancellous tissue in the maxilla and also in the mandible. In this specimen it is seen that the edge of the process is not so close to the necks of the teeth as in the lion. These are points that I wish you to carry in your mind's eye a few minutes this afternoon, viz, the anatomical features of these bones and the edge of the alveolar process. The polar bear does not do such hard masticatory work as the lion, and the teeth are provided with sockets of more friable bone than the harder ones of that animal.

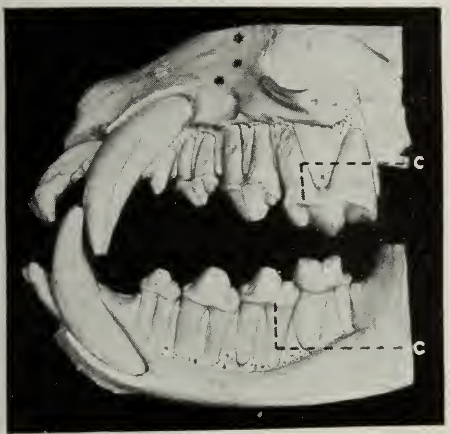
FIG. 2.



The next slide shows a condition in which there is a good deal of absorption of the terminal margins of the bone at the gingival region. (Fig. 2.) This is the jaw of the orang-utan, rather an old skull, and of course it is obvious that the orang-utan is a fruit-eater generally speaking, but its dentition emphasizes the point that a physiological absorption. or normal wasting, or natural atrophy of the bone is going on, which must be taken into consideration in connection with the pathological absorption of the bone which occurs in acute and extensive "pyorrhea."

Here, I think more and more, there has been some absorption of the edge of the bone, which normally must terminate at the necks of the teeth in this particular instance. Animals, as they get old, lose their teeth by physiological means; they shed their teeth the same as man, if exposed to disease of the gums, but they also lose their teeth by senile changes in the jaws, which is mainly a physiological process. I shall show you shortly photographs of the jaws of a man forty-five years of age who had about as good a set of teeth as one could meet if he looked through the museums throughout the country. In human skulls you will find numbers of instances in which the bone does not come to the necks of the teeth as it did at an early period. In the Red-

Fig. 3.



path Museum of the McGill University of Montreal, the other day, I inspected the skulls of certain Eskimos—who, as you know, are renowned for the soundness of their teeth—and I found that even here there was this physiological resorption of the bone.

The next slide is one in which we have the best condition obtainable in the mouth with regard to the shapes and sockets of the teeth. It shows what obtains in the hyena. (Fig. 3.) Here the bone comes to the necks of the teeth in every instance; the bone is not so cancellous but more compact than that of other animals, and the teeth are provided with that ridge of enamel which is known as the cingulum, which protects the edge of the gums and soft parts from being damaged by the food the animal eats.

THE SOCKETS OF THE HUMAN TEETH.

Then we come to man, and similarly examine the conditions when the external alveolar plate has been removed. (Fig. 4.) This is supposed to have been a normal skull, with teeth fairly normal, although it is the most difficult thing in the world to find a typical skull with typical teeth and bony attachments about them.

You see how marked these bones are, and how very much this terminal edge has become absorbed, and how cancellous

Fig. 4.

the nature of the bone appears to be, both in the upper and lower jaws. Now, I do not say, and it is impossible for anyone to say, whether or not the owner of that skull ever had "pyorrhea alveolaris." Of course you see this is where certain difficulties come in. If one could follow the individual through life, and be positive that he had had no gingivitis, no caries, and no oral disease, we would then have an established fact in this respect.

The next slide shows a similar skull, in which a section has been taken vertically through the teeth themselves and through their sockets, thus exposing the pulp cavities, and showing very clearly, again, the cancellous character of the bone. This disappearance of the free margin of the bone is perfectly obvious. Why does it disappear? I think there is no reason to question the opinions given by Talbot and by Znamensky of Moscow, who point out that the terminal edges of the alveolar plate are of poor quality, that they are feebly supplied with blood, and very liable to undergo degenerative changes—physiological resorption, in other words. Now I will show you certain lines in some radiographs, and you will see at once, I think, what I am driving at, because I am still dealing with the normal conditions. I think it is highly important to look at that aspect of the question, because the day before yesterday you heard Dr. Kirk's paper in which he spoke of practically the same thing from a different point of view. Unfortunately I arrived too late to hear his paper, although I know practically the gist of it; but there are many sides to a question like this, and particularly in regard to the etiology of "pyorrhea."

Fig. 5.

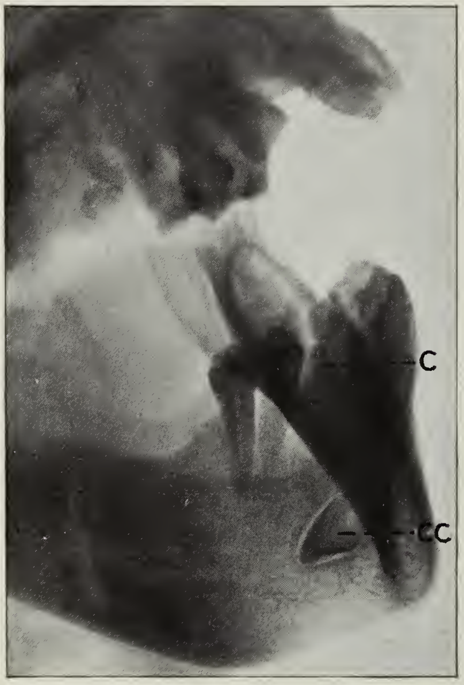


Fig. 6.

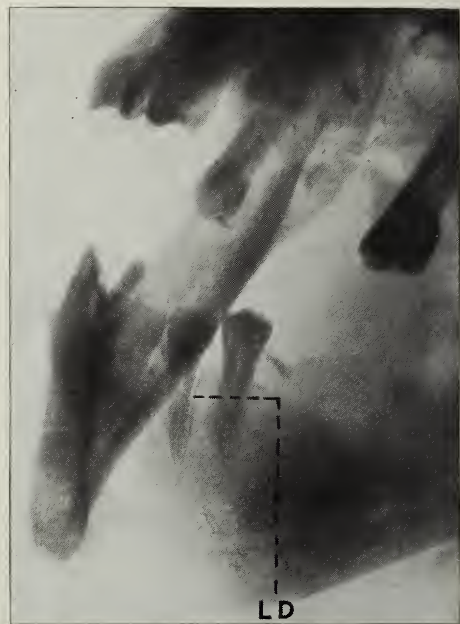

NORMAL CONDITIONS.

Case I. (Woman, aged twenty-seven.)

Here is a radiograph of the jaws of a woman twenty-seven years of age, in which, incidentally, a unique condition prevailed. (Fig. 5.) I put this on the screen for two reasons: First, to draw your attention to an unerupted canine the crown of which is directed toward the angle of the jaw. Here is the radiograph of the crown of the canine, and beside that is a white line which of course corresponds to the dental sac or follicular crypt of the tooth; then, outside that, is a dark line which is distinguished from the other portions of the bone—and you will see this occurring very frequently. A very interesting condition in connection with this slide is that here there are two canines on the right, one partially erupted (c), the eruption not being completed on account of the position of the crowns of the neighboring teeth, and the other embedded in the jaw in an inverted position, the crown leaning backward (cc). On the other side of the same mouth there was no canine at all. There were two canines in the mandible, but both were on the right side.

Again, in Fig. 6 we see the clear space

around the first premolar root, then the dark line beyond, L D, as revealed by the radiograph. I give this line the name of the "linea dura,"* this dark, extremely thin lamina of bone, much more compact than the rest, which surrounds the roots of the teeth. (See also Figs. 32 and 33.)

Case II. (Boy, aged ten.)†

Another case in which an unerupted first incisor in the maxillary bone shows the same. *This* is the incisor which had failed to erupt, and *here* is the deciduous incisor which was retained, having beneath it the permanent maxillary incisor, not erupted on account of the existence of this deciduous tooth. Here is visible the linea dura, which exists as a normal condition of the sockets of all teeth.

Case III. (Boy, aged ten.)†

Here is a radiograph of the jaws of a boy ten years of age. (I have arranged the slides mainly from the point of view of the age of the patients.) This is a photomicrograph of what I have called the linea dura. Here is the root of the tooth, and here the extreme apex of the root; this dark line is the periodontal membrane, that normal membrane which measures about six times less in width than when affected by periodontitis. And then, beyond that, is this line, which stands out as a delicate hard line around the roots of the tooth. This portion being cancellous tissue is filled with bloodvessels, connective tissue cells, etc.

Fig. 7.

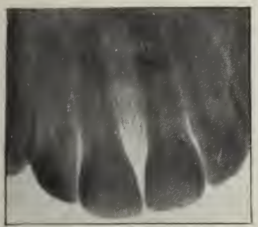

Fig. 8.

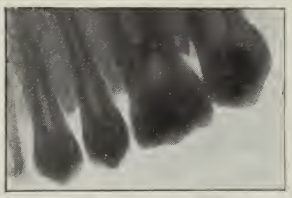

Fig. 9.

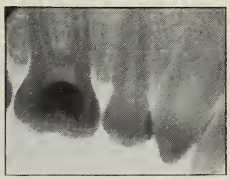

Fig. 10.

Fig. 11.

Fig. 12.

(*A*) The Jaws in Health.

Case IV. (Boy, aged fourteen.)

I wanted to learn what was the nature of the sockets of these teeth in children, and here you see the radiograph of a child of fourteen, in which this edge comes up to this point of the bone, and, in every instance, the linea dura is seen surrounding the substance of the root. This (Figs. 7, 8, 9, 10, 11, and 12) is as normal a case as it is possible to get in a boy of fourteen, but the free edge is somewhat atrophied, and I believe there is here a certain physiological absorption

* The term "linea dura" is obviously applicable only to radiographic subjects. It should be known anatomically and clinically as the "lamina dura."

† Lantern slides not reproduced.

beginning. To my mind, that edge ought to have extended a little nearer the necks of the teeth. I do not know positively where the bone ends—I mean the anatomical position of the bone; we do not know exactly where the periodontal membrane ends, but I show this to demonstrate the fact that, to my mind, there is physiological absorption beginning without any symptoms of inflammation near, with no gingivitis, and with no caries.

Incidentally I may point out that here you see a sort of double edge to the shadow of that tooth, which is due to the tilting of the radiographic film. It is most important that radiographs should be taken in every case of "pyorrhea" to show the relations of the parts, and the radiographs must be taken in a proper manner so as to admit of no errors of diagnosis.* The next picture shows some other portions of the same mouth in which the linea dura is perfectly clear, but here you see it is very thin in the incisor region (Fig. 10), and there is a certain amount of loss of this edge of the bone. In Fig. 9 a deep potential pocket can be noted on the mesial surface of the neck of the first maxillary molar. No tartar is present.

Case V. (Boy, aged fifteen.)*

Next there are two radiographs of the mouth of a boy of fifteen years of age who has never had a particle of dental caries, although he does not pay any particular attention to oral hygiene. He has had no gingivitis or any dental disease. I have had this case under observation for nine or ten years, and he has always had a normal mouth, except that the second maxillary incisors have been suppressed, which is, in this case, hereditary. Here again appears the linea dura on each side; it can also be discerned on the other side of the mouth; but again there are appearances of the beginning of the shrinkage of the edge of the alveolar process, which can be nothing but a physiological absorption of the bone.

Case VI. (Boy, aged nineteen.)

The next lantern slide shows some films of the mouth of a boy, nineteen

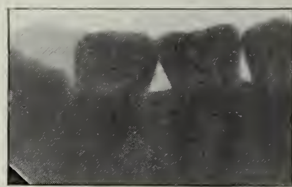
Fig. 18.



---

* In relying upon radiography as a help to prognosis, it must be remembered that there are radiographs *and* radiographs. In order to avoid a false and obtain a true conception of the conditions under examination, the vacuum tube must be of recent manufacture, and not exhausted; the plates or films must be new; the films must not be tilted while held in position in the oral cavity; the length of the exposure must be normal, and the developer fresh and its powers not exceeded.

* Lantern slides not reproduced.

years of age. (See Figs. 13, 14, 15, 16, 17, and 18.) Here is a condition in which there were clearly two lines, produced, I believe, by the junction of two lineæ duræ. In the middle line of the face there are four of these distinct lineæ duræ, both in the upper and lower jaws. That, I take it, is normal; but here I think you will agree with me that there is a certain amount of loss of bone. This patient had what I believe to be a normal mouth. He came to me complaining about the difficult eruption of a third molar which was giving some trouble in the way of neuralgia—that is why he came to me in the first place. The next slide shows another portion of the same mouth and exhibits exactly the same condition of things.

Case VII. (Girl, aged twenty.)

The next two radiographs are those of a normal, healthy patient twenty years of age. (See Figs. 19, 20, 21, 22, 23, 24, and 25.) Here you can see clearly, I believe, that there has been loss of bone. There may have been some tilting of the film—as it is a little difficult to determine in the incisor region—but I think there is a certain amount of absorption of this alveolar border even here, particularly in the premolar region. The two lines are clearly seen in this portion of the jaw,

Fig. 19.

Fig. 20.

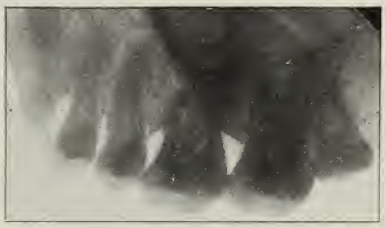


Fig. 21.

Fig. 22.

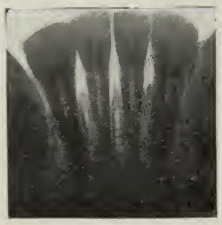

Fig. 23.

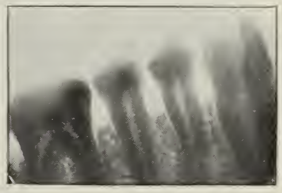

Fig. 24.

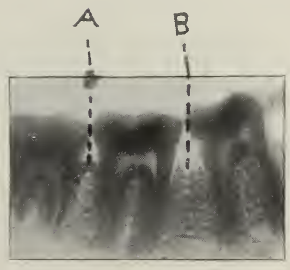
Fig. 25.



the middle line (marked *a* in Fig. 19). The next slide shows another part of the same mouth; and here, curiously enough, is a very condensed, compact condition of that portion of the bone (marked A in Fig. 25; *cf.* with B on the mesial aspect of the same tooth, where the edge is absorbed), which probably is, if we only knew it, the real normal condition in the molar region. It may be perhaps a little exaggerated if compared with this portion between these two molars. So far as I could make out, there was absolutely

Fig. 26.

no diseased condition in connection with that mouth.

Case VIII. (Woman, aged twenty-nine.)

The next photograph is that of the left jaw of a woman twenty-nine years of age.

Fig. 28.

(Fig. 26.) There is a history attached to it, because it was sent to me from a hospital in London to be examined microscopically after removal from the mouth. It was believed to be a case of syphilitic ulceration of the palate by one surgeon, and by another a malignant disease, and the specialist who thought it was an epithelioma excised it. I found that a cystic adenoma of the antrum had caused its enlargement, and of course the jaw should not have been excised! I show this specimen because it exhibits a fairly normal dental condition. I think

Fig. 27.

you will agree with me that there is a fairly normal condition of the interdental papillæ. There is a certain amount of tartar on some of the teeth, because the teeth were thrown out of use

Fig. 29.

for some time, and functionless teeth are teeth in a state of degeneration, but, on the whole, I think we may assume that this is a fairly representative normal gingival margin.

The radiograph reveals the condition of the bone. (Fig. 27.) You see here the loss of the bony edge of the process, absorption in the molar region being particularly well marked.

Case IX. (Man, aged forty-seven.)

The next photograph was taken from a man forty-seven years of age. (Fig. 28.) Here is a portion of the upper jaw. What is the nature of the alveolar process of these teeth? The radiograph in the next slide will show that condition. (Fig. 29.) This, as I said, is in a man of forty-seven. There is absorption of the bone, but the linea dura is pretty well intact in some situations and at several

FIG. 30.

points. These three teeth have sockets which are in a normal condition.

Case X. (Man, aged about forty-five.)

Next I show you photographs and radiographs of the finest jaws that I have ever seen (see Figs. 30 to 33), occurring in a man of about forty-five, an Irishman who for many years smoked a pipe and had attrition of four teeth. (Fig. 30, A.) His jaws are as typically normal as possible. Note the porous nature of the edge of the alveolar process. Here is a radiograph of the incisor region of his mouth, and the linea dura is clearly distinguished, but there is some absorption of the bone, which is associated, in places, with the presence of a few nodules of tartar. Here again is one side of the jaw showing the linea dura and a certain amount of absorption of the bone. To repeat, this was the jaw of a man of middle age, and naturally the bone was beginning to be absorbed, and ultimately the teeth would have loosened from physiological causes. This is the other side of the mouth—that is to say, the right side—and here you see these sockets of the teeth clearly defined by the lineæ duræ, but here again there is a certain amount of absorption of the bone.

Now, so far I have been dealing with what I believe to be normal conditions (with one possible exception), and if anybody can come across the skull of an *adult,* say of twenty years or over, which shows the retention of the external alve-

FIG. 31.

olar plate about the margins of the necks of the teeth just below the free edge of the enamel, then I shall be glad to examine such a specimen. I do not believe such a one exists!

THE GINGIVAL TROUGH.

Here is the photomicrograph* of the jaw of a kitten, showing the internal and external alveolar plates and the anatomical differences between them. The external is quite thin, but the internal is thicker, but over the termination of the edge of the jaw it is again very blade-like. That is absolutely normal; it cannot be otherwise in the jaws of this young cat. The relative proportion in size of the periodontal membrane to the pulp tissue and the dentin of the tooth and the cementum is apparent. In this external plate there are spaces filled with soft tissue, but at the extreme margin these medullary spaces are practically absent,

* Lantern slide not reproduced.

and the bone is liable to be ill-nourished in that situation as a consequence.

The next is a radiograph of a patient ten and one-half years of age, and this

Fig. 32.

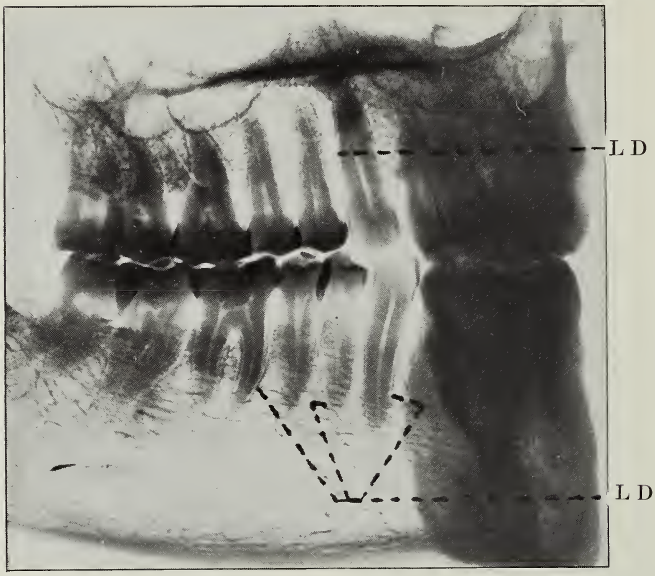


Fig. 33.

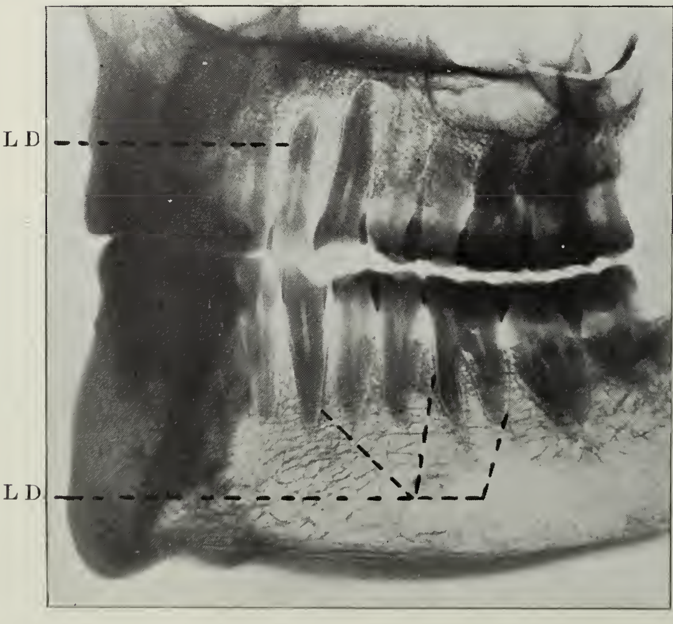


(*B*) The Jaws in Disease.

Case XI. (Girl, aged ten and one-half.)

little girl had "pyorrhea" at the age of eight years. That is to say, she had a flowing of pus from the necks of the teeth in the incisor region of the lower jaw at about that time.

She had had chickenpox followed by anemia at about three years of age. She was a fairly healthy child, but unfortunately she had this pyorrheal affection around the necks of the incisors, and here you see the bone has become absorbed, not physiologically, but pathologically. Here is no linea dura. (Fig. 34.) The character of the bone had changed from compact bone to tissue that has undergone decalcification and other osteoid or fibroid changes through halisteresis. The "pyorrhea" in this case was stopped in eighteen months. I managed to get rid of the pus in that time, and from that point of view the case is cured; but ultimately hypertrophy of the gum occurred, and she had to have

FIG. 34.

an operation in the incisor region. She was operated upon just a short while before I left England.

Case XII. (Man, aged twenty-one.)*

A case of chronic general gingivitis in a man of twenty-one years of age forms the next subject. When the X-ray photograph of the jaw was taken, I tried to learn the condition of the sockets of the teeth, and I think in cases of gingivitis one should often do that, if there is any doubt about the condition of the parts. I now show another portion of the jaw, which I am sorry to say is not a particularly good photograph, because of the fact that the film was tilted; but it leads up to what is coming.

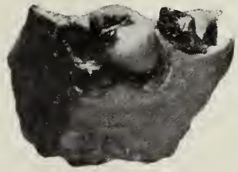
Case XIII. (Man, aged thirty-six.)*

This is the jaw of a man of thirty-six years with chronic periosteitis following "pyorrhea alveolaris." The teeth are broken down, and the next picture shows the condition of the roots of the teeth. Here it is obvious that this enlargement of the root is due to hyperplasia of the cementum. The linea dura has entirely disappeared.

Case XIV. (Man, aged thirty-nine.)

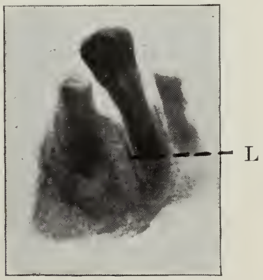
The jaw of a man of thirty-nine years with local chronic periosteitis, due to tartar, is the next specimen (Fig. 35),

FIG. 35.



but in this case it was most difficult to determine whether there was any condition of "pyorrhea." That is to say, after the tartar was removed there was no continuation of that unceasing flow of pus which is a symptom of that condition. The next is a radiograph of these

FIG. 36.



parts, and shows here (Fig. 36, L D.), even in a man of thirty-nine years, that these lineæ duræ are present, but in portions of the jaw there was absorption of the bone.

One can have a deep pocket without having any purulent exudation from it. Here is a photomicrograph* which appeared in the DENTAL COSMOS for September 1911, showing this condition. The dentin of the tooth, the cementum,

* Lantern slides not reproduced.

* Lantern slides of the cases referred to in this and the following paragraphs are not reproduced.

and the soft gum tissue are shown. The gum should be attached to the edge of the cementum. The specimen is so decalcified that the enamel is dissolved away, but normally that should be attached to the free edge of the cementum.

This was a case in which the bone was beginning to be absorbed—as you can see by this margin, this dark area here and there—showing, from the staining of the specimen, the decalcification of the bone. Here is the periodontal membrane. There is no inflammation, but it is hyperplastic, thus showing the destruction of the bone, in a case in which no pyorrhea was present. The bone becoming decalcified is probably due to senile conditions.

Here is a photomicrograph again showing the parts around the apices of the roots of the teeth in cases of pyorrhea which have persisted for some time. The periodontal membrane is thicker, sometimes five or six times thicker than it ought to be. Here is the apical space in which the bone has been altered in character; and here is a small sequestrum of bone in the soft parts.

The next slide is another picture showing the apex of the root of a tooth beginning to become absorbed; here is the apex, and here are deep cavities produced by the osteoclasts, which have arranged themselves around the bone in various places while absorbing the bone. Here is a portion showing periodontal inflammation, and below is a portion no doubt due to hyperplasia. You will see in the next photograph this same thing highly magnified. The upper portion of the photomicrograph shows inflammatory periosteitis, and the lower portion a hyperplastic condition of the cementum. You will remember one radiograph that I showed you in which there was an involution, at the neck of the tooth, of the soft tissues, and this is the gingival "space" as described by Black, but which is really a trough. I was not so sure in my mind as to the structure of this gingival trough, and I made a few investigations, and found some astonishing things. I found that, in every instance, I could pass a sterilized explorer into something deeper than a mere space; that an instrument would extend in the normal mouths of children of six, seven, and ten years of age, a distance of two and one-half millimeters. That was a point that struck me as very important. I then proceeded to examine this trough a little more carefully. I carefully sterilized the mouth, applied the rubber dam, and found micro-organisms, chiefly of the micrococcus catarrhalis group, with streptococcus brevis. This is a thing that anybody can do in ten minutes by observing all the rules in regard to exclusion of alien bacteria—one can prove the existence of hundreds of germs in the normal trough, or what appears to be a normal trough, by sterilizing the mouth and with an explorer removing the germs, making a film on a cover-glass, and staining and examining the latter under a microscope. As I say, we found micro-organisms, and after a few days, by cultivating out, managed to separate these, and found streptococcus brevis and micrococcus catarrhalis.

Here is a photograph of the jaw of a man of forty in which we have "pyorrhea" beginning in the early stage. You see the appearance of the gum, which is in good condition; and then, by means of the radiograph, we find the pathological changes which you see in the next slide.

This is a radiograph of this condition and the linea dura is clearly defined; although pyorrhea is present, there is a persistence of the linea dura, which is a hopeful sign. And that is the next point I want to make—first ascertaining the normal condition, and secondly the conditions which may give rise to encouraging prognosis in these cases.

Case XV. (Man, aged forty-two.)

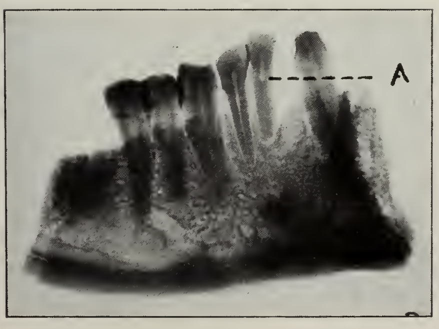
Here is the mandible of a man forty-two years of age, showing the external appearance on the labial side. (Fig. 37.) The next is the same jaw looked at from the lingual side (Fig. 38), showing the appearance of these teeth and the character of the gingival region round about.

Here is a slide showing an incisor affected by "pyorrhea" (Fig. 39, A), and other teeth apparently unaffected by that condition.

Fig. 37.

Fig. 38.

Fig. 39.



Case XVI. (Man, aged forty-five.)

The next slide shows the jaw of a man of about the same age—that is, forty-five —showing a chronic condition of gingivitis, a most marked condition there. (Fig. 40.) A radiograph shows the condition. (Fig. 41.) Here is the linea dura, and the premolar itself is firm. The laminæ duræ were absent from the other portions of the jaw.

Fig. 40.

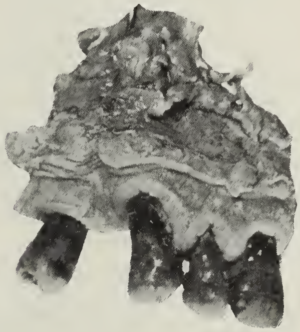


Fig. 41.

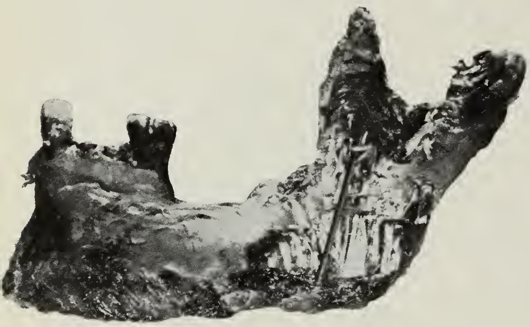
Case XVII. (Man, aged forty-eight.)

Here is the jaw of a man of forty-eight. It demonstrates how a molar and two premolar roots appeared when we examined to find out the condition of the roots of these teeth. (Fig. 42.) In the radiograph (Fig. 43) the molar appears as though it were hanging by a hair, so to speak, nevertheless it was firm, and this other tooth was also fairly firm. Note the premolar abscesses.

A photograph of the right side of the same mandible (Fig. 44) shows the condition of the roots of these teeth. Here, you see, the bone is gone, and the socket of the tooth has entirely disappeared (Fig. 45), but it is itself comparatively firm and might have been useful for

FIG. 42.



some years if the man had not died of lobar pneumonia.

Case XVIII. (Woman, aged fifty.)*

Then I wanted to find out what were the conditions in the case of marginal gingivitis, and the opportunity occurred

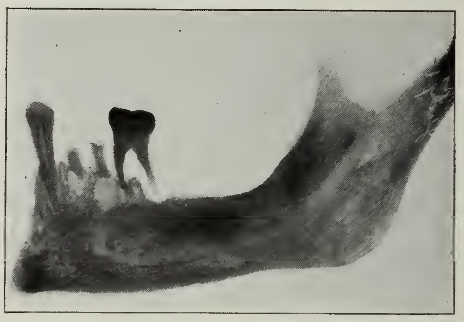
FIG. 44.

in the case of a woman of fifty years of age who had acute gingivitis. In order to be sure about the condition, I called into consultation two house surgeons, and they both agreed it was marginal gingivitis. We then removed the teeth and made some sections in order to ascertain

* Lantern slides not reproduced.

the condition of the bone; and you see it here *in normal condition.* The bone has become physiologically absorbed, but in no sense was it pathological absorption

FIG. 43.

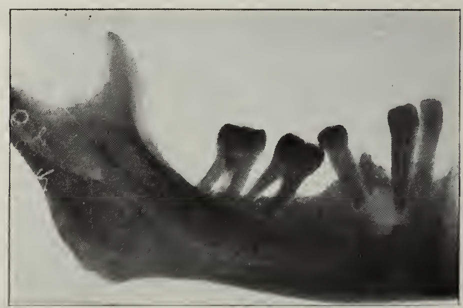


in that case, although and in spite of the fact that there was an inflammation of the gum.

Case XIX. (Man, aged fifty-two.)

Here is the mandible of a man of fifty-two—the labial surface (Fig. 46);

FIG. 45.



and it is obvious that these teeth are covered with tartar, while "pyorrhea" is present in a marked degree, and the case is a particularly bad one. The next slide shows on the lingual side of the jaw the same condition in a more marked degree and tartar developed more markedly. (Fig. 47.) The different radiographs, of course, show accretions of tartar on the teeth, together with the loss of tooth sockets by pathological absorption. (Fig. 48.)

Fig. 46.

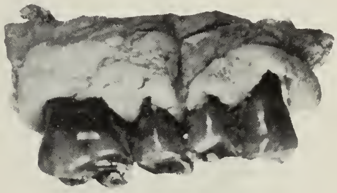
Fig. 47.

Fig. 48.

Case XX. (Man, aged fifty-four.)

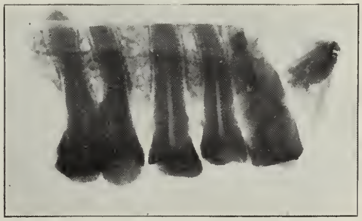
This is the case of a man of fifty-four, in which the interdental papillæ are well marked (Fig. 49)—I think you will agree with that—showing to the naked eye some disease in the gingival region.

Fig. 49.



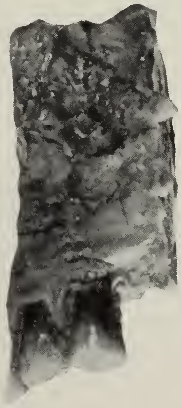
There was a slight amount of "pyorrhea," not particularly marked, but when a radiograph was taken (Fig. 50) we

Fig. 50.



found that there was a good deal of bone absorbed. Here is absorption of the bone, but not much more than would be expected physiologically in a man of his age.

Fig. 51.



Case XXI. (Man, aged sixty.)

Here is the jaw of a man six years older (Fig. 51), which shows slight gingivitis and a hyperemic, senile periodontal membrane. The photograph shows that there has not been so much

FIG. 52.

absorption of the soft tissue around the necks of the teeth, but we will next ascertain what the radiograph reveals.

Here is the radiograph (Fig. 52), and it is remarkable to notice that in this man of sixty the lineæ duræ remain, probably due to an effort on the part of nature to resist injury, and even in this patient of sixty, in whom there was a slight gingivitis, the protection in the form of the lineæ duræ is present.

Case XXII. (Woman, aged forty-two.)

Next are radiographs of the jaws of a woman of forty-two years who has every tooth in her mouth loose, and whom I have had under observation for fifteen years and never have known of any "pyorrhea" occurring in her mouth. She has frequently visited my consulting rooms, and I have seen her several times each year, and she has always had a particularly clean mouth. All the same there is much absorption of the bone, physiological absorption, or wasting, and her teeth are loosened, and I learned from her that her mother's and her brothers' teeth are similarly affected, so that one may say that it is an hereditary condition. (Figs. 53, 54, 55, 56, and 57.)

FIG. 53.

FIG. 54.

FIG. 55.

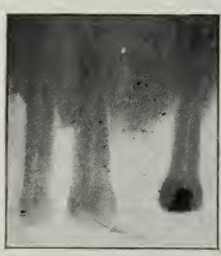


FIG. 56.

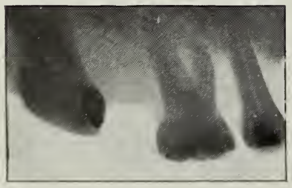

FIG. 57.

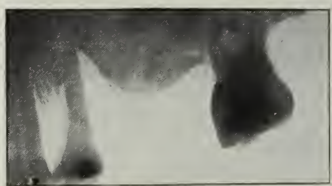

Here are other portions of the same mouth showing absorption of the bone and absence of the lineæ duræ. (Figs. 58, 59, 60, and 61.)

Case XXIII. (Man, aged forty-five.)*

Finally we have a case of a man, forty-five years or so, who, in July of last year, overworked during the hot spell of weather, and became "run down," and had an affection of the mouth, and then had "pyorrhea" in three teeth only in the mandible, viz, the left canine and two first incisors. Another film of the same mouth exhibits a condition where there is no "pyorrhea," in contradistinction to this, where "pyorrhea" is present. Now, I believe, the "pyorrhea" has ceased. I treated this patient, looked after him carefully, and as far as I am able to tell the "pyorrhea" has ceased. I will not say that the case is cured, but the pus has ceased, and I think there is hope for these affected teeth on account of the persistence of the lineæ duræ in this particular case.

Fig. 58.

Fig. 59.

Fig. 60.

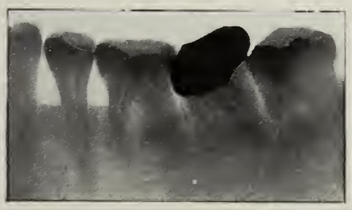

Fig. 61.

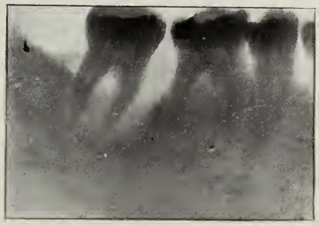

A CASE OF HEREDITY.

I will conclude by referring very briefly to a case of heredity, of which I have models on the table and which I can explain in a few words. I only introduce this to emphasize the influence of hereditary conditions and to show to you a very remarkable case. This [exhibiting] shows the upper and lower jaws of a woman of twenty-one years, who came to the Royal Dental Hospital of London a few years ago to be operated upon for bilateral empyema of the antrum. I examined her mouth, and found no crowns on the teeth in either the upper or the lower jaw. The teeth looked as though they had been filed off level with the gum. She informed me that her sister had the same condition, and I asked to see her sister. She came to the hospital too, and I took an impression of the mouth. She was ten years older than the original patient, and there has been absorption of the bone going on, but these conditions existed ten years ago in this mouth—practically the same as in the mouth of the first patient. There was no attrition, no erosion, no abrasion, nothing but an hereditary absence of formation of the crowns. I was careful to make inquiry as to caries. I was then informed, further, that her

* Lantern slides not reproduced.

mother had the same condition, that her grandfather had, that his father had, and that his father had, also that two of her brothers and a nephew suffered similarly. I was sufficiently interested in this case to go into the country to see as many of these people as I could, and here are exhibited the casts of the mouth of the brother, who was the oldest of the family represented by these models, a man of thirty-eight years of age; and you see the same condition existing there. This is the model of his son, eight and one-half years of age, and these are permanent teeth which have been erupted. They, too, show the same leveling of the crowns of the teeth, and the same yellow, hard surface of their roots.

The last two are the two younger brothers—a boy of nineteen, with exactly the same condition, and a boy of sixteen, in whose case there was a distance of eight millimeters between the two jaws in the incisor region. I may say that the other dermal appendages were apparently unaffected, but there was a certain amount of mental deficiency in two of the boys.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

INDICATIONS OF DENTAL RADIOGRAPHY.

By E. J. EISEN, D.D.S., and PAUL EISEN, M.D., Milwaukee, Wis.

THE value of radiology to dentistry is becoming more manifest every day. It elevates dentistry at once to a higher plane as a branch of medicine, and opens ways whereby we can make of our work a more exact science. It is possible, with the necessary equipment at hand, to make one's work easier, and infinitely more satisfactory.

When the use of the Roentgen rays becomes more general, it will not only prove an aid in revealing changes in tissue density due to pathological conditions as such, but will enable one to estimate the possibility of future trouble. In this respect, the writers have in mind many conditions which may determine the feasibility of certain remedial measures, such as possible surgical procedures in relation to pus accumulations, and, in a general way, means for determining the advisability of mechanical replacement of lost teeth. Many times a roentgenogram, taken as a mere diagnostic guide, will reveal conditions entirely unrecognizable by methods heretofore at our disposal, and therefore unsuspected. Again, pathological conditions often find expression in a radiograph, but are unrecognized because the interpreter cannot read the plate.

In this connection it is here recommended that, wherever possible, a plate in preference to a film be resorted to. Not only does a plate cover a larger field for observation, but it has other advantages in judging different tissues according to their respective degrees of density. The different degrees of density of the tooth as compared with the surrounding bony tissue of the alveolus, as well as with the soft tissue of the gum, is brought out just as sharply in a film, but the field is very limited. This is the more important when one considers the real value of radiology. It should not only give us information of the condition of the bony, inaccessible tissue in the near neighborhood of the field of investigation, but should disclose any possible relation with more distant tissue; in other words, one expects a complete roentgenological diagnosis. This is only an aid to the clinical diagnosis. Both help us estimate the underlying pathological condition, but neither reveals this condition; that can be done solely by the microscope.

Again, conditions in the mouth are such that they may be either magnified or minimized by false interpretation of a radiogram. This is the more apparent to those who are using the radiograph as a basis for operative as well as post-operative procedures. The fundamental basis of both, however, must be built upon a knowledge of pathology.

Indications for Roentgenological Classification.

The indications for employing the Roentgen rays may be classified into fields distinguished according to different pathological conditions, or according to their clinical phases. The former is more scientific, the latter often more practical. A distinction may also be drawn between the intra- and extra-oral method of exposure or technique. Since none of these, however, meet all requirements, a strictly roentgenological classification has been decided upon here, which obviously calls for the following indications:

Fig. 1.

I. Location.

The first consideration, and the pre-eminent point of interest, is the location of the trouble. The lesion will either be found in the suspected area or removed from it upward or downward, backward or forward, to the right or the left, as revealed by the radiograph.

A patient complained of soreness (at point A, in Fig. 1) unaccompanied by any clinical symptoms of inflammation. The radiograph reveals a canal filled almost to the apex, nevertheless an area of diminished density to one side (black on the film, light on the print). At the margin of this area may be seen a very dense area of irregular shape. The cause of this was found to be a piece of gutta-percha, probably remaining in the tissues following extraction of the intervening tooth.

II. Position.

Having ascertained the location, the next factor to be determined is the position which the object has in the tissue. This has been somewhat difficult to ascertain with the three planes projected on to one plane. Thus the accompanying film shows only one of these planes, and that incorrectly, as it is impossible to have the tooth parallel to the film. (See Fig. 2.)

Fig. 2.

Here is the acknowledged field of stereo-radiography, as shown in the accompanying stereo-radiogram, in which the exact position of a tooth can be actually seen in space. The view is distorted only in so far as the binocular rotation of the focus was sidewise instead of up-and-down—bringing a hairpin into the projected area. (See Fig. 3, A and B.) Nevertheless the position comes out well when viewed in a parlor stereoscope.

III. Relation to Surrounding Tissue.

The next important step to ascertain is the relation of the lesion to the surrounding tissue. This can only be shown with a plate—if possible, stereoscopically. The relation of cavities, containing pus, to the teeth as well as to the superficial tissues, the relation of growths, benign or malignant, to the adjacent tissues, and the involvement of surrounding tissues, must be looked for. Such visible changes shown up by the X rays are destruction of cancellous bone tissue, especially noticeable around the roots of teeth, irritative apposition of calcifying pericementitis and calcifying periosteitis.

The accompanying radiograph (Fig. 4) is that of a patient referred by Dr. G. V. I. Brown, with a tumor of the lower jaw, being external but not movable upon the lamella, egg-sized, round, and firm. Its origin, the involvement of tissue, and its etiological nature, were sought for. The radiograph shows involvement of cancellous tissue, but ill-defined in its limitation, protrusion of a calcifying nature into the soft tissue, spreading out in fan-shape, lifting a piece of the bone-lamella and causing a zone of reactive calcification around the border, not involving the molar, however, or originating from any sub-involved tooth root, as at first surmised. These characteristics justify one in assuming a malignant growth of a bony nature, involving a large area of the lower jaw. The operative removal disclosed an osteo-sarcoma of unknown origin.

IV. SHAPE.

The first factor apparent in a radiograph is the shape presented by an object or area. By comparison with a known form of an object, the probable nature can at once be recognized. Thus the shadow of a molar in the antrum can be recognized by the shape of the tooth with its crown and roots. By its shape alone, an unerupted canine is revealed as such. The hyoid bone, when its shape is once noted, can be recognized, even if projected into areas above it. The shape of the dense shadow at the angle of the mandible in the accompanying print (Fig. 5) leaves little doubt as to its being an unerupted tooth, its location justifying one in assuming it to be the lower third molar. The patient had the corresponding one of the other side extracted under identical conditions.

V. SIZE.

Generally, the size of the teeth is of little diagnostic value, but when an enlargement or diminution, viz, by apposition or absorption, has taken place, it becomes important to determine the real size of a tooth. Its length and breadth can be accurately ascertained only in cases where there is no distortion. As an illustration the accompanying film (Fig. 6) is shown. The question of replacing these ill-fitting crowns arose; the radiograph, however, shows the length and breadth of the roots greatly undersized. Besides, destruction of the roots at the gingival margin is evident. Under these circumstances a different procedure than at first thought feasible was decided upon.

VI. DISTANCE FROM SURFACE.

In locating foreign substances or bodies, it is essential in operative work to know beforehand how far distant labially or palatally the object is from the surface.

The accompanying film (see Fig. 7) was made in a patient complaining of soreness in the region of the upper right canine, without any visible manifestations of inflammation. Between the lateral incisor and canine roots a circular area of decreased density is seen on the palatal side of the alveolus, overlapping the canine, surrounding an oval area of marked density, both being sharply outlined against each other and the surrounding cancellous tissue. To approach this area it is valuable to know beforehand its depth from the surface.

VII. EXTENSION.

In a growth which is of an inflammatory nature a knowledge of the extension in both directions is absolutely necessary to fulfil the requirements of a diagnosis. This can only be done on a

Fig. 3B.

Fig. 3A.

plate. The lesion, however, is only recognized in so far as it shows progression of the area of altered density into that of surrounding tissue, viz, protrusion of a growth or destruction of surrounding bony tissue. The destruction which involves soft tissue cannot be recognized by any gradation of density in the radiograph, but can be brought out by injecting bismuth paste. The radiograph in Fig. 8 shows the extension of destruction of cancellous tissue in the mandible, originating from the anterior root surface of the lower molar, in a patient presenting a fistulous opening under the jaw, discharging pus. The course of the fistula in the cancellous tissue is shown in a broad line of lessened density leading from the anterior root downward and forward to a round area, being a larger cavity, then backward and downward to an opening at the margin of the mandible. The further course of the fistula in the soft tissue to the skin surface is not shown here, but could be brought out by filling with bismuth paste. In this way the total extension of a lesion is made visible by a radiograph from its origin to its termination.

Fig. 4.

VIII. OUTLINE.

In order to obtain the finer definition, a magnifying glass will be found a great aid. The outlines, whether sharp or indistinct, smooth or rough, showing protrusions or indentations, may all have their importance. In this way the apposition in exostosis is defined. Therefore only such radiograms should be considered as show absolutely sharp outlines in parts not involved. Any fogging or

Fig. 5.

Fig. 6.

Fig. 7.

false projection must be eliminated beforehand. It is especially essential to have the tips of the roots sharply outlined, as they are in the field mostly involved.

FIG. 8.

FIG. 9A.

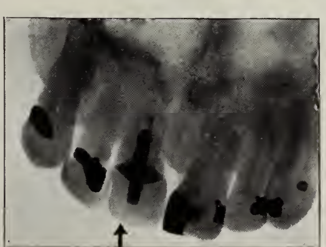

FIG. 9B.

Faulty technique is to be blamed for wrong diagnosis. The film (Fig. 9, A) and extracted tooth (Fig. 9, B) are evidence that the radiograph shows details in outline which may easily be overlooked at first glance. Upon closer examination, however, the outline of destroyed tooth substance is shown in accordance with that of the tooth.

The outlines of all the lower teeth

shown in Fig. 10 are sharply defined, with the exception of the roots of the apices in the nature of exostosis, preventing its successful elevation.

Fig. 10.

lower first molar. This tooth was being subjected to force in order to bring it to place. Failure to accomplish this led to an X-ray examination. The case was referred by Dr. G. P. Brenner. Following the course of the roots, one sees apposition of a dense tissue around their

IX. DENSITY.

The most difficult part of roentgenology for the novice is the judgment of density of tissue. Here physical laws alone prevail, nothing being left to the imagination. Air shows the least density, because no rays are absorbed, and therefore reach the plate with full intensity, blackening it deeply. Water and soft tissue, skin, muscle, etc., have the same density—that is, absorbability for the Roentgen rays. They allow only a certain amount of rays to penetrate them, and act chemically upon the plate; the area is accordingly of higher density. Bone tissue has the density of the quantity of mineral (calcium) salts in its composition, the degree of density varying with the atomic weight of the mineral. Therefore decalcified bone shows less density, and eburnated or ebonized bone greater density. The first will be found in rhachitis and tuberculosis, in arterio-sclerosis, etc., the second in certain stages of syphilis or osteomyelitis. Enamel shows even greater density than the last-mentioned alteration. Proper exposure, therefore, can be recognized by comparing the density of the teeth to cancellous tissue. It must be remembered, however, that in metals density does not equal firmness—lead, being of higher atomic weight, offering more resistance, *i.e.* being absorbed to a greater extent, than iron. To get the greatest contrast a tube is therefore preferred having the greatest variation in the penetration of the rays emanating therefrom. The softer the tube, the more contrast in the different tissues.

FIG. 11.

It is next to impossible to show in a print the different degrees of density shown on the original negative, but the accompanying print (Fig. 11) may serve to give an illustration. The high-lights are no denser than the antrum—neither offering resistance, as they are air.

The soft tissue shows the next degree

of density, then the cancellous tissue of the alveolus, and then the unerupted tooth; still greater density is exhibited by the enamel of the teeth and crowns of the artificial plate, while the plate itself, consisting of hard rubber with a certain percentage of sulfur, the pins in the artificial teeth, and the metal tooth-fillings appear, of course, darkest of all. This case was referred by Dr. C. W. Hall.

FIG. 12.

X. NATURE.

The exact nature of a lesion cannot be definitely shown radiographically, but by following the before-mentioned signs a conclusion as to the probable nature can very often be reached. For instance, on taking into consideration its location and its degree of density, a pulp-stone can be recognized as such.

Of all bone lesions, whether they be neoplasms or of some specific origin, none give so clear a Roentgen diagnosis as bone-cysts, a case of which is shown. (See Fig. 12.) This case was referred for radiological diagnosis by Dr. Carl Case. The area of diminished density is located in the mandible; it is of oblong shape and nut size, and the area is so dark (light on the print) that it must contain air, with clear-cut outline, sharply marked off from the surrounding tissue of unimpaired density. These characteristics justified one in assuming the area to be that of a bone-cyst, and of benign nature. The subsequent curetment and microscopical examination by Dr. G. V. I. Brown bore out this diagnosis.

XI. ETIOLOGY.

Most men unaccustomed to the interpretation of radiograms fall into the error of trying to make an etiological diagnosis from the plate. Just as the expression "kidney stone" is heard in medical parlance, so in dentistry the word "abscess" is employed, when the only conclusion which can be drawn from a radiograph is that of an area, or in a stereo-radiogram, of a cavity of lesser density of tissue. The nature of the contents must find clinical explanation. The word syphilitic, tuberculous, etc., should not be heard in making a Roentgen diagnosis.

Fig. 13.

Fig. 14.

Fig. 15.

The two films, Figs. 13 and 14, show how a radiograph may nevertheless help clear up the obscure etiology of a cavity filled with pus. In this case, pus was exuding at a point above the first bicuspid. The radiograph shows the location, extension, and relation of the cavity to the adjacent teeth, but not, of course, the source of infection. Removal of the crown, also root-filling of the first bicuspid, and drainage through this root giving no relief, the tooth was extracted, under the belief that necrosis at the apex was the cause. This extraction also having no effect, the second bicuspid was drilled into and found to contain a dead pulp. Suitable treatment now cleared up the diseased area, and established the etiology.

XII. ACUTE OR CHRONIC CASES.

Similar faulty phraseology is often used in trying to express whether a lesion is acute or chronic, recent or old, there being no roentgenological points of differentiation to warrant any such term.

The accompanying radiograph (Fig. 15) was taken to determine the cause of irritation following the filling of a root-canal. It shows clearly an area of lessened density around the apex, with a line of increased density in continuity with the root-canal. In other words, the root-filling was forced out through the apical foramen, causing local irritation, visible in the area of decalcified cancellous tissue. Here an acute stage without infection is underlying, the irritation being due to formalin in the root-filling material. A chronic irritation will naturally give the same picture.

Fig. 16.

XIII. PROBABLE CLINICAL COURSE.

Very often the Roentgen findings help one in estimating the probable clinical course, supplementing the other clinical findings heretofore out of the field of observation. In this way the clinical course may be followed by means of the rays, as for instance the resorption of an area of inflammation showing less density than the surrounding tissue. Likewise it is possible to follow the restitution of normal tissue in an area of destruction —for instance, of an abscess cavity after drainage. Even the exact size in diminution can be demonstrated by inserting bismuth paste into the cavity.

In illustrating one of the probable clinical courses of treatment, the following case is cited: The patient, a man of thirty-four years, had bridge work inserted, as shown in the radiograph, Fig. 16, as an aid in the treatment of pyorrhea. The appliances did not take into consideration the proper laws of mastication, hence an extensive destruction of

Fig. 17.

alveolar tissue was the result, as recognizable in the plate. With proper mechanical appliances, having lateral support, it is to be assumed that no further destruction of cancellous tissue will ensue, or will at least be minimized.

FIG. 18.

XIV. NEGATIVE AND POSITIVE DIAGNOSIS.

A negative diagnosis, based on Roentgen findings alone, is absolutely unwarranted. Inflammations in the nature of round-cell infiltration find no radiographic expression. On the other hand, a positive diagnosis must in every case be in accord with the clinical data, if the dental roentgenologist would avoid bad pitfalls. Far from bringing the value of the Roentgen rays into disrepute, this exact limitation to its designated field only enhances its application, and makes of it a real diagnostic art.

Roentgenologists will be able to say at a glance that the print in Fig. 17 has been made in a case of acromegaly. The partially destroyed sella turcica, the encroachment on the sphenoid sinus, the protruding frontal sinus, and especially the protruding upper and lower jaws, with the separation of teeth, is too characteristic to need further comment. The enlargement of the tongue and of the hands and feet, with menstrual disturbances, etc., bear out the clinical diagnosis.

The following two prints (Figs. 18 and 19), however, present a good illustration of how careful one must be in making a positive diagnosis, even if the clinical symptoms seem to bear it out. The first print (Fig. 18) is one of the upper left side—the print reversing the sides—of the jaw of a boy suffering with dementia præcox. This came on in his last year at college, he being then about sixteen, and suffering from an intense trifacial neuralgia of unknown origin. A roentgenological exploration of his denture, at the age of twenty-three, revealed dark shadows back of and above the upper third molars, as shown in the print of the upper left side.

In looking over all previous exposures, a similar area of density in this identical position was found but once—in the second plate (Fig. 19), the case of an insane woman. Naturally the conclusion was drawn that this might be the focus of irritation, inasmuch as unerupted or misplaced teeth are well-known factors in the etiology of cases of reflex neuroses and psychoses. To make a long story short, the patient was turned over to the family dentist, Dr. Kuhnmuench, who extracted what proved to be unerupted supernumerary upper third molars, one on each side. The extraction, which

Fig. 19.

was made two years ago, was followed by some improvement but no cure. The dementia still persists, in spite of the correct diagnosis of both physician and dentist.

TECHNIQUE OF DENTAL RADIOGRAPHY.

Penetration of tube. A correct dental radiograph demands a suitable X-ray tube. For intra-oral exposures, employing dental films, the penetration should not exceed 6.5 Wehnelt—4 Benoist, equaling a terminal spark gap of 6 to 12 cm., or $2\frac{1}{2}$ to $4\frac{1}{2}$ inches. The focus must be sharp and absolutely steady during exposure (the cathode terminal of the tube, held up, must not rattle when shaken), and the penetration must also be stable during the whole time of exposure. Exposure must be interrupted as soon as the vacuum changes. This is discernible with the millimeter. Short, frequent exposures are the best to keep up the vacuum. For extra-oral exposures, employing a plate, the penetration should not be over 7.5 Wehnelt—5 Benoist, corresponding to a terminal spark gap of 7 to 15 cm. or 3 to 6 inches.

Distance. The distance from the target of the tube to the film or plate should be standardized in dental work at 20 inches. This will not only facilitate a correctly timed exposure, but will insure a correct reproduction of the desired area, thereby minimizing distortion.

Time of exposure. The time of exposure depends upon the amount of current at disposal. If the following rules are adhered to, even a small machine will give excellent results. Exposures of one second or less are convenient, but in no case a necessity.

Time of development and developing solutions. The time of development must be judged by the time it takes for the desired area, not the high-lights, to appear. This time is multiplied by the factor of the developer in use. For instance, having hydroquinone as a developer, the developing factor is 5. The solution may be put up as follows: Solution A—Dissolve 2/3 oz. or 20 cc. hydroquinone in 33 oz. or 1000 cc. of distilled water; add $2\frac{1}{3}$ oz. or 66 cc. of dry, or $3\frac{1}{3}$ oz. or 100 cc. of crystallized pure sodium sulfite, and add 15 minims or 1 cc. of crystallized potassium bromate. Solution B—Dissolve 5 oz. or 150 cc. of crystallized sodium carbonate in 33 oz. distilled water. The filtered solutions are taken in equal parts. The roots of the teeth, being the area desired, appear in 90 seconds; this is multiplied by the factor 5 of hydroquinone, making 450 seconds, or $7\frac{1}{2}$ minutes. This completes the development, the films being washed,

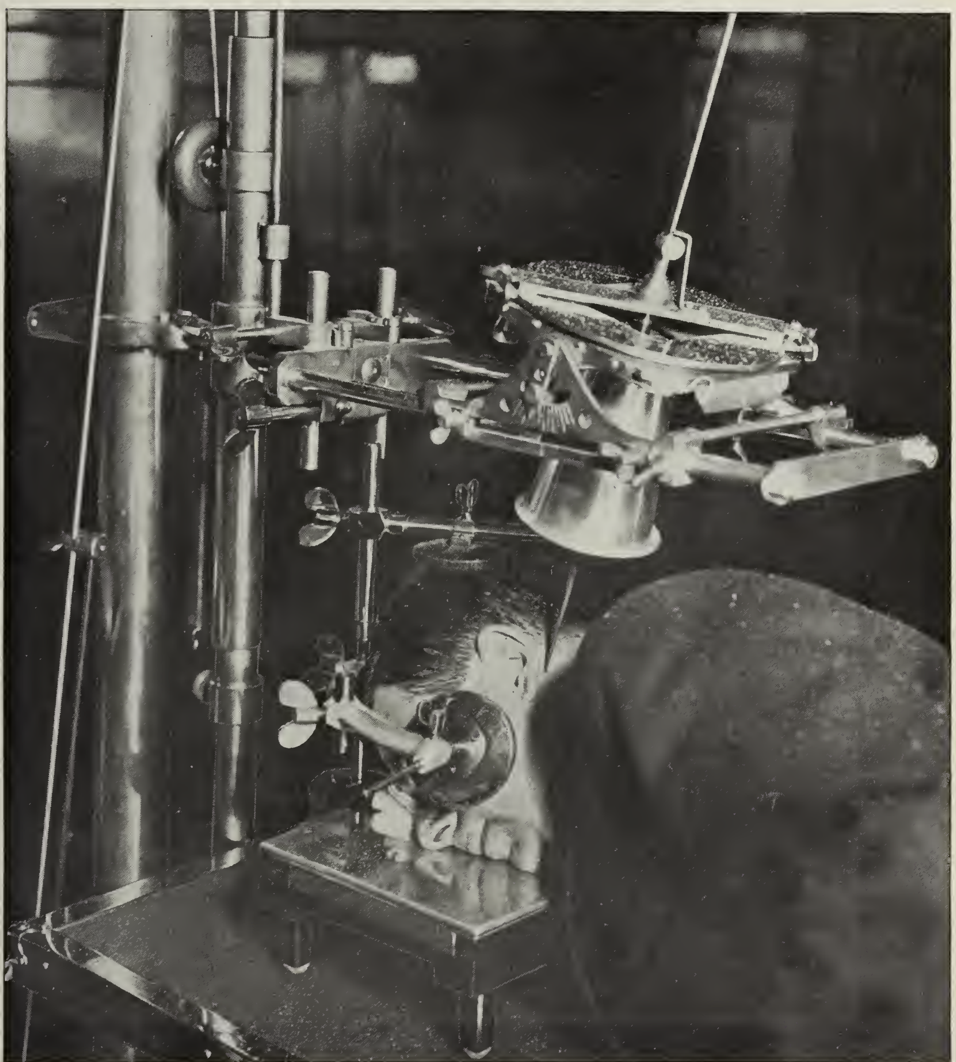
Fig. 20.

fixed, washed, and dried in the usual way.

Obtaining contrast. Greater contrast may be obtained if a sheet of lead, 1/16 inch thick and of the size of the 5 x 7 plate, be placed underneath its glass side and inside of the enveloping black paper. Films must not be over three months old, and must be kept in a dry state, else they will show fogging and a black margin on developing.

Contact and immobility of film or plate. The film or plate must be brought into closest possible contact to the desired area, and absolute immobility be maintained during exposure. With the film in the mouth this is accomplished satisfactorily by the patient holding the film as placed by the operator. In using plates the face is brought down upon the head-rest holding the plate, the patient lying on the same table as the head-rest.

Fig. 21.



Position of the head. The position of the head not only demands perfect immobility, but must be so adjusted as to allow correct focusing of the central ray upon the part desired. While padded head-rests serve to immobilize the head, they also prevent the slightest movements from respiration, arterial palpitation, or tremor, which blur the outline. The proximity of the desired area to the plate is made possible by rotating the head to the necessary angle and bringing this area down upon the center of the plate, the center of the plate having previously been brought into the area of the focal ray. This minimizes distortion. In the case of a tooth, the apex should be in the center of the focus; this also brings the apex into the center of a film.

Fig. 22.

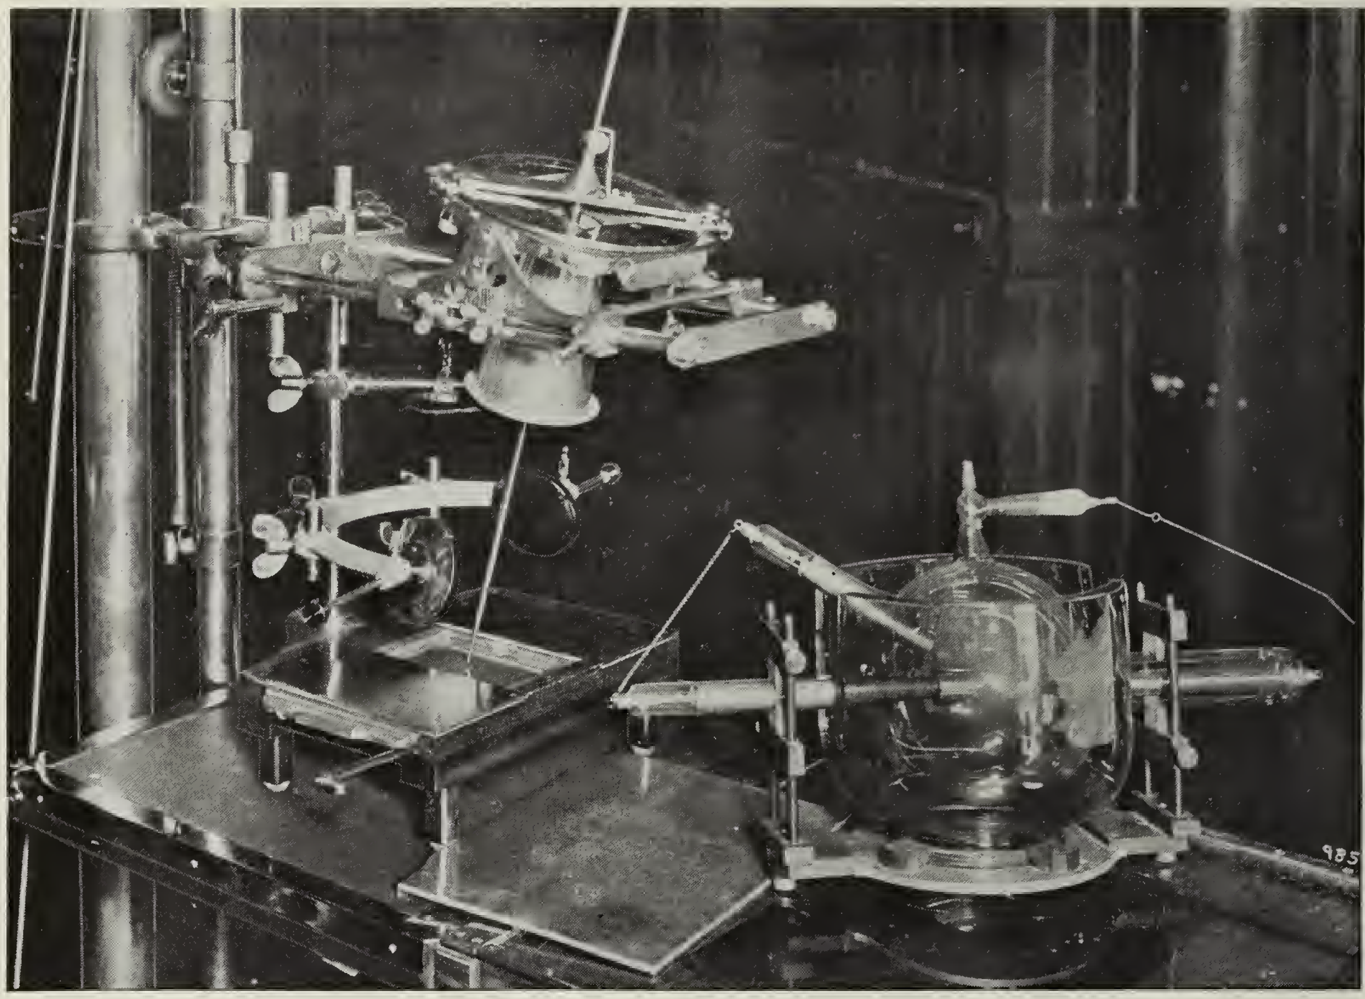


Fig. 23.

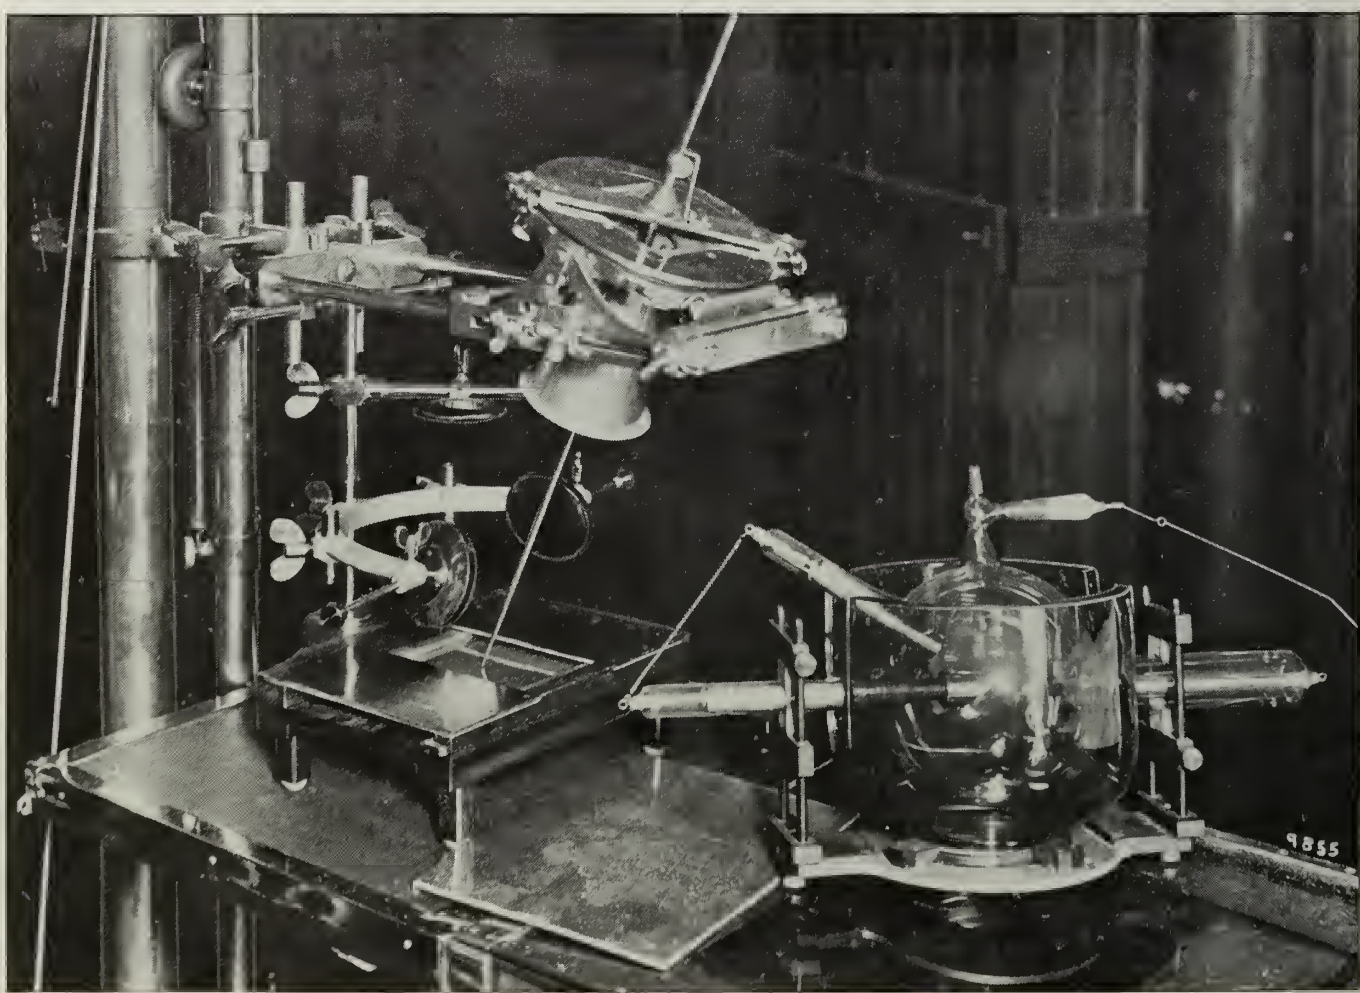


After centering the required area by rotating the head, the central or focal ray is rotated to strike this center in such a way as to avoid the opposite ramus. For this step, besides taking note of the position of the head as a whole, certain landmarks come into consideration. The focal ray is adjusted correctly, if it passes behind the ascending ramus of the mandible and at a point just below and behind the external auditory meatus, ahead of the mastoid process, as shown in the accompanying tracing and photograph. (Figs. 20 and 21.)

Besides avoiding the opposite ramus. the cranium, with its thick occiput and inner ear parts, is projected out of the field. The angle of rotation of the head is 70°, the angle of rotation of the focal ray is between 65° and 70°, the two stereoscopic angles being 73° and 75° respectively, as shown in the accompanying plates. (Figs. 22 and 23.)

STEREO-RADIOGRAPHS.

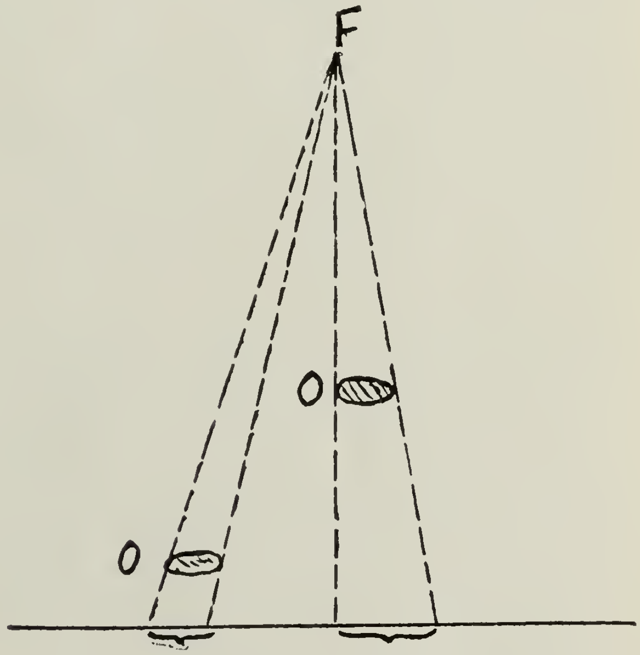
In some cases it is desirable not only to get the projected parts on a plane, but also actually to see their position, their extension, and their relation to the surrounding tissues. This is accomplished by taking two separate exposures of the same area, with shifting of the exposed half of the plate and binocular rotation of the focus between exposures. The two views, each covering half of a 5 x 7 inch plate, are viewed in a common parlor stereoscope. This places the parts and objects viewed into space. The two separate exposures, at the same time, eliminate the necessity of taking two exposures at right angles, showing the proper depth in themselves. They may also clear up any misconception of a defect in one of the plates. In no part of the human body is stereo-radiography of more value than in unraveling the confusing lines of views of the facial skull.

LAWS OF PROJECTION.

To understand a plane radiograph, though, it is most essential to recall some necessary laws of projection. Why does one take such pains in bringing the desired parts into such close contact to the film or plate? Simply because the nearer the object to the plate or film, the less the distortion, when the rays emanate, as in a Roentgen tube, from a focal point. The accompanying drawing (Fig. 24) illustrates this.

Of course, the distance from the focus to the film or plate is taken equal, also

Fig. 24.



F, Focus. *O*, Object.

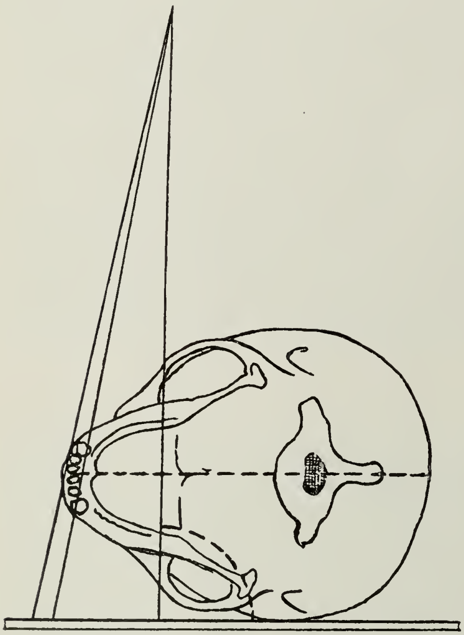
the plane of the two equal-sized objects is assumed to be in a plane parallel to the plane of the film or plate. One avoids at the same time the harmful secondary rays originating in the space between the object and film from fogging the latter; this insures sharper outline and clearer detail.

ASCERTAINING RELATION OF APICES OF UPPER MOLARS TO FLOOR OF ANTRUM.

Exception to this rule is taken advantage of in ascertaining the relation of the apices of the upper molars to the floor of the antrum. Here we can neither rotate the head nor the focal ray, but must have the middle plane, represented by the nasal septum and the protuberantia occipitalis, parallel to the plate, the ray striking the latter perpendicularly, passing transversely through the floor of the antrum in the region of the molar desired, as shown in the accompanying tracing and photograph. (Figs. 25 and 26.)

The distance of the focal point to the plate is not twenty inches as in all other dental work, but is minimized to twelve inches. This not only enlarges the teeth of the distal side, but also makes them

Fig. 25.



indistinct enough, so that their shadow does not interfere with reading the relation of the area of the side next to the plate. The accompanying drawing (Fig. 27) illustrates this, the focus being brought down from F to F_2, the distal teeth being in the plane a–b, and enlarged to a_2–b_2.

SHOWING ACTUAL LENGTH OF A TOOTH IN RADIOGRAPHY.

In dental radiography it is impossible to eliminate distortion, but distorted lengthening or shortening should not exceed one-tenth of the actual length of the tooth, as demonstrated by Cieszynski. The latter has shown by constructive methods, as seen in the following drawing (Fig. 28), that the actual length of a tooth can be shown in a radiograph.

But it is practically out of the question to fulfil the requirements of bringing the rays and the film into correct angular relationship, although this is theoretically possible—the slightest movement of film, the patient's head, or the focal ray, frustrating all our previous painstaking efforts. When size, position, and location in space are essential, a stereo-radiogram will far better meet the requirements.

As previously mentioned, we have two ways of producing a dental radiograph. One is to have an X-ray photographic plate external to the mouth—the extra-oral method; the other, to have an X-ray film, suitably trimmed, bent, and adjusted, in the mouth—the intra-oral method. The latter being the older, convenient, and more easily understood, it will be discussed first.

COPING WITH DISTORTION IN THE INTRA-ORAL, OR FILM METHOD.

Why is it impossible to bring the tooth next to and parallel to the film? Because we must strive to have the apex of the tooth in the center both of the focus and the film. Further, the film must be pressed against the alveolar process and palate, and is not only bent, but is at an angle to the root-canal of the tooth. The intervening space or angle should be divided, and the focal ray brought down vertically through the apex upon this plane, as shown in the accompanying drawing. (Fig. 29.)

In this way we minimize the unavoidable distortion. Practically this is quickly brought about by adjusting the plane of the open side of the cone, which touches the mouth parallel or nearly so to the film or the plane it is held in. According to the height of the palate, this will be found more or less easy to do. Following this advice, the dental regions of the upper jaw are quickly and accurately focused, the rotation of the head and of the focal ray being readily accomplished. A focal pointer is of great aid, doing away with any tedious construction and angular measuring.

antrum. The accompanying drawings, from Cieszynski, explain this error. On the film picture (Fig. 30), J J is the outline of the malar bone J S; the line A the lingual line of the alveolar process.

Fig. 26.

Errors of interpretation are many to those unaccustomed to tracing an elevation from a projected area. One of the most common is the one of supposing the labial roots of a molar to be in the antrum, being above the line K representing its floor. But the frontal section below (see Fig. 31) shows how p

cess. One might be led to believe that the palatal root p of the first molar was in the antrum, being above the line K representing its floor. But the frontal section below (see Fig. 31) shows how p

is projected above *a*, the latter corresponding with K.

Fig. 27.

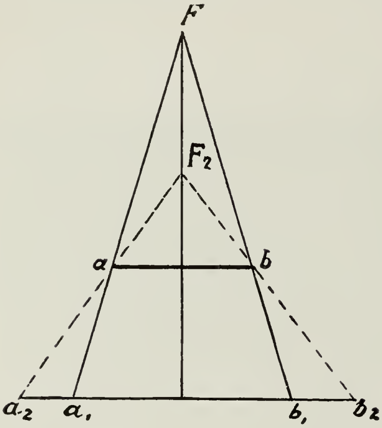


Fig. 28.

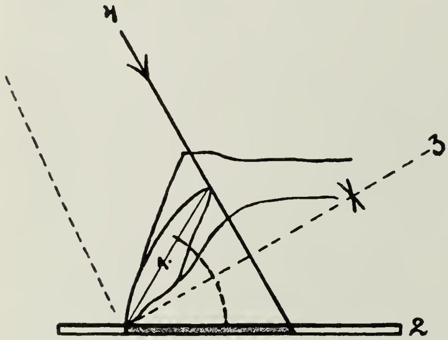

Fig. 29.

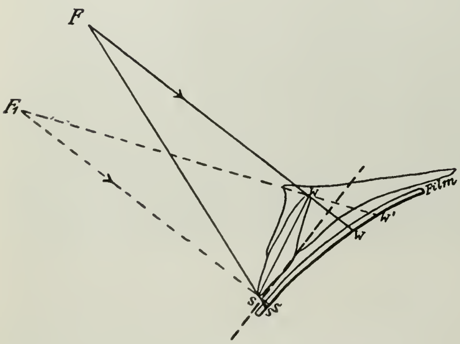

A similar error to which Cieszynski called attention is the presumption that a root-canal is not filled to the tip, while in reality it is—the planes overlapping, however, as shown in the accompanying illustration. (Fig. 32.)

Fig. 30.

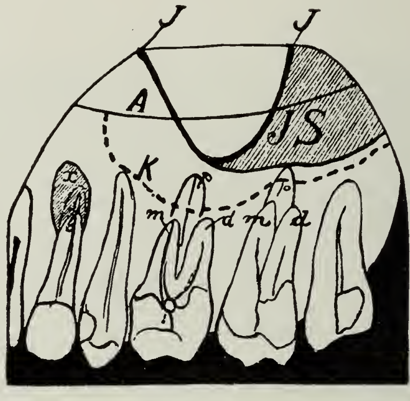

Fig. 31.

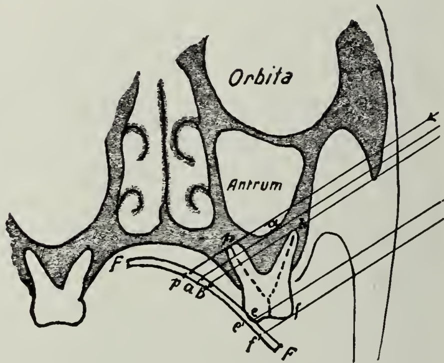

Fig. 32.

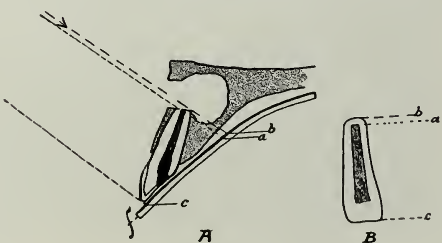

INDICATIONS FOR THE EXTRA-ORAL, OR PLATE METHOD.

Should repeated intra-oral exposures leave any doubt, an extra-oral radiogram will quickly clear up the situation. The lower jaw offers less advantages for intra-oral exposures, the lower incisors alone furnishing a suitable field. The correct angle is difficult to maintain, as the film cannot be pushed down far, and will even move when held between the teeth, by upward pressure of the underlying

Fig. 33.

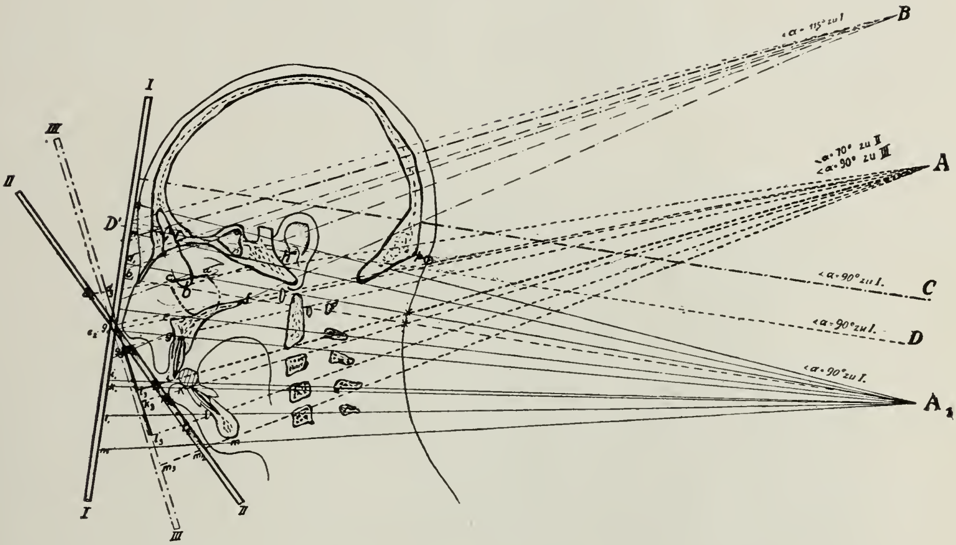

Fig. 34.

tongue. The lateral teeth give poor results with this method, and the extra-oral method is always the method of first choice.

The extra-oral method, although more difficult for the beginner, nevertheless gives results so far superior in most cases to the intra-oral method that it should be resorted to in all cases where the least doubt remains.

Radiographing lower incisors. The incisors of the lower jaw are taken in the following manner: The patient lies face downward on the plate in such a way that the chin and tip of the nose are the resting-points. The head must be centered and laterally steadied by head-rests or sand-bags. The rays are focused, as in the diagram in Fig. 33, from A perpendicularly upon the plate, II.

If this or any view subsequently described be taken stereoscopically, the shifting of the focal point should be done vertically, not sidewise, in order to correctly bring out the horizontal planes of the facial skull. Even the antrum is taken best in this way, stereoscopically. It will be noted that the focal ray strikes the neck from two to three inches below the protuberantia occipitalis, and goes through the piece of cork inserted between the teeth.

Fig. 35.

Posterior lower teeth. For all the other teeth of the lower jaw the head is gradually rotated, but also the focal ray, so that the distal jaw is projected out of the area of the proximal one. In this way the hyoid bone is also projected upward, and often into the lower ramus shadow; it must therefore be recognized as such.

Upper incisors. To take the incisors of the upper jaw, the patient lies likewise face downward, but resting on the tip of the nose and forehead. The rays should be directed, as shown in the aforementioned diagram (Fig. 33), from A I perpendicularly upon the plate I, the focal ray entering at the same point of the neck, but directly upward through the antrum.

Frontal antrum picture. For a frontal antrum picture the manner is the same, but the third molars will project into the area of the antrum.

Upper posterior teeth and canines. For teeth from the canine posteriorly the head and focal ray are again rotated in the aforesaid manner. For the canines the nose is flattened sidewise on the plate, as shown in Fig. 21.

Unerupted teeth. In unerupted teeth, a stereo-radiogram offers opportunity for correctly estimating the position of the tooth in the tissue in a way for correctly adjusting the lines of traction to be employed.

Growths. In case of a growth, the destroyed area can be accurately estimated in its extension in the three dimensions. With sufficient rotation of the head, the styloid process can be brought into view and recognized as such. All earrings and combs should be removed before exposure.

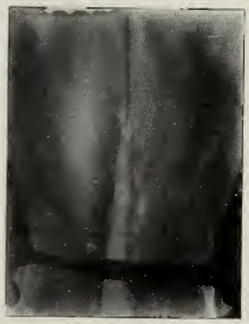
Antrum cases. The antrum, for dental purposes, is best taken laterally, the focal rays parallel with its floor. The accompanying plate (Fig. 34), taken in this manner, shows in addition a probe in the antrum.

The adjustment of the head and ray must be done with painstaking care, the least angulation of either producing false projections. The stability of the head is especially difficult, as it rests on the malar bone alone. Here also a stereo-radiogram is essential in doubtful cases. If, however, a tooth is within the antrum, the head is rotated to great advantage, but not the focal ray. The tooth is in both cases equally distant from the plate, making its outline somewhat indistinct, as the accompanying view shows. (Fig. 35.) One tooth is seen *in toto* and another partially in the antrum. A cavity in the lower jaw, showing a deposit, will also be noticed.

The frontal view of the antrum has the advantage over the transverse view that it allows of comparison of the two sides in case of empyema.

Hard palate. The hard palate offers an easily accessible field of investigation. If a film is held against it, and the rays are directed vertically down upon the plane of the film, the breadth of the separated palatal suture is readily revealed. This estimation is of value in the course of treatment in appropriate cases, as shown in the film in Fig. 36, which was made in a case referred by Dr. G. V. I. Brown.

FIG. 36.



SUMMARY.

To summarize, the indications for using the intra-oral method are few, being limited to the lower incisors in some, to the upper incisors in most cases, to the upper canines, bicuspids, and upper molars in many cases. A negative film, however, should never be taken as conclusive evidence of normal conditions except in rare instances. In all doubtful cases, a plate—and if still doubtful, a stereo-radiogram—should be resorted to. And if even this leads to no definite conclusion, examination of the other jaw should be made. In cases involving the angle of the lower jaw, a film should not even be taken into consideration; the same holds good with the rear portion of the upper jaw. A plate alone should be employed in determining the origin and extension of cysts, tumors, osteomyelitic processes, necrotic areas, fractures of the maxilla or the mandible, and in the location of foreign bodies and teeth, or in disease conditions of the antrum and nasal cavities.

ENLARGED CERVICAL GLANDS, WITH SPECIAL REFERENCE TO THE MOUTH AS AN ETIOLOGICAL FACTOR.

By GEORGE MORRIS DORRANCE, M.D.,

SURGEON TO THE ST. AGNES HOSPITAL AND DEMONSTRATOR OF APPLIED ANATOMY, DEPARTMENT OF DENTISTRY, UNIVERSITY OF PENNSYLVANIA.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, April 10, 1913.)

BEFORE discussing the question of the cause of the glandular enlargement, it would be well to rapidly review the position of the different cervical glands and the regions drained by their tributaries. The chief group of glands is situated along the course of the internal jugular vein. It consists of a large number of nodes, and is a continuous chain extending throughout the entire length of the neck, but for convenience it is divided into superior and inferior deep cervical groups. In addition to these, some smaller chains occur more superficially, forming the superficial cervical group, so that there are three main groups in this region. The superficial group may be divided into two subgroups, the external jugular and anterior cervical group. The external jugular nodes, situated along the external jugular vein and resting upon the outer surface of the sterno-cleido-mastoid muscle, are few in number, ranging usually from four to six; they receive tributaries from the pinna and parotid region and empty into the superior deep cervical group by passing over the anterior border of the sterno-cleido-mastoid muscle. The anterior cervical chain is situated beneath the depressor muscles of the hyoid bone, resting upon the anterior surface of the larynx and the anterior lateral surfaces of the trachea. These drain the larynx and the trachea and empty into the superior deep cervical chain. (The tributaries of the deep cervical chain are the posterior, auricular, occipital, retropharyngeal, parotid, submaxillary, submental, and the superficial and anterior cervical chains.) The regions drained are the occipital portion of the scalp, upper part of the back of the neck, tongue, palate, nasal and buccal membranes, tonsils, teeth, pharynx, larynx, and upper portions of the esophagus. The inferior deep cervical chain—supraclavicular—is situated in the supraclavicular triangle of the neck and rests upon the scalene muscles. The tributaries, in addition to the superior deep chain, are those from the integumentary and muscular tissues of the lower part of the neck and the pectoral regions and the axillary groups. The jugular trunk on the left side empties into the thoracic duct, and on the right side into the right lymphatic duct.

The lymphatic system consists of lymphatic glands and lymph channels. The glands are situated in the course of the channels, and act more or less as filters. By the action of the leucocytes contained in them, they assist in the absorption of the infection, and unless overpowered by a very severe or long-continued source of irritation are able to overcome the infection. The so-called lymph glands are peculiar to the lymphatic apparatus; they are inappropriately designated glands, for they really represent only many-branched lacunar labyrinthine spaces.

THE PATHOLOGICAL AND BACTERIOLOGICAL STUDIES OF INFECTED GLANDS.

The cervical glandular enlargement may be only a part of a general glandular enlargement which in turn is due to a constitutional disease, such as syphilis, tuberculosis, Hodgkin's disease, leukemia, typhoid fever, or the infectious diseases of childhood. If the glandular enlargement is localized in the neck, it may be unilateral or bilateral, and caused by pus-forming micro-organisms, tubercle bacilli, or malignancy—carcinoma or sarcoma. Many authorities claim that practically all the chronic glandular enlargements of the neck not due to malignancy are due to the tubercle bacilli. Dr. P. A. Lewis reported a careful study of fifteen consecutive cases; in nine of the glands he found tubercle bacilli of the bovine type and in the remaining six tubercle bacilli of the human type. W. Leterer (*Southern Medical Journal,* January 1911) reported a study of eleven consecutive cases; in five cases the human type was isolated, in six the bovine. A. H. Tubby mentions a fact which is very interesting in this condition, *i.e.* that the human type flourished better in well-oxygenated tissue, such as the lungs, while the bovine requires less oxygen. Possible infection by milk would better explain the problem as far as the cervical glands are concerned.

The tuberculin test is of little value in determining whether a gland is tuberculous or not. A negative tuberculin test is of value in that it usually excludes the presence of tuberculosis in the entire body. A positive reaction, on the other hand, may be due merely to the presence of an arrested tuberculous process elsewhere in the body, and have no bearing at all upon the actual lesion under observation. Another interesting factor in this connection is heredity. Until recently the question of immunity has neither been adequately discussed nor sufficiently understood, but as Kelynack states—"Recently, clinical and pathological researches have shown that the character of the soil is of almost equal importance to that of the seed"—and he mentions the striking examples of family tuberculosis related by Sir William Whitla. (These, I think, are cases of house or direct infections.) On the other hand, investigations such as those of Stick, Schnitzlein, and Cornet, demonstrating the rarity of tuberculosis in orphan asylums, show that the heredity factor cannot be very large.

CHANNELS OF INFECTION.

The most frequent starting-point of the infection in children and young adults in my experience is the tonsil. The tonsillar involvement in such cases is usually associated with adenoids. Those who have examined tonsils and adenoids after removal have found in small percentages—3 to 10 per cent.—tubercle bacilli deposits therein. Sewell (*Journal of the American Medical Association,* September 9, 1911) reports the result of a histological examination of 772 pairs or 1544 tonsils, of which 6.2 per cent. were tuberculous. He was able to follow 160 patients who had been operated upon for diseased tonsils, and found that 92 had no enlarged glands and 68 had enlarged glands. Fifty-seven of these glandular enlargements disappeared permanently following the removal of the tonsils. If tubercle bacilli are found in the tonsils and in the cervical glands, it is natural to infer that the latter formed the avenue of invasion.

The teeth as a mode of invasion are frequently overlooked, although as an avenue of infection they are second in importance to the tonsils. As these glandular enlargements occur most commonly at the shedding of the first teeth and the eruption of the second set, one frequently finds very imperfect teeth. Stark, in *Revue de la Tuberculose,* July 1896, was the first to demonstrate clearly that the bacilli in the case of tuberculous glands may gain entrance through carious teeth. He cites the case of a youth who had always been healthy previous to his eighteenth year, when he developed enlarged glands. Carious molars were present on both sides. The glands were removed and the teeth extracted. The glands proved to be tuberculous and the cover-slip preparations from the teeth revealed tubercle bacilli. I have twice found the tubercle bacilli present upon the teeth and in the glands in the same case.

Interesting in this connection are the statistics of Odenthal. Among 987 children examined he found glandular enlargement present in 697—70.7 per cent. Carious teeth were also present in more than one-half of the children. Only 7.7 per cent. of the children showed carious teeth without the glandular swellings. He found that when dental caries existed on both sides, glandular enlargements were present on both sides. Of the 267 children—28.6 per cent.—who had no glandular enlargements, only five had carious teeth. Hoppe of Leipzig, in an examination of 269 cases, found glandular swellings in 73 9 per cent.; in nearly all the cases it was associated with dental caries. The percentage of children with carious teeth and without glandular swellings was 21.5 per cent.; 44 per cent. had neither carious teeth nor glandular swellings.

I wish to lay special emphasis upon the tonsils as the most common source of infection, but in most cases it has been shown that carious teeth are associated with them.

It is essential to have a complete physical examination made of the patient, to rule out the constitutional diseases before seeking for the local source of infection. On examining the mouth, the tonsils should be carefully gone over, and if diseased their removal advised, together with any adenoids that may be present. The teeth should be carefully cleaned well up on the roots and subsequently treated with five per cent. iodin and alcohol, and all the cavities of the teeth noted. The subsequent course of treatment of these teeth will of course be influenced by the social standing of the patient. In children, if it is not near the natural time for their shedding, it is advisable to have them filled, in this way preserving the natural arch and preventing any secondary deformity in the eruption of the second or permanent teeth. If this is not possible, they had best be extracted. It is of course understood that all diseased roots should be removed at once. It is advisable to save as many teeth as possible in the case of the permanent teeth, and care should be exercised in examining these teeth to see that no apical abscesses exist. The best method of ascertaining this is to have an X-ray examination made. Any localized tumors of the tongue and gums which resemble carcinoma are of course not within the province of this paper, as they demand immediate radical surgical operation. The most important consideration in the treatment of any cervical glandular enlargement is the removal of the source or sources of infection. No variety of treatment will permanently cure a glandular enlargement, if the primary source of infection is not removed. After the removal of the source of the infection, the general condition of the patient should be considered and the diet, method of living, etc., regulated.

METHOD OF TREATMENT OF THE GLANDS THEMSELVES.

If the glandular involvements are moderate or small in size, a large percentage of them will disappear within a few weeks or months after the removal of the source of the infection, but there are a number of cases that will require further treatment. Just which cases are going to clear up without this further treatment, it is impossible to say. Much too frequently the glands have been attacked first and the source of the infection entirely neglected. This is particularly true of the teeth as the source of infection. A surgical removal of the glands is in my opinion not justified in the cases of moderate size, or at least until several other methods for their removal have been attempted, as much too frequently these glands recur after their surgical removal. In fact, it is not a rare occurrence for these patients to have three or four operations. Under the assumption that they are all tuberculous, tuberculin has been injected subcutaneously, both the bovine and human type having been used. The literature upon this treatment is very uncertain, some noting very promising results, and others none. My personal experience with tuberculin has not been satisfactory, but many competent men have obtained excellent results by its use. I have not seen results that would not have occurred without the use of tuberculin, but I have seen two cases in which I think I set up an acute tuberculosis of the lungs from its use. One cannot of course be positive upon this point, as the tuberculosis may have been simply quiescent, and any other treatment might have had the same effect. Local applications of ointments cannot act otherwise than as a poultice. The application of collars, plaster jackets, etc., are of very little value. A series of X-ray treatments have given the best results in my cases. This consists in a series of treatments—about twenty—given twice a week, being careful to regulate the dosage as you would in any drug, and to carefully filter the rays to prevent burning. If suppuration occurs, puncture the abscess and allow the abscess to drain. If, when the case is first seen, a sinus exists, give the treatments as in any other case. If they are removed surgically, a subsequent course of the ray will prevent a recurrence.

The treatment which I advocate is the removal of the source of the infection, careful attention to the hygienic condition of the mouth, and a course of X-ray treatments.

BACTERIOLOGY AND VACCINE THERAPY OF PYORRHEA ALVEOLARIS.

By JEWELL M. GOMPERTZ, D.D.S., New Haven, Conn.

(Read before the Connecticut State Dental Association, at its annual meeting, Waterbury, Conn., April 15, 1913.)

MUCH attention has been directed lately toward the bacteriology of pyorrhea alveolaris, a condition which is not only extremely disagreeable, but also has an important bearing upon the general health of the patient. That this condition does not respond to conventional treatment cannot be disputed.

ETIOLOGY.

Pyorrhea alveolaris is considered by many to be a purely local disease, affecting the teeth, and in its early stages I believe this to be true. After the irritative stage has existed, however, for an indefinite period, production of pus may take place, and absorption of toxins occur as a result. It must then be regarded as a constitutional disorder.

This course of the disease depends largely upon the degree of resistance which the individual may possess, as it is a well-known physiological fact that some patients may be able to withstand disease to which others fall easy victims.

In some cases the irritative condition can exist indefinitely, and never progress to the pus-producing stage, but this must not be considered as true pyorrhea alveolaris. After pus has appeared, with all its unpleasant symptoms, patients consult the dentist, seeking relief.

Micro-organisms. Among the organisms probably engaged in producing pyorrhea alveolaris are the staphylococcus aureus and albus, the streptococcus pyogenes, and the pneumococcus. These have all been found in cultures made from cases of pyorrhea; they are found singly or in combination, and just which group produces this condition has not been definitely determined, as no specific organism has been isolated.

While the local manifestations consist of the breaking down of the tissues adjacent to the pus pocket, a more serious condition arises in the effect produced upon the general health from absorption of pus, which certainly takes place in this disease in the same way as when pus is present in other parts of the body.

The literature on pyorrhea alveolaris is abundant, and a great deal has been said about the predisposing constitutional causes of the affection, such as anemia, malaria, etc. Likewise, many other disorders have been mentioned as causative factors in producing this condition. From our knowledge of infectious diseases it is fair to assume that these conditions may be due to toxic materials, first finding lodgment in the irritated alveolar tissues, producing pus, these toxic materials being subsequently absorbed into the system from the infected alveolar tissues.

Rheumatoid arthritis. I wish to call attention to various so-called rheumatic symptoms in persons subject to pyorrhea alveolaris, particularly in the case of rheumatoid arthritis. In a number of cases of this joint-affection under my observation, careful inquiry was made for infective foci. In the majority of the experimental cases, some inflammation of the mouth existed, but only those cases in which definite pus was to be found were recorded as pyorrhea alveolaris. To sum up these cases, a large number of cases of arthritis deformans are now recognized to be of infective origin.

Mouths that are unclean or in a septic condition may be the starting-point of any infectious disease. We have a very striking example of this fact in the case of infective arthritis. When the diagnosis has been made and vaccine therapy instituted, accompanied by local cleanliness, the results have been surprisingly gratifying.

The association of the mouth with rheumatoid arthritis and certain other forms of rheumatism will be referred to at some future time.

VACCINE TREATMENT.

The routine method of treatment that has been followed for a number of years in pyorrhea alveolaris is familiar to you all, and I will therefore not discuss it.

The more modern method of combating this disease is by the use of vaccines, and in order to treat pyorrhea alveolaris successfully by this method it is important to ascertain in every case the organisms most actively engaged in breaking down the tissues bounding these pus pockets.

By removing the tartar from the teeth and preserving the strictest cleanliness, relief has been obtained, but no permanent cures have taken place.

During the past two years the writer has treated a number of pyorrhea cases by the use of vaccines, and the results have been very encouraging. While I do not wish to be considered over-enthusiastic, I am optimistic enough to believe—and this belief is borne out by facts—that these cases can be considered permanently cured. I therefore am of the opinion that the vaccine treatment of pyorrhea alveolaris is one that will prove to be of extreme value in competent hands.

Autogenous and stock vaccines. The vaccines used were of the autogenous character, which give the best results. For the benefit of those who have not given special attention to different vaccines, a word regarding them will not be amiss.

When the vaccine is made from the bacteria obtained from the patient, a so-called autogenous vaccine results. A vaccine thus produced must necessarily correspond to the bacteria causing the disease. Vaccines obtained from any other source than that of the patient under consideration are termed stock vaccines. Such vaccines may consist of bacteria morphologically similar to those causing the disease.

Unfortunately, their being morphologically similar does not guarantee that they will correspond exactly to the bacteria at fault, for the reason that many of the great groups of bacteria have a large number of subdivisions.

The methods of procedure in obtaining the material for the preparation of a vaccine may be described as follows: One method consists in exerting gentle pressure on the gums to procure some of the pus, which is received on a sterile loop and *plated immediately.* The other method consists in the use of a sterile swab. From these cultures the vaccines are obtained.

As I expect to demonstrate the different methods later, I will not go into detail at this time.

Dosage. The dose of a vaccine varies with the manner of its preparation, and also with its bacterial content.

I have made no attempt to measure the effects of the vaccine by taking the opsonic index. The technique is too elaborate, and the results vary too much to justify the time and labor required. Clinical symptoms, plus the aid of general rules, afford a sufficient guide as to dosage, intervals between doses, etc. In reference to doses of autogenous vaccines, I cannot recall a single instance where any evidence of harm resulted.

I claim the virulence of the pus found in pyorrhea pockets to be very low compared to that found in other pus disorders of the body—which is due either to long standing or the general surroundings in the mouth.

Recording-charts. For the sake of control, charts indicating the respiration, pulse, and temperature are marked every four hours for a period covering fifteen injections of an autogenous vaccine. These charts, which are familiar in the routine of every hospital, show surprisingly slight changes, if any, following the several injections.

Injection. In my practice, the upper arm is selected as the site of injection. The usual measures for surgical cleanliness are followed.

ILLUSTRATIVE CASE.

The following case will serve as an illustration:

The patient was a man, forty-eight years of age, who had been a sufferer from pyorrhea for a number of years. He had received the usual local treatment for this condition without benefit.

A vaccine was made, and on December 2d he was given an injection of 50,000,000 streptococcus, and successive injections of 100,000,000 were made at five days' intervals. General improvement followed each injection. Then injections of 200,000,000 were given one week, two weeks, and three weeks apart. Slight local reactions followed these injections. A new vaccine was made, and injections of 75,000,000 and 100,000,000 were given at five days' intervals. The soreness in the gums subsided, and the pus discharge disappeared entirely, no inflammation being noticeable. At the end of six weeks, granulations appeared and continued during the treatment.

At the end of ten weeks the treatment was discontinued.

ADJUVANT LOCAL TREATMENT.

I might mention that appropriate local treatment should also be employed in conjunction with the vaccine, and I believe that the more thorough this treatment, the more permanent the results.

The case above described may serve to illustrate the value of vaccine therapy in the treatment of pyorrhea alveolaris. While my experience has been limited, I repeat my belief that this method of treatment gives promise of results that have not been obtained by any other means.

TECHNIQUE OF PREPARING AUTOGENOUS VACCINE.

In what follows I wish to demonstrate the initial steps in the making of an autogenous vaccine, and show the finished product, also the method of injection, demonstrating pure cultures of from twenty-four to forty-eight hours' growth made on agar, milk, and potato, and their cultural features; also pure cultures of different bacteria as found in pyorrhea cases on slides stained by the Gram method as seen under the microscope. I shall also show suspensions of definite quantities of bacteria killed by heat in a 0.9 per cent. normal salt solution, and demonstrate the method of determining the number of bacteria by the Thoma-Zeiss blood-counting chamber.

Three tubes of sterile agar are placed [demonstrating] in a water-bath, and the water is brought to the boiling-point; it is then reduced to about 38° or 42° C., a temperature which is just above the solidifying point of agar, and not injurious to bacteria.

It must be understood, of course, that it is impossible to carry out the technique, which is a very important factor in the making of an autogenous vaccine, in such a brief demonstration; to insure success this procedure must be carried out in the laboratory. An improper procedure means danger, or no results at all.

The platinum loop is one of the most important instruments used in bacteriological work. After freeing it from all septic matter by placing it over a Bunsen burner, the pus is pressed on this platinum loop with the aid of a piece of sterile cotton or gauze, by applying slight pressure on the gum, and tube No. 1 is inoculated with a loopful of the material to be plated.

The cotton plug is then replaced in the mouth of the tube, and the contents of the tube are mixed by carefully tilting it back and forth and rotating the tube on its long axis. From this tube, two loopfuls are transferred to tube No. 2, and, after mixing, two more loopfuls are carried from tube No. 2 to tube No. 3.

The contents of the several tubes are then poured into Petri dishes. As soon as the cotton plug is removed, the mouth of each tube should be passed through the flame and inserted under the edge of the lifted Petri dish cover, and the agar be quickly poured out. The covered dish may then be tipped cautiously back and forth in order to distribute the agar evenly before it solidifies. If there are a great many bacteria in the original material, the plate from tube No. 3 will probably contain the organisms in small enough numbers to develop well-isolated colonies; contrariwise, if there are very few bacteria in the material inoculated, plate No. 1 will probably present more satisfactory conditions. Gelatin plates are made in the same manner as agar plates, except that gelatin may be cooled as low as 25° C. without solidifying. These are placed in a thermostat for from 24 to 48 hours. If the platinum loop is not used, the pus is collected in the same fashion as described, but the tube is inoculated by the use of a sterile swab. I am in the habit of making two sets of plates; when both upper and lower jaws are affected, swabs are taken of each.

By using the Gram method of staining, one is able to ascertain whether the tubes we intend to use for the vaccine contain a pure culture. After selecting tubes, a small amount of sterile 0.9% sodium chlorid solution is poured into tube No. 1, and by gently tilting the tube from side to side, the bacteria are washed off. This normal salt solution is poured from tube No. 1 to tube No. 2, and from tube No. 2 to tube No. 3, etc. The solution is then poured into a sterile bottle, which is placed in an automatic mixer for one-half hour, in order to break up the clumps.

The next step consists in the killing of the bacteria, which is accomplished by immersing the bottle in a water-bath at 60° C. for one hour.

Two control specimens are then obtained by pouring a little of the sterile solution into test tubes containing agar. These are placed in a thermostat for 24 hours. If the appearance of these test tubes gives rise to doubts as to the sterility of their contents, stains are made to ascertain the possible presence of an active bacterial colony. If the solution proves to be sterile, the vaccine is distributed in sterile bottles, containing 50, 250, 500, and 1000 million to the cc. I generally start by the use of 50 million and increase the dose, injecting it in the upper arm. Iodin is applied to sterilize the point of injection, and thorough attention is paid to the sterility of the hypodermic syringe and accessories, such as pliers, cotton, etc.

The determination of the number of bacteria is made by the Thoma-Zeiss blood-counting chamber. This chamber is manufactured by Zeiss for counting blood plates by the Helber method, and should be supplied with an especially thin cover-glass (No. 146). The blood count is made by the use of a high-power dry objective. The chamber is ruled like the Thoma-Zeiss blood-counting chamber, the ruling having the same value, except that the chamber is 0.02 mm. deep instead of 0.1 mm.

For counting, the suspension of bacteria is diluted with distilled water. 1 : 200, with the aid of the red-blood corpuscle pipet of the Thoma-Zeiss apparatus.

By a simple calculation, it will be apparent that the product of the multiplication of the average number of bacteria per square by 4,000,000,000 will be the number of bacteria per cc. mixed with sterile 0.9 per cent. saline solution, to give a dilute suspension of the volume of 50 cc. containing the required number of bacteria per cc.

To recapitulate: A small flask containing 50 cc. of 0.9 per cent. saline solution, closed with a rubber nipple, and the whole sterilized, is prepared, the quantity of the suspension necessary to give the desired number of millions of bacteria per cubic centimeter in a volume of 50 cc. of saline solution having been determined by calculation. This quantity is withdrawn from the flask by means of the sterilized hypodermic syringe, the needle of the syringe being plunged through the rubber nipple while the flask is inverted. Then the calculated quantity of the suspension is drawn up into the syringe and injected into the saline solution by passing the needle through the rubber nipple as before.

Following this, 0.15 cc. of lysol is similarly injected into the flask through the rubber nipple, and after shaking, this diluted suspension constitutes the vaccine. Before injecting it should have been proved sterile.

A local reaction at the site of the injection is the rule. A typical reaction consists of an indurated, tender area at the site of the inoculation. This area varies in size, depending upon the amount of vaccine used, from that of a dime to that of a silver dollar, and presents the appearance characteristic of a burn.

THE NEW DENTAL ERA.

By S. BLAIR LUCKIE, D.D.S., Chester, Pa.

(Read before the Philadelphia Auxiliary Chapter of Delta Sigma Delta Fraternity, April 10, 1913.)

AS this old world moves on in the lathe of time, its social, economic, and political conditions change. We become more complex as we advance in years. Government of the body politic and of the individual must at times be subjected to a new order, and this often produces what appears to be a severe strain or a threatened disruption of the usual, well-established and "good-enough-for-our-fathers" way. At these periods of stress, men arise known as insurgents—the word is an antonym of stand-patters—who, like Lowell, recognize that—

New times demand new measures and new men.
The world advances, and in time outgrows
The laws that in our fathers' days were best.

NEW TIMES, NEW PROBLEMS.

Even the constitution of the United States is being attacked by a large and growing body of students of economic and industrial affairs, who declare that it is no longer sufficient as a guide to our national progress or a lamp to our social advancement. Alexander Hamilton had the foresight to recognize this, for in discussing its adoption he gave expression to these words: "So long as we are a young and virtuous people, this instrument will bind us together in mutual helpfulness, but when we become old and corrupt it will bind us no longer."

Today, more than ever, at least in the lives of us present, new duties and new measures are making demands on our attention. The last presidential campaign forcefully indicated that an unrest was abroad, and that the time had come to adopt new measures. We have municipal problems to solve. There is the child-labor question, shorter hours for women, equal franchise, sex hygiene, purity of the ballot, conservation of national resources, conservation of health, efficiency of the worker and the machinery with which he produces, the education of the young so that they may be prepared in the most efficient way to meet requirements in the various pursuits of life, and, not the least to many of us, the high cost of living—or perhaps better, the cost of high living.

These are but a few problems that confront us as citizens. In every activity of life, secular, religious, and professional, it is the same. Problems unheard-of or unthought-of a few years ago are pressing for solution. These problems are not only up for solution, but they must be solved in the best possible way for the best interest of all concerned. This means that we who are now on the scene must get busy and study conditions, get the milk of truth out of the cocoanut, and start with new methods.

THE NEW PROBLEMS OF DENTISTRY.

But what of our own beloved profession? Even a myopic eye can see that we are pressed for a change of measures that in our fathers' days were really best. All that dentistry is today—and it is a grand profession—is due to what was done by the fathers. Today we are recognized to such a degree that it is a question, unless we arouse ourselves to the exigencies of the situation, whether we can fulfil the demand. This recognition has been going on for years, slowly but surely. Dr. Oliver Wendell Holmes, with keen sense of observation, defined dentistry in these words:

> It has established and prolonged the reign of beauty; it has added to the charms of social intercourse, and lent perfection to the accent of eloquence; it has taken from old age its most unwelcome features, and lengthened out enjoyable human life far beyond the limit of the years when the toothless and purblind patriarch might well exclaim—"I have no pleasure in them."

Could a more truthful and highly deserved tribute be paid to any calling? Has any other such a record?

Brothers, you who are giving thought to the etiology of dental and oral diseases, you who are practicing filling and crown and bridge operations according to the theories of immunity and hygiene, you who are teaching and practicing prophylaxis, and you who are correcting facial and maxillary deformities, are contributing to this humane work.

Municipalities are establishing dental clinics for the treatment of the teeth of poor children, boards of education are allowing clinics to be conducted in the public schools, industrial concerns and life-insurance companies are recognizing the importance of having the mouths of their employees and policyholders attended to by trained experts, hospitals are adding dentists to their staffs, and physicians and surgeons are proclaiming that a clean and healthy mouth is necessary to assist in preserving health and curing disease. Aye, one who is an authority has spoken with a challenge in these words: "The next great step in medical progress in the line of preventive medicine should be made by the dentists. The question is, Will they do it?"

Are we going to accept this challenge? If we do—and I believe we will—it will be done in the spirit uttered by Cardinal Richelieu in his address to the young man—"In the lexicon of youth, there is no such word as 'fail.'"

I am no pessimist, but as a good optimist, who belongs to that large club of optimists without officers or dues, I must see things from the pessimist's angle.

NEW RESPONSIBILITIES FOR THE DENTAL PROFESSION.

Education, both preparatory and collegiate, must be given attention. This is being well and ably attended to, and in due course of time will be worked out in a manner that will produce trained dental practitioners who will meet future requirements. There is, however, a duty, a responsibility resting on each member of the profession, that cannot be shirked. We who are in the activities of practice must assume responsibilities, take up the duties, even making it our prerogative to see that the profession will take up the next great question in medical progress, viz, preventive medicine.

There is much to combat; the commercial spirit is abroad. A professional life has a commercial side; we cannot get away from this fact. We must live in a manner commensurate with our social environments, we must have the means with which to acquire knowledge and keep up with progress, be prepared with a foster-nurse when old limbs lie lame; health must be husbanded and physical efficiency be kept up to the top notch. These are the arbitrary demands that the individual must meet first—for self-protection and self-preservation. Then, if we accept the dictum of Bacon that every man is a debtor to his profession, the life of a dentist must be full to overflowing, and when Dr. Charles H. Mayo puts the question, "Will they do it?" no one better than the man who stands in one corner of a room by the side of patient after patient all day, taxing his ingenuity and vital force, sees and understands the enormity of the proposition.

But it is up to us, it has been put up to us, and we must not fail. How shall we keep from failing? I will not formulate a plan, but let us tonight consider this great question, and see if this representative body cannot contribute its share toward the solution.

DENTAL ETHICS, AND THE QUESTION OF PUBLICITY.

It might be suggested that the individual see that he be imbued with the ethical spirit. I use the word in the broadest sense—duty, responsibility to self, the profession, and the public. Dentists too long have been keeping their knowledge under a bushel—which sordid measure should be kicked aside, not to be used again for such a purpose.

There is a necessity for the public to know more about us, not as craftsmen, but as healers of disease, correctors of deformities, and hygienists.

Commercial men with printer's ink and glaring showcases have been and are doing more to impress the public about dentistry—fakes, to be sure—than the average ethical practitioner. Especially is this the case outside of the centers of population.

Facts concerning the causes and prevention of dental and other oral diseases, the relation of mouth conditions to other parts of the body, and their significance for the community, should become common knowledge. This requires reading, study, and investigating as a preparation; then going out and mingling in the various channels for the dissemination of knowledge that fortifies and helps humanity in the struggle against the enemies of health.

TOO LITTLE READING AND RESEARCH AMONG DENTISTS.

A better and more universal conception of what dentistry is must be established. A few years ago a gentleman who waited on me in a publishing house in this city made this remark—"Dentists are not readers; they are not book-buyers." The remark stung, for I feared it was true, and you know it is the truth that hurts. To show that I thought he was mistaken, I made a defensive remark. He immediately quoted figures to show the amount of money that had been expended on certain works in the way of advertising which did not repay him, and closed his argument by saying that his firm had concluded to be very careful in investing in advertisements designed to attract dentists.

Brothers, this should not be so. There is plenty of valuable material offered by those who do research work for us, worthy at least of reading, and there are many problems yet unsolved to which to turn our attention.

SOLIDARITY URGED.

There is not a phase of dentistry, from the education of the student to the smallest detail of practice, that does not merit the attention of the professional, ethical body, and it is as much the duty and responsibility of the units of our calling to be interested and alert as it is the duty of the college professor or the editor of a journal.

The profession is itself a large fraternity: the fraternity life and fraternity spirit should be cultivated, and the members of the dental profession be brought together into one solid, strong, and vital body.

AN INDEX OF THE WORLD'S DENTAL LITERATURE.

By THEO. VON BEUST, D.D.S., M.D., Dresden.

FARSEEING promoters of dental learning have long recognized the value of an index embracing all dental publications. Few dentists have the privilege of receiving more than four or five dental journals, excepting those connected with dental schools and large university libraries. As a matter of fact, there exist upward of one hundred and fifty dental journals, and besides these a great many articles related to our profession appear in medical journals.

Every dentist has a field of work which interests him specially, and eagerly seeks the writings of other investigators on his favorite topic. The orthodontist favors articles on orthodontia, often to the exclusion of all others; for the prophylactist the publications on prophylaxis are of prime interest. In view of the great number of periodicals, it is an absolute impossibility for the individual practitioner to glean from this mass of literature that which appeals to him, even if he should have access to all publications. The inevitable result is a loss to the student, to whom the greater part of the contributions touching upon his specialty are inaccessible. A loss is also suffered by the author, who has taken great pains to present his valuable ideas to anticipated readers, few of whom, really, will ever learn of the existence of his article. A third loss is suffered by the scientist, who finds, after devoting weeks or months to a certain subject, that he has been wasting his time and energy upon already explored territory. A further and by far the greatest loss is inflicted upon dental science, since progress is impeded by the inability of the world's dental investigators to remain in steady communication with one another.

The first attempts, to our knowledge, to establish an index were made by the American Academy of Dental Science between 1839 and 1849. Then followed the work of J. Oakley Coles of London, who published a list of works on dentistry in 1882. At about the same time, Taft and Crowley gave their lists of books and periodical literature to the profession.

At a meeting of the Institute of Dental Pedagogics, held in December 1908, it was decided to establish a classified card index of the leading dental journals, and a committee composed of prominent members of the American profession was appointed to take initial steps for the realization of this idea. This has since led to the organization of the Dental Index Bureau, which has been fully described in the DENTAL COSMOS and other journals. In Germany an attempt at bibliography was made by Professor Port of Heidelberg, whose tabulation was discontinued in 1902. During the Fifth International Congress, held in Berlin in 1909, much time was devoted to the discussion of the value of a permanent index, which could be issued regularly and if possible monthly. This led to the establishment of the index in the *Ergebnisse der Gesamten Zahnheilkunde.* This index was edited by the well-known author, Dr. Paul de Terra, Zollikon-Zürich. After a short period, however, it was transferred to the *Deutsche Zahnärztliche Zeitung,* where its continuation was prevented by a sudden change in the management. Now it has been given a place in the *Archiv fuer Zahnheilkunde,* Dresden, a monthly magazine published by the Society of American D.D.S.'s Practicing in Germany, which will endeavor to do all in its power to supply the material necessary for its maintenance, and to make the *Archiv* its permanent home. Dr. de Terra, who is endowed with exceptional capability and large experience, has access to over a hundred dental journals, and over two hundred medical periodicals.

The journals that are used in the compilation of this index represent all the civilized countries of the globe, to wit: Germany 16 periodicals; Austria 13 (7 German, 4 Hungarian, 1 Bohemian, 1 Polish); Switzerland 2 (1 German, 1 French); Belgium 3; Holland 1; France 11; England 8; Italy 3; Spain 1; Sweden 2; Norway 1; Denmark 1; Russia 4 (3 Russian, 1 Polish); North America 12 (in English); South America 11 (10 Spanish, 1 Portuguese); Australia 1.

In the subsequent issues of the *Archiv,* starting with the June 1913 issue, the headings of the various chapters will be translated into English and French, thus making the index useful for those unacquainted with the German language.

There is little doubt that the index, as at present instituted in the *Archiv,* with its 300 to 350 subject titles monthly, will meet all the requirements demanded for a serviceable index by the essayists of the Fifth International Dental Congress.

THE IMPORTANCE OF DENTAL EXAMINATION FOR LIFE INSURANCE.

By ALONZO MILTON NODINE, D.D.S., New York, N. Y.

"A MAN should not practice the art which he attempts to criticize." Matthew Arnold's third tenet, in his essay on "Criticism," gives me my license to criticize life insurance medical examination.

Medical examination for life insurance ignores or forgets that teeth and gums play both a direct and an indirect part in the causation of organic and systemic diseases.

Diseased teeth and gums are the most considerable, consistent, insistent menace to health to which a person is exposed; they are a serious source of insidious infection in the individual, and a dangerous depot for the dissemination of disease to others.

If the great function of medical examination for life insurance is to secure selected lives, and to furnish the company with an estimate of the applicant's physical condition, if it is to guard the company against insuring any applicant having any illness, disease, disorder, or condition that mortality tables or medical observation show tends to shorten life, then the condition of the teeth and gums must certainly be included in that estimate.

The examination of teeth and gums should be made to enforce and re-enforce the medical examination, otherwise the medical examinations are far from reasonably complete and trustworthy.

Judging from a great number of experiments and observations made in England, France, Germany, and the United States, bearing upon the improvement in health and cure of disease that follow dental attention and personal hygiene of the mouth, surely the medical examiners are neglecting to consider a very prolific source of infection in diseased teeth and their faulty artificial substitutes! Over one hundred life insurance companies have shown some interest in the proposal which the essayist has made for dental examination for life insurance.

Dr. Ramsey's latest book on "Medical Examination" points out that it is the undeveloped and immature symptoms that are of greatest importance, and the examiner must use his ability and medical knowledge to recognize them. Such immature and obscure conditions it will be a part of the dentist's work to look for, and of dental service to guard against.

It is well to note that insurance companies like the Metropolitan, the Postal, and the Equitable are including, in their educational campaigns of personal hygiene, the presentation of the subject of mouth hygiene and dental attention. These conservation departments start with a very sound economic end in view, based upon the experience of a number of years, which shows that the spread of the knowledge of personal hygiene and sanitary measures has extended the average duration of human life several years.

The proposal, the institution, and the development of dental examination is the reasonable and logical sequence and extension of the medical examination. Dental defects and disease conditions of the oral cavity are so frequently the cause of many serious systemic and organic disturbances, that only a dental expert is able to discover the original source of such trouble, particularly infectious diseases, arthritis deformans, rheumatic fever, septic infection of the alimentary canal, liver, kidneys, heart, and nervous system.

It has been estimated by Mr. Hyram J. Messenger, actuary of the Travelers' Insurance of Hartford, Conn., that if the companies were to expend the sum of two hundred thousand dollars a year for the purpose of spreading information in regard to personal hygiene and in co-operating with other agencies in health movements, also extending to policy-holders the privilege of frequent medical examination, and if the result should show a decrease in the losses of the companies amounting to the insignificant sum of 16/100 of one per cent., they would save enough to cover the cost! If this plan were carried out under good business methods, with all the companies working together, he would expect a decrease of one per cent. of the death claims. This decrease of one per cent. of the death claims would result in the saving to the companies of $1,005,000, or seven times the amount expended. It is also the expressed opinion of an insurance man and newspaper editor that the institution of dental examination would decrease the losses more than two per cent.

From the dental standpoint it is recognized that diseased, decayed, deformed, and deficient teeth and their faulty artificial substitutes are important contributors to any number of diseases that might be named. A septic, disorganized masticatory apparatus is a depot for harboring, propagating, and disseminating micro-organisms, and the manufacture of toxins, ptomains, and other poisons; it provides for their absorption into the blood and the lymph and their distribution to the structures of the mouth, accessory cavities, and the gastro-intestinal and respiratory tracts.

Defective dental conditions are known to produce profound effects on the nervous system, respiratory apparatus, and digestive apparatus; they also contribute to the etiology of cancer and sarcoma in the mouth, stomach, and small intestine. Further, defective dental conditions make possible the putrefaction of undigested food in the intestine, which produces all grades of symptoms from simple headache to epilepsy and endocarditis.

Dr. Key's very striking experience in the St. Vincent Orphan Asylum of Boston is worthy of our serious attention. Six months after the beginning of the dental treatment in this institution of 325 inmates, there was a decrease in the number of infectious diseases of fifty-nine per cent. over that of the previous year. In the second year of its establishment the number of infectious diseases was reduced to less than two per cent., and at this date there has not been an infectious disease in twenty months—a record not yet equaled.

The medical profession, except in isolated examples, have a defective and deficient appreciation of the true value of a clean and correct masticatory apparatus. For this reason, perhaps, life insurance companies have not had their attention directed to the oral cavity. It seems just and reasonable that a policy-holder having sound, clean, normal dental organs is a better risk than one having disorganized and diseased ones, and should pay a smaller premium, or else the client with a poor masticating apparatus should pay a larger one.

The problem of conserving health and prolonging life is one that cannot be solved solely by the efforts of the individual, so far as his own particular mode of life is concerned. It requires the concerted action of entire communities toward the improvement in those manifold activities embraced by the term "public health." In order to make this campaign an effective one, the insurance companies must enlarge their scope by directing their efforts not merely toward the individual, but toward the community.

The institution of the dental examination for life insurance will do more than any other single measure to raise high the standard of dentistry in technical achievement and the just appreciation of its great field by the profession, individually and collectively, as it will equally and as surely raise high the appreciation of dentistry by the public.

No other one influence will act in any degree so forcefully in discouraging and checking that type of dentistry—American or Abyssinian—that Hunter and others flay so mercilessly and so justly. No other positive influence will stimulate and increase that type of dentistry which is scientifically sound and mechanically correct as the fact that the operations and restorations will come under the inspection and scrutiny of a disinterested and capable judge.

Every dentist who believes in the benefits of the service he renders, and every dentist who believes in the good of mouth hygiene, every dentist who would like to see his services appreciated justly, will recognize that the institution of a dental examination will bring this about, and that he may add his influence to have the companies consider it. No other one force will do so much to safeguard the health of the nation as will the institution of this dental examination. The life insurance companies are in a position to render a great public service, and at the same time to make an investment that will return a substantial profit.

Focus your attention for a moment upon dental examination! Consider what it would mean should even but one company require that all applicants for life insurance have sound and sufficient teeth or correct artificial substitutes before they will be accepted for life insurance.

The army, navy, national guard, police and fire departments require sound and sufficient teeth—consider the educational value of such a requirement for life insurance! What more forceful argument could be evolved than that a great business—whose very foundations rest upon health—require sound teeth or proper artificial substitutes in order to render that health more secure and the menace of disease less fatal?

It is the opinion of men like Dr. Dwight of Boston, Dr. Egbert of Philadelphia, Professor Fisher, Dr. Wells, and others, that tangible and practical results already in evidence warrant the prediction that the conservation and public health departments of life insurance companies are a permanent and growing field of usefulness, and that the privilege of periodical examinations is being increasingly taken advantage of and valued by their policy-holders. There will be a growing tendency to employ physicians as inspectors and regulators of human machinery rather than as necromancers who are expected to work the cure of progressive and established disease. The same may be said of dentists.

The appointment of dental inspectors, to examine the masticating apparatus upon the soundness of which depends the proper working of the rest of the human system, will constitute practical co-operation in a field where it is needed most.

The medical examiners are neither trained for such examinations nor do they desire to undertake them. It remains for dentists to call consistently the attention of the insurance companies to the great good to the policy-holders, the profit to the companies, and the public-health benefit to the community that dental examination for life insurance would bring.

Further information on this subject of the influence of dental conditions on systemic and organic disturbances may be gained by reading some of the many books and articles which the writer has perused in view of his endeavor to convince the medical profession as to the contribution that diseased and disorganized mouths make to the sum of the causes of constitutional disease. Particularly, Collier's latest book on "Dental Disease and Systemic Disease," and papers published in the DENTAL COSMOS, November 1912,* the *Items of Interest* for September 1912, the *Oral Hygiene* magazine for May, June, July, August, and September 1912, contain interesting contributions to the study of the constitutional effects of oral sepsis.

Rose and Careless, in "Manual of Surgery," one of the latest books published, devote many pages to the subject of oral sepsis, as do Wylie, in *British Dental Journal* for 1912, page 246, and Niles, *American Journal of the Medical Sciences* for February 1912.

All these articles show convincingly that the mouth is one of the most important parts of the human organism, and that dental examination for life insurance is a subject which must necessarily engage the attention of the most skilful and the best-informed men of our profession, also that every policy-holder is concerned very intimately with this phase of preventive medicine. The protection of the company in which the policy-holder is insured against insuring people with these conditions is his protection.

The great social unrest is effecting changes in the adjustment of the social and economic relations of every man toward his neighbor, of every neighbor toward the community, and of every community toward the central government. The economic and social adjustments started by Bismarck in Germany operate in Switzerland, Belgium, Denmark, and Sweden. This wave has been augmented by Mr. Lloyd George and Earl Grey in England, and it has now reached the United States, Australia, and New Zealand. However it may clash with personal ideas, we shall soon have industrial workmen's insurance, old age insurance, and accident insurance for the working-men in the United States, and dentists will be called upon to enter the great calling of public health in connection with these enterprises.

Dr. Murphy of Chicago, the great surgeon, who has just returned from Germany, tells us that there are few charity patients in the German hospitals. They are all pay-patients, and paid out of the workmen's insurance, to which they have contributed. This is a far better condition than exists in this country, which we consider the most progressive in the world. Further, the great prosperity of Germany during the last thirty years has been ascribed in part to these insurance provisions and factory regulations.

As dental practitioners we have a part to play, because of our special knowledge, experience, observation, and skill, in adding to physical and mental efficiency and to human happiness.

Proceedings of Societies.

SEVENTH AND EIGHTH DISTRICT DENTAL SOCIETIES OF THE STATE OF NEW YORK.

Forty-fourth Annual Union Convention.

(Continued from page 729.)

SATURDAY—*Afternoon Session.*

The meeting was called to order Saturday afternoon at 2 o'clock by Dr. R. H. Hofheinz, Rochester, who presided at this meeting.

Dr. Hofheinz announced as the first item on the program for the session a paper by Mr. A. HOPEWELL-SMITH, London, England, entitled "Some Studies of the Jaws in Health and Disease."

[This paper is printed in full at page 765 of the present issue of the COSMOS.]

Discussion.

Dr. EDWARD C. KIRK, Philadelphia. Mr. Chairman, it must be evident that it is quite impossible to discuss this address; it is not a discussable thing. When one brings before us a presentation of data of this sort, it seems to me that there is nothing to discuss. This has been a very beautiful exhibit of "things as they are," but of course the question of our deductions from these phenomena is of importance, and quite another matter. Therefore, while I cannot discuss this exhibit, I may make some running remarks upon it. In the first place, I am filled once more with the desire to go immediately to England. I want to go there because I have been hunting for specimens of this sort, and I gather from the rich collection of teeth *in situ* in connection with their surrounding tissues, and from the very particular specimen in which we have one-half of the maxilla removed by a surgeon for cystic adenoma of the antrum—"which should not have been removed"—that they have no difficulty over there in cutting the jaws out of living Englishmen for scientific purposes. We are not permitted to remove jaws in that way over here—when we do, we remove the surgeon. Seriously, I do not know of a place where such a wealth of material for investigation can be obtained, and I want to get close to that source of material for scientific study.

I am interested mainly in what seems to me to be the essential feature of the paper, the one that impressed me most strongly, and, I believe, the one which the essayist emphasizes more than anything else, and that is the question of absorption of the margins of the bony alveolus. I wish he had been a little more specific, and I hope he will be when he comes to the discussion on the subject—more specific as to his use of the terms physiological and pathological as he applied them in respect to the process of absorption that we see there. When he talks about absorption of the edges of the alveolar borders in youths, children, and adults of early or middle life, he speaks of it as physiological, and I am rather inclined to raise an interrogation point after it. I am not sure that it is physiological. Then he has spoken of the absorption process, which he says is an indication of senility. We recognize that senility is not by any means a question of years, but when senility appears early in life, can we regard that as physiological? Is it not pathological then, as it is later? I would therefore like to have a little more precise definition from the essayist, and know his point of view with reference to the use of these terms with respect to these processes or manifestations of processes which he has shown us as occurring at different periods in life.

Then, again, with reference to the absorption of the alveolar border and the emphasis that he lays upon the significance of the linea dura in his radiographs as indicative of the process, I would like to have him interpret or explain a little more fully his thought with reference to where that linea dura terminates at the alveolar border in so far as it is demonstrated by the radiographs. As I read the radiographs, the linea dura is transparent. These pictures which the essayist has shown are photographs, I believe, of a radiographic film, therefore the linea dura is shown in the photographs as being transparent, and the gingival space is also represented as being transparent in these pictures, and there is no line of demarcation limiting the extreme end of the linea dura, defining it from the appearance of the gingival space. Is it not possible that that tissue which has recurved over the edge of the bone exists as tissue there which is not represented in the photograph of the radiograph?—there is no line of demarcation visible between them, while there is between the teeth and alveolus.

Of the specimens that were supposed to show decalcification of the bone—atrophy of the bone, as I remember it—each was a photomicrograph of a specimen that had decalcified afterward. Without wishing to question the accuracy of the result, I should like to have the essayist explain whether certain appearances of the bone texture were not possibly artifact, due to the decalification of the specimen itself.

The other point that impressed me strongly is what may be called the practical application of this matter to operative dentistry. It is true that the anatomical neck of the tooth and its relationship to the peridental ligament is a movable thing, not unlike the feast of Easter, and there are changes going on in the tissues which retain the teeth *in situ,* and there is a tendency to constant shrinkage, we may say, of the tissues at the cervical border, and in view of the fact that the gingival margin is a movable quantity, I should be glad to have someone who is an exponent of extension for prevention decide what technique is best to be followed in fixing the location of cervical margins of cavities with reference to the movable gingival attachment.

Dr. H. E. Friesell, Pittsburgh. Later on in the discussion I shall, if necessary, try to explain to some of the audience how the location of the gingival margin, the gingival outline of the cavity, can be decided upon according to the teachings of extension for prevention. I doubt very much whether I shall now or hereafter be able to convince Dr. Kirk in this matter, for the reason given by the greatest of teachers nineteen hundred years ago, namely, that there is "none so blind as he who will not see." If somebody, therefore, can devise a method for enabling Dr. Kirk to desire to see, then perhaps the rest of us may be able to convince him.

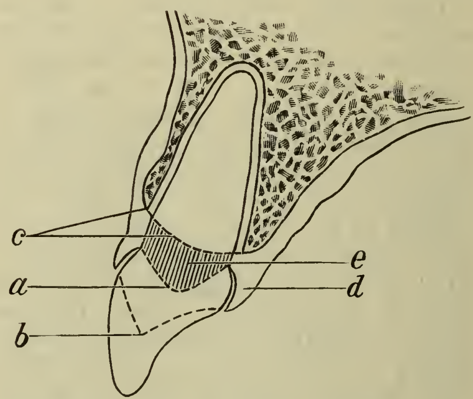
I am very much pleased to attend this meeting and to make the personal acquaintance of Mr. Hopewell-Smith, because I have studied his writings ever since they have severally appeared. He has given us in his first edition a textbook which, in the field of dentistry, has greatly simplified the technique for histology and pathology. A little later, in 1903, when he issued his larger volume of histology and patho-histology of the teeth, he gave us something that will stand as a classic in our literature. Many of the slides shown could not have been better, and I know that we are all glad to have seen them.

Mr. Hopewell-Smith has said that the establishing of facts in anatomy, physiology, or pathology is an important step in scientific study, and also that the inferences drawn therefrom may be entirely different from the facts themselves; that correct interpretation of these established facts is something entirely different from the establishing of the facts. As far as the establishing of facts is concerned, of course we all must agree with the essayist, but so far as the interpretation of quite a number of these facts is concerned, I take a different view from that of the essayist and Dr. Kirk. In the first place, perhaps some of the differences of opinion may be due to inability to transmit to each other the inferences drawn from the study of the facts. We need in dentistry something that I fear Dr. Kirk will also disagree with, because he despises the term I am going to apply to it. We need a standardized nomenclature. Both the preceding speakers used a number of terms which I feel conveyed obscure ideas to this audience. I believe that a standardization of our nomenclature is as necessary as the establishing of facts and their correct interpretation—for of what benefit is it to establish a fact, and to interpret it correctly, if one is unable to communicate his interpretation intelligibly?

I am glad that Mr. Hopewell-Smith has applied the term linea dura to the condition which he has pointed out. He has shown an important condition, an important fact, in the radiographs of the tooth tissues and the bones of the jaw. The linea dura, I take it to mean, is a line indicating a harder, denser portion of the bone. We know that the bone of the alveolar process is composed of cancellous and cortical bone; that the outer portion of the bone is denser and harder, does not contain as many spaces, and is therefore known as the cortical bone; that the inner portions contain many air-cells and spaces, are much less dense, and are called the cancellous portion. We know also that the reason why we can make radiographs is that the light is transmitted differently through these bony tissues, and this linea dura interferes with the passage of the X ray through the cortical portion of the bone. The socket in the alveolar process in which we find the root of the tooth is a natural cavity, lined with bone that is cortical in character as compared with the cancellous portion of the bone, and it is this condition that gives the effect on the radiograph which the essayist terms the linea dura.

The term "neck of the tooth" was used, also the term gingival margin. What is the neck of the tooth? I know of at least four interpretations—or misinterpretations—of the term "neck of the tooth," and about four for "gingival margin."

Fig. 1.



a, Gingival line, occlusal extremity of cementum; apical extremity of enamel. *b*, Gum line, occlusal extremity of gingiva; *c*, Crest of the alveolar process, or socket. *d*, Gingiva, or free margin of the gum; *e*, Neck of the tooth (shaded portion of root).

If we are to understand definitely what a speaker means, we must understand the language he speaks, and in technical, scientific language a term should mean one thing only. There should be no question of its meaning any one of three or four things.

If we examine a cross-section of the jaw-bone, we find a condition as illustrated in Fig. 1. We have here the root of the tooth covered by cementum to the point *a*. The enamel also extends to this line, forming the cemento-enamel junction. The gingiva or free margin of the gum is also attached at this point, and for that reason the term "gingival line" is given to the cemento-enamel junction by the man whom we must recognize as our authority in dental anatomy, Dr. Black.

The term gingival line refers to the junction of the enamel and cementum. The term gum line refers to the occlusal extremity of the free margin of the gum as seen at *b*. We may examine any number of skulls, and will find in every one that the alveolar process does not envelope the root of the tooth occlusally as far as the gingival line, but that in the average jaw three millimeters approximately of the root extends above the crest of the socket. The portion of root that lies between the gingival line and the crest of the socket, and which is not enveloped by the alveolar process, should, in my estimation, be called the neck of the tooth. (See *e*.)

While I shall not discuss the four or five definitions of the neck of the tooth as applied to different portions of that organ, I think the part that lies between the crest of the socket and the gingival line should be called the neck of the tooth. Why? Simply because it is necessary to designate this particular portion by name—just as necessary, when we understand all of its relationships, as it is to call the portion that is covered by enamel the "crown," and to know that by crown we refer to the portion covered by the enamel and not solely "the portion of the tooth that protrudes above the gum and that we see when the patient's mouth is open," as the term is defined in some of our text-books. It is just as necessary for scientific exactness to name this portion of the tooth the neck, or "cervix," if we want to call it that, as it is to name the line Dr. Hopewell-Smith has referred to as the "linea dura," in order that we may know definitely what portion of the tooth is referred to when we use the term.

What condition do we find in the neck of the tooth to distinguish it from the remainder of the root? It is covered by peridental membrane, just as is the rest of the root. But, whereas the principal fibers of the peridental membrane covering the alveolar and apical portions of the root have their origin in the cementum and their insertion in the cortical portion of the socket, the principal fibers of the membrane covering the neck of the tooth have four different points of insertion, namely, (1) in the wall of the socket, (2) in the periosteum on the outer side of the alveolar process, (3) in the cementum of the approximating tooth, and (4) in the free margin of the gum or gingiva.

These fibers of the peridental membrane, which extend into the free gum margin, hold the free gum against the crown of the tooth very firmly, and as long as the gingiva is being held firmly to the crown of the tooth, which it will be as long as this tissue is normal, there will not be any pyorrhea nor any absorption of the alveolar process. When anything interferes with the attachment of the principal fibers of the peridental membrane and that attachment is broken, the first condition results in a relaxation of the free margin of the gum, and then, instead of hugging the crown of the tooth firmly, excluding food matter and preventing the ingress of infection from the mouth, the gingiva is relaxed. This relaxation of the gum is the first step in the formation of a pocket. Many of the cases which the essayist showed as gingivitis are typical cases of pyorrhea; they had this relaxation, pocket formation, and consequently infection, which of course could be demonstrated by bacteriological tests as well as by clinical observation.

The mouth is lined with mucous membrane, which protects the deeper tissues from infection, just as the skin protects the subcutaneous structures. We can operate in the mouth, and, if the surface of the mucous membrane is not broken, we shall not have any infection; but if we expose the deeper tissue, we are likely to have infection. The same condition exists in the peridental membrane, which is covered and protected at its gingival border by the free margin of the gum, and as soon as it is exposed, an infection sets in which it is practically impossible to cure. Why? Simply because the peridental membrane is a deeper tissue which has not acquired the same power of resistance, and a wound in that tissue lies in a field that cannot be kept sterile, and is always liable to infection, because there is no dirtier cavity than the mouth, and micro-organisms are always there. When this fold of the gum becomes lifted, and the gingival trough which the essayist referred to forms, a pocket results for infectious material, which is held in contact with the gingival margin of the peridental membrane, and pyorrhea ensues.

What, then, is pyorrhea? Probably each of us has his own opinion. I believe that it is nothing more nor less than infection of the peridental membrane. A tissue that nature did not intend to be subjected to infection is exposed through some condition, frequently caused by the dentist by improper operative procedures, by lack of knowledge of anatomy, or by lack of scientific knowledge of the pathology of caries of enamel, the foundation stone of which is extension for prevention.

What the essayist has spoken of as physiological absorption of the alveolar process does not exist, in my opinion, for the reason which I have tried to show here, viz, that we never find, in any human skull, the alveolar process grown up to the gingival line.

In the skull of an animal like the hyena, a strictly carnivorous animal, that not only eats meat but crushes bones, what do we find? The facts shown by the essayist are that the cancellous portion of the bone in jaws of that kind is much narrower than the cortical layer as compared with the condition present in animals like man, and the bone is much denser, for the reason that the hyena, or any animal of that type, exerts a good deal more force in mastication. Imagine one of us biting through the femur of some animal as the hyena does—what would happen to our jaws, to say nothing of our teeth? The hyena's jaws are built by nature to enable that animal to live on food that it can seize. Another evidence thereof lies in the condition that the essayist showed in his illustration of the hyena's skull, viz, the cingulum on these teeth forms a very prominent ridge. If man had to live for a few ages on the same kind of food as the hyena does, the chances are that the cingulum in his teeth would assume the same form and location as found in the teeth of the carnivora. Horizontally engirdling the crowns of human teeth we have a pronounced ridge, which protects the gingivæ from injury during mastication. This is analogous to the cingulum on the hyena's teeth, and I have frequently called attention to it under the name of "height of contour." The crest of this height of contour on the approximal surfaces is the contact point.

The essayist illustrated the denture of the Eskimo, and we know that the Eskimo has probably the best set of teeth of any modern race of men, because his life or station requires vigorous use of the teeth, jaw-bones, and muscles of mastication. The jaw-bones of the Eskimo skulls preserved in the museum at Washington are very different from the jaws of the more civilized races. The essayist says we often find the crest of the alveolar process absorbed between the teeth. I do not believe that it ever extended any farther occlusally than we find it in the Eskimo, and I think that is where nature intended it to reach.

In regard to the casts and models shown by the essayist today, I believe personally that the condition exhibited is a marked example of hereditary malnutrition; "hereditary atrophy," Dr. Black would call it, and Mr. Hopewell-Smith would perhaps call it "hereditary hypoplasia." We see these conditions in teeth with defects in the formation of the enamel, viz, grooves, pits, etc., and in some cases entire absence of the enamel from the occlusal half of the crown of the tooth. We recognize that condition as atrophy, or, as our friends across the water would call it, hypoplasia of the enamel. I think the phenomenon exhibited by the essayist is simply an exaggerated case, hereditary in character. I have seen one case exactly like it, and three or four not quite so bad. In the most marked case, the patient, male, age twenty-six, presented with all of his teeth worn even with the gum line. There was no infolding of the lips or marked prominence of chin or nose, as is the case when the teeth are extracted, and the patient reported that his teeth had always been even with the gums. His sisters, brothers, mother, and mother's aunt have the same condition; his father had fine teeth. When this patient's teeth were extracted, some of the roots were only one-eighth of an inch, and none over a quarter of an inch in length; the root-canals seemed to have been obliterated by secondary dentin.

Dr. L. G. LeRoy, New York, N. Y. It is with a great deal of pleasure and profit that I have listened to the excellent paper of the essayist, whose writings we have known for a long while. Those who have been observers have seen conditions which they have interpreted in their own way, and with the assistance of others who have been investigators in this field. Mr. Hopewell-Smith spoke of the orang-utan and the disappearance of the alveolar process, and interseptal bone, and showed slides of cases among the carnivora where apparently the alveolar bone, too, had disappeared to some extent, but not in the same degree as it does in man. He also showed the marked changes that may take place in the mouth of man. Much depends in the latter upon his habits and environment, and the peculiar pathological changes that he is subjected to through them. It is conceded that there is no other portion in the human body where bacterial invasion is so pronounced as the oral cavity, which is the port of entry, so to speak. Because of this peculiar condition, it is extremely difficult in case of lowered resistance to establish a quarantine against pernicious bacteria, and to prevent the establishment of so-called pyorrhea, or even the lesser manifestations of oral disease. I concede, with Mr. Hopewell-Smith, that all these conditions are pyogenic in character, consequently the generic term should not be "pyorrhea alveolaris." In a recent article I endeavored to get away from that term by adopting the nomenclature which has been spoken of today, namely, "atrophic alveolitis." In whatever way these conditions are studied, we find that atrophy does take place in individuals where there is no pus. In other words, there can be atrophy of the alveolar tissue without infection of this tissue or of the peridental ligament. In these cases we have true atrophy, but in most cases there is bacterial invasion. In either instance, impairment of function is present, which makes for the resorption of the poorly nourished end-organ, permitting a condition which brings about loss of tissue and consequently of function. Mr. Hopewell-Smith practically corroborates this by referring to the preponderance of bacteria in the mouths of children. Most gingival and alveolar diseases have their inception in childhood. We can prove clinically that pyogenic organisms are the cause of the degenerative processes that take place about the soft tissues, and in due order and time degeneracy of the hard tissues must come about by lowered resistance and impaired function. I think Dr. Waugh is correct when he says that just in proportion as local conditions are the cause, so will local treatment of pyorrhea succeed in curing the disease. He is simply affirming the irrefutable law of cause and effect. I have never felt, at least in recent years, that local conditions alone cause pyorrhea alveolaris, and I will go a step farther, and say that precipitation of lime salts about the necks of the teeth is not due to local conditions. Some preceding constitutional disorder must have brought about that pathological peculiarity, and unless there is lowered resistance constitutionally, there cannot and will not be any local symptoms. Local symptoms cannot obtain in the mouth of an individual with normal saliva, for the reason that the normal saliva has an immunizing value and exerts its germicidal property, preventing the proliferation of bacteria about the dental ligament. There will be no precipitation of the mucin to act as a medium for the incubation of bacteria. The point I wish to make is that these local evidences of atrophy or disease are primarily constitutional, and what has been responsible for the *cause* of these conditions must be sought for elsewhere than in the oral cavity, if we are to establish and maintain *cures.*

Mr. Hopewell-Smith (closing the discussion). I find it extremely difficult to reply. I have never listened to a more illuminating and really interesting discussion than that which we have just had. I have learned a great deal from it, because my work, as I said in my introductory remarks, is in a transitional stage. I am groping for the light. I am very pleased to note that what I have said has been the cause of such an interesting discussion.

One or two questions have been asked particularly which I will try to answer. There seems to be a little difficulty in the understanding of the term *linea dura.* The cortical portion of the alveolar process, such as pointed out by Dr. Friesell, is composed of a thin plate of compact tissue, and the hard dense sheath of compact bone on the outer edge of each socket is the *lamina dura,* which is probably physiological. In a radiograph, it is the *linea dura.*

In regard to the "glands" of Serres, I believe that they are an embryological product found under the gum margins in fetal states, but certain epithelial cells in the periodontal membrane are often erroneously called the glands of Serres. The glands of Serres are merely epithelial cells in the gum margin in an early stage of development, but the bodies in the periodontal membrane are the epithelial remains of the epithelial sheath of Hertwig, which probably has something to do with the formation of the root of the tooth. If portions of this sheath persist, they remain as small masses of epithelial tissue.

I perhaps do not agree fully with Dr. Kirk when he thinks that the periodontal membrane itself is infected before these cells are infected; that would, of course, produce periosteitis; but they are not always found in connection with "pyorrhea alveolaris." Before I can reply to Dr. Kirk, I will have to think it over very carefully.

Dr. Kirk. This is not a theory of Kirk's, the question of the infection of these epithelial rests that I am calling attention to, but the result of a definite statement of Black's observation that these bodies were the seat of phagedenic periosteitis and filled with micro-organisms. This seems to me a significant observation, which I mentioned for the sake of further study. It is an open question in my mind.

Mr. Hopewell-Smith. I myself consider it an open question, because I have scores of times looked for these bodies in human teeth, and have seldom found them. Dr. Black described them in the teeth of sheep. I admit that they are fairly largely developed in these animals, but in man they seldom occur. In the average section they are small and insignificant, and the little masses one finds occasionally are, of course, the same thing as Dr. Black described, but I do not think they have so much importance as Dr. Black ascribes to them. Of course, I am not absolutely positive on this matter; we need more light on that point.

Dr. Waugh. Is it your opinion that it is epithelial tissue?

Mr. Hopewell-Smith. Yes. I think they are epithelial remains of the unatrophied portion of the sheath of Hertwig, when traced down in vertical sections of the jaw as it passes down and turns up again, and these are the unabsorbed portions of the epithelium. That is the only way they can get into that tissue.

Dr. Waugh. Do you not think they are endothelial?

Mr. Hopewell-Smith. They might be, but I think they are epithelial. As to whether they are glands or not, I do not know. Most glands require ducts, and I have seen no ducts in these bodies. I have not paid any special attention to them, having thought of them as parts of the periodontal membrane, but I should like to know more about these bodies themselves.

The physiological absorption that I have talked about, I believe to be atrophy of the bone due to local senile conditions. Some may say that, if this condition is senile, it would not be found in a child of ten years of age. I have studied plenty of cases of children where there were senile conditions in the deciduous teeth. Many people have senile conditions of the hair and other parts without being themselves old.

I agree with Dr. Friesell largely in

what he said as to the need of more definite nomenclature on this subject. I myself would like to see a clearing up of the nomenclature. About sixteen terms for pyorrhea exist, which is very confusing, but I think we must retain the term pyorrhea alveolaris, because it is known all over the world, and this term, to my mind, means nothing more nor less than the flowing of pus from the alveolar process. If we could agree upon an exact terminology for the gingival anatomy, and would clearly define the neck of the tooth and the surrounding hard and soft tissues, we should have our way clear to perform a great deal more work, and I hope that somebody on this side will elaborate this subject and elucidate these debatable points for us.

Dr. Belcher referred to the case in which the patient was forty-two and had lost all the teeth. I would not call that a case of pyorrhea, because no pus was ever present around the necks of the teeth, to my knowledge. I have another patient who has the same condition—a disease which is called by some "phagedenic pericementitis," that is to say, deep pockets, loosening of the teeth with the formation of pockets. That is what I believe Dr. Black thinks is phagedenic pericementitis.

A MEMBER. Were there any observations of calculus?

Mr. HOPEWELL-SMITH. No. Simply degeneration of the periodontal membrane, from I do not know what, but I think from constitutional causes; in one case I am not sure but that mercury was the cause. That is another factor which I think should be taken into consideration with regard to bone absorption—the use of drugs.

Dr. KIRK. When you do have what we agree is a senile condition affecting the natural conditions early in life, do you regard that as pathological or physiological? Of course a senile condition in old age is physiological, but when it occurs early in life, do you then regard it as physiological?

Mr. HOPEWELL-SMITH. That is just the point. I think you are right, but I am not sure.

Dr. KIRK. That is a lovely straddling of the question! I do not know this myself, but I am glad to know that I am right!

Motion was made and carried to adjourn until the next annual session.

CONNECTICUT STATE DENTAL ASSOCIATION.

Forty-ninth Annual Convention, held at Waterbury, Conn., April 15 and 16, 1913.

TUESDAY—*Morning Session.*

THE forty-ninth annual meeting of the Connecticut State Dental Association was called to order at 11 o'clock, Tuesday morning, April 15, 1913, by the president, Dr. E. J. Abbott, Waterbury, in Buckingham Hall, Waterbury, Conn.

The first order of business was the reading of the minutes of the last meeting, which was, on motion, dispensed with, because of the fact that they had been published in book form, and sent to each member of the association.

TUESDAY—*Afternoon Session.*

The meeting was called to order on Tuesday afternoon, April 15th, at 2.30 o'clock, by the president, Dr. Abbott.

The first item on the program for the afternoon was an address of welcome to the society by the mayor of Waterbury, Hon. FRANCIS D. REEVES.

The next item for the afternoon session was an "operative clinic" by Dr. E. J. GREENFIELD, Wichita, Kans., on "Implantation of Artificial Roots."

The next order of business was the reading of a paper by Dr. J. M. GOMPERTZ, New Haven, Conn., entitled "Bacteriology and Vaccine Therapy of Pyorrhea Alveolaris."

[This paper is printed in full at page 811 of the present issue of the COSMOS.]

Discussion.

Dr. C. J. BARTLETT, New Haven, Conn. I have been interested for some years in vaccine therapy, and have practiced it in a variety of conditions. I wish to congratulate Dr. Gompertz on the very great success he has obtained in his work in treating pyorrhea. I must disclaim, however, any special knowledge of the local conditions present in this disease. As a medical man, I have not had occasion to study these at first hand. To me, as a pathologist, this disease appears to be a localized condition in which pus is being formed for a more or less prolonged period. To the pathologist such a condition always signifies two facts: First, that bacteria are present, and secondly, that resistance to the action of these bacteria is lowered; and these two factors immediately suggest the question, Can we increase the resistance to these bacteria, and so destroy them? That bacteria are always present in conditions in which pus is formed is now well recognized. It is possible to produce pus experimentally without bacteria, but in more than ninety-nine cases out of a hundred of pus produced in animals or in human beings, it is due to bacteria. That the growth of bacteria in living tissue is due to lowered resistance is evident in a great majority of cases. The time of year when we see boils, for example, is in the spring, when persons are "run down," as we call it, viz, when the resistance is lowered. A hundred people may be exposed to typhoid bacilli and some of them will contract the disease, while others will not. In other words, the resistance of the former is lessened, and for that reason bacteria can become virulent. As a general rule, when bacteria grow, systemic resistance is lessened. Is it possible to increase this resistance so that the bacteria will be destroyed? Generally it is impossible to administer any drug that will kill bacteria in the tissues. When the physician gives medicine in typhoid or pneumonia, he does not hasten the recovery of the patient at all; he cannot in any disease administer any drugs that will kill bacteria, with one or two exceptions—a notable example of this being salvarsan in syphilis. The result is that, until a specific chemical is found capable of killing disease agents, we have to try some other means of increasing the resistance of the tissues themselves, so that they can destroy the germs. This is done in typhoid fever and in pneumonia; the body itself is stimulated by the toxins produced by the typhoid bacillus in the tissues, and the same is true in pneumonia, or in abscess formation. The reason why an abscess does not spread is that there is a locally increased resistance in the tissues inhibiting the process.

When we apply these findings to pyorrhea alveolaris, we recognize beyond question that bacteria are present—in fact, almost always, one or two varieties of bacteria. The streptococcus viridis is the most common. Less frequently, the hemolyzing streptococcus is present. I am not sure whether we may be able to show eventually that one single microorganism is the cause of this disease, but certainly there are only a small number of bacteria to be looked upon as producing it.

Dr. Gompertz has justly emphasized the value of making plates from pyorrheal pus as soon as possible after it has been obtained. After such pus has been obtained, it must be ascertained which bacteria are present in the largest numbers, but such a culture may be contaminated by oral bacteria, some of which grow so fast that they may outgrow the micro-organism that really produced the disease. Hence the necessity of at once isolating them by the plate method. In making a plate, the object is to spread the bacteria over the surface so that, wherever one lodges, it will grow and produce a mass of bacteria big enough to be seen by the naked eye. This is called a colony, and if these colonies are nearly all alike, it may be assumed that they are of a single micro-organism. Very often, however, different cultures are found. One of these colonies is then detached, and planted on agar-agar, thus producing a pure culture.

It is absolutely essential to know just what organism is producing the disease, as Dr. Gompertz has stated. There is no more reason to expect good results from a vaccine made from one organism in case the trouble is produced by another, than it is to expect to grow corn when we plant beans. Vaccine immunity means a specific immunity against one particular bacterium, and none other, and for that reason the particular organism causing the disease must be isolated, else the desired immunity cannot be produced.

In certain patients pus is produced for a considerable period of time around the roots of the teeth, which indicates a lessened resistance to the germ causing the pus production. We can ascertain this, of course, by the opsonic index, but this is so complicated that it is not of much practical use in ordinary cases.

The question arises whether it is possible in pyorrhea to increase the resistance of the tissues by means of vaccines? Theoretically it is. We can increase the resistance of a person to the typhoid bacillus. We are now injecting typhoid vaccines to protect individuals against typhoid fever, and the results are excellent. Resistance to the ordinary germs that produce boils can be increased by isolating these germs, growing them, and then killing them by heat and injecting the vaccines thus made into the person, with excellent results. Theoretically we should be able to obtain as good results in pyorrhea; I see no reason why this should not be possible, and the results obtained by Dr. Gompertz are what I would naturally expect. A few cases that I have observed personally have been satisfactorily treated by this method.

In regard to the question of dosage, I would take a slight exception to the essayist's statement. I think the initial dose should be smaller than indicated in the paper. It seems to me that a dose of 25 million is safer than 50 million at first. I have even had two cases in which I found that 25 million of streptococcus was too large a dose, and in which I obtained undesirable results. In one case the susceptibility was so great that, when I administered a very few millions, the reaction was still too pronounced. On the other hand, I wish to emphasize that the results of too large a dose are not injurious. An overdose may produce discomfort for a day or two, but there is no danger, such as is produced by overdoses of morphin or other strong drugs.

The danger to the constitution arising from a chronic disease combined with pus production requires great emphasis. Every now and then the physician notes a case of pernicious anemia, and he always expects to find a history of bad teeth, pyorrhea alveolaris, or some similar condition. In pyorrhea not merely is the chewing of food done improperly, but the prolonged swallowing of pus and its absorption through the stomach and intestines is very injurious to the body as a whole, and this vicious combination, in later life, when resistance is lowered, gives rise to chronic constitutional disease.

Dr. G. B. Vroom, New Haven. I have had rather special opportunities of seeing Dr. Gompertz' work and his results, and perhaps that is the reason why I have been chosen to take part in this discussion. This subject seems a very large one, and the more I look into it, the more different aspects it presents to me. For a time it was a question with me whether such work as Dr. Gompertz presented to us would be of any benefit to us in our work. I have thought for a long time and still think that pyorrhea is not a local trouble, and that in our treatment we shall have to reach the general system in order to produce a cure. The essayist's results that I saw not only very much surprised, but very much pleased me, and had I his energy and his ambition, I would not be as modest as he is, but would try to convince you of the wonderful superiority of vaccine treatment.

Pyorrhea is not a local disease, but simply a local expression of a general disorder. The tartar accumulations around the teeth are the most prolific cause of the trouble and are due to a precipitation from the saliva that is unnatural, showing disordered function. It has been the habit of the physician to look at the mouth and mucous membrane of the tongue for signs of general trouble, and there is hardly a more exaggerated sign of trouble than pyorrhea. When the resistance is so lowered that the irritants precipitated from the saliva or secreted from the blood, or any injury to the gums, produce pyorrhea, these factors act simply as exciters; the system being in a state of lowered resistance, pus is formed, and this pus being taken in by the system day after day, produces pus-poisoning, the result being an increase in the trouble already present.

I have brought up the question of whether this is a local disease caused by micro-organisms, or whether it is due to a lowered condition of the system, because I wish to have suggestions made as to whether it is not better for us to use something besides our local treatment to raise the resisting power—that is, whether we should use also remedial measures in conjunction with the physician, or take up the cudgels by ourselves and administer medicines.

Dr. A. C. FONES, Bridgeport. I am opposed to the vaccine treatment—from the standpoint of an impressionist. A man has no right to an opinion unless he has investigated both sides of a question, and tried a therapeutic agent practically and scientifically; if it has failed in his hands, he may then have reason for being opposed to it. Therefore, never having tried the vaccine treatment, I cannot have an opinion, but as an impressionist I am opposed to the vaccine treatment in dentistry, because I can produce a cure of pyorrhea, as anyone can, by the simple method of treatment of which I will speak later.

Without wishing to be discourteous, this method of treatment which Dr. Gompertz advocates reminds me of an occasion upon which some people were propounding riddles. Someone asked—"What is it that has no teeth, goes around on two legs, and barks like a dog?" No one could guess the answer, and finally the propounder said, "A chicken." The objection was immediately raised that a chicken did not bark like a dog, and the one who offered the riddle said: "No; I just put that in to make it harder." That is my impression of the vaccine treatment.

I do not doubt that Dr. Gompertz and Dr. Bartlett can produce a condition of health in the mouth by vaccines. I believe they can stop the flow of pus, but they must also be thorough in instrumentation and cleanliness, in the same way as any of us must. Pyorrhea is not cured merely by arresting the flow of pus. Dr. Gompertz must be as thorough with his instrumentation as you or I. No dentist alone ever cured pyorrhea. The dentist's failure to produce a cure is due to the fact that two-thirds of the cure lies in the hands of the patient. How many of you gentlemen have ever seen a case of true pyorrhea alveolaris in a person sixteen years of age, or under? [Three hands were raised.] How many have seen dozens of cases of true pyorrhea in persons over thirty-five years of age? [Many hands were raised.] There are so many hands that it is not necessary to count them. What is the cause? There are filthy conditions in the mouths of children, such as carious deciduous and permanent teeth. Frequently the first permanent molars are destroyed by caries to the gingival border. All such conditions are ideal for local infection. Many of these children are anemic, sickly, and of lowered resistance, but do we find pyorrhea alveolaris? Most of us do not. And why? The pericementum in youth and up to thirty years of age is so thick, so vascular and so resistant that it resists any action of decomposing food or bacteria around the gingival border of the gums and the necks of the teeth. After that period, the membrane gradually grows thinner, becomes less vascular, less resistant, and more susceptible to the irritating action of decomposing food particles around the necks of the teeth and to the action of bacteria. In a majority of cases, when a person has reached the age of thirty-five or forty, and the mouth has been neglected, there will be a gradual death of the pericementum at its border, the margin of the alveolus will be absorbed slightly, and small pockets, in which food will lodge, will be formed. If the resistance in these tissues is then low enough, it is a simple matter for infection to take place.

What, then, are the necessary conditions for the development of pyorrhea? First, the tissue must be susceptible to infection; second, there must be exciting causes, which are decomposing food and bacteria. In correcting these conditions, cleanliness is one essential, but not the only one; it is equally important that the resistance of the tissues be raised. Such resistance may have been lowered by faulty metabolism produced by improper food supply, under or overeating, lack of exercise, excessive drinking, and various other dissipations. There are a number of conditions besides senility that may have brought about a lowered vitality. Irrespective of what the constitutional conditions may be, the resistance of these tissues can be raised. How? By vaccines?

Dr. Bartlett, will you kindly tell me how long the action of vaccine lasts in the system of these patients after injection, so as to render them immune from further infection of bacteria?

Dr. Bartlett. Two years seems to be the limit in typhoid. I am not sure as to pyorrhea, but I should say several months at least.

Dr. Fones. The resistance of the tissues in the mouth can be raised by artificial stimulation in the form of gum-brushing. This measure is so simple that the patient, if he is taught how to use the tooth-brush, can develop perfect circulation. Satisfying results are obtained so easily that other methods seem difficult and complicated by comparison. This measure calls for the brushing of the teeth and gums four times a day. If I were to do this convention one service, it would be to show you how I believe the gums and teeth should be brushed; and in doing so, I am of the opinion that I would be showing you three-quarters of the cure of pyorrhea. The other quarter rests in your own hands—it consists in the thorough removal of deposits on the roots and around the necks of the teeth, and the thorough cleaning and polishing of all surfaces.

I believe Dr. Gompertz can stop the flow of pus, and I am in sympathy with vaccine treatment in cases of deep infection, which would require a considerable operation to get at the seat of infection. Vaccine treatment under such conditions may be warranted, but, as dental surgeons, everyone of us must know how to control pyorrhea, and it is within our power to do it. When we speak of pyorrhea being constitutional and incurable, and send patients away, telling them that this disease cannot be cured, we do them a great injury. It is curable, it can be controlled, but the dentist cannot do it alone; he must have the co-operation of his patient. It is for you, then, to teach your patients how to brush their gums, thereby raising their resistance. I am not theorizing in making these statements: I have followed this procedure time and again, and anyone can adopt it. It requires no special skill, merely an appreciation of the two fundamental facts that the exciting causes are decomposing food and the susceptibility of the tissues due to lowered resistance.

Dr. Gompertz (closing the discussion). Dr. Fones maintains that it is within our power to "control" pyorrhea alveolaris, and that no dentist should send a patient who is suffering with pyorrhea away from his office with the idea that it cannot be cured. Gentlemen, all a dentist can do without the assistance of vaccine is "control" the disease, but, according to my interpretation, that does not mean a cure.

Dr. Fones has asked the question as to how long immunity will last in the case of vaccine treatment. We have a number of cases which have been immune for two years and more. We have had cases in which extraction has been advised by several dentists, and these cases are in good condition today. Something which was more than simple control of the disease took place in these patients. It was the success of the vaccine treatment and nothing else. Furthermore, Why is it that dentists, as long as I can remember, have been puzzling over pyorrhea, and have never done anything more than "control" it? The question of the permanence of cures, of course, is at the present time not absolutely settled.

Dr. Fones. Can you cure caries by vaccines?

Dr. Gompertz. Caries is an entirely different process. There is no blood supply involved in caries. We are looking for results. I have no reason to question Dr. Fones' results any more than he has to question mine; these results are before you, and they have been demonstrated in a great many instances. I have no doubt that Dr. Fones can train patients in the correct way of brushing their teeth, and there is no question that this helps. I have had patients who have had the same training—I do not say that they came from Dr. Fones, because I think he has the ability to keep his patients, and I am trying to follow his example—but, in all seriousness, no permanent results have been obtained in pyorrhea alveolaris previous to the vaccine treatment.

Dr. Bartlett spoke of dosage, and I think he is correct; it is just as well to commence with small doses, perhaps 25 million. Even if no marked reaction be obtained, the patient gains confidence, and no harm is done by gradually raising the dose. If one should, however, give too large a dose at first, no great harm is done by it.

Someone has asked about the local reaction. The local reaction is generally produced in twenty-four or thirty-six hours. It has the characteristic appearance of a burn of the first degree—this may continue for forty-eight or fifty-six hours but the patient is unaware of soreness.

There is just one more point that I would like to emphasize before closing, and that is the regulation of the dose. This, in my opinion, is one of the important factors toward getting good results in vaccine treatment of pyorrhea alveolaris, but this can be obtained only by careful observation and clinical experience.

I want to thank the members of the society for their courteous reception and interesting discussion of my paper.

The meeting then adjourned until the evening session.

(To be continued.)

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

Fifth Annual Meeting, held at Boston, Mass., April 22 and 23, 1913.

First Session.

THE fifth annual meeting of the Dental Faculties Association of American Universities was called to order on Tuesday, April 22, 1913, at 10.30 A.M., by Dr. Eugene H. Smith, president, in the faculty room of the Harvard Dental School, Boston, Mass.

The secretary, Dr. Edward C. Kirk, called the roll, and the following representatives responded: Dr. Alfred Owre, University of Minnesota, College of Dentistry; Dr. W. S. Hosford, University of Iowa, College of Dentistry; Dr. Eugene H. Smith, Harvard University, Dental School; Dr. N. S. Hoff, University of Michigan, College of Dental Surgery; Dr. W. E. Sharp, University of California, College of Dentistry; Dr. Edward C. Kirk, University of Pennsylvania School of Dentistry. Others present at the meeting were Drs. W. E. Boardman and L. P. Hall.

The next order of business was the reading of the minutes of the previous meeting by the secretary, Dr. Kirk.

Motion was made and carried that the minutes be accepted as read.

The next order of business was the Address of the president, Dr. EUGENE H. SMITH, D.M.D., Boston. Dr. Smith, asked the vice-president, Dr. N. S. Hoff, to occupy the chair, while he read his address, as follows:

PRESIDENT'S ADDRESS.

Gentlemen, honored members of the Dental Faculties Association of American Universities,—It is a great privilege, permeated with much pleasure, to welcome you in the name of Harvard to our university.

The dental department has courageously striven to keep abreast of the time, to increase dental education, and to advance the standard of the profession.

Since the memorable meeting of the National Association of Dental Faculties at Asheville, when Harvard felt it necessary to withdraw its membership, followed shortly after by the several dental departments of universities here represented, our united efforts have made this advance steady and safe. This step, however, indicates only a beginning—a good beginning, to be sure—and also a danger of contentedly hovering around our beginnings rather than the investigating of the newer problems in education, with a determination to adopt whatever may seem to be in the line of progress.

Let us, then, consider in the first place what we have accomplished, and in the second place, what our progressive problems are and how we are to solve them.

We have accomplished a sodality of six university departments whose aims are identical, and whose purpose is to bring about a higher standard in the profession.

PREDENTAL REQUIREMENTS.

To that end we are united in a predental requirement of four years' training in an accredited high school.

This uniformity of requirements means, I hope, that for the moment only we may rest while considering further advancement in predental training. I find, however, that while in the main our entrance requirements are the same, we differ somewhat in details. For instance, the Harvard Dental School definitely states the courses that a student must take during his four years in high school.

Those courses must include English, algebra, physics, chemistry, the study of a foreign language for at least two years, and history, if the student has not taken Latin. He may elect geometry, botany, zoölogy, anatomy, wood-working, blacksmithing, chipping, filing, fitting, or machine-tool work. If one or two of the required subjects have not been taken by the applicant during his high-school course, he may be admitted with a condition in these two subjects, but must remove the conditions previous to being admitted to the senior class.

Other schools, however, in our association make a different statement in the interpretation of a four-year high-school course, namely—

The University of Minnesota makes obligatory English, algebra, geometry, chemistry, and manual training; the University of Iowa does not seem to make it clear what obligatory subjects are required; the University of California, after August 1913, requires four years of high-school plus two years of college work; the University of Michigan makes obligatory English, algebra, geometry, physics, Latin, and chemistry; in the University of Pennsylvania, chemistry seems to be the only obligatory subject, coupled with a large field of electives.

Such a wide latitude of obligatory subjects among us is not, I think, desirable.

As above stated, the College of Dentistry of the University of California has already committed itself to a requirement of two years of college training and the College of Dentistry of the University of Iowa is contemplating a similar change. It therefore seems to me to be expedient and wise to have more uniformity in this matter, especially in regard to the obligatory subjects.

Further steps along these lines must, I think, be taken with great care, not so much owing to the fear of lessening the number of our students, as to the fear that men may be unwisely trained for the duties required of the dentist.

It therefore becomes one of our most important problems to decide how much of college or academic training shall be required of men entering upon the study of our profession. Shall it be one, two, three, or four years of academic work, and what subjects shall be required from the elective field now offered in academic work?

PROBLEM OF STANDARDIZING THE DENTAL CURRICULUM.

While the predental training required by our several schools, as I have pointed out, is not quite the same, we are much more at variance in the sequence of our curriculum. It would help to standardize the professional training which we give to our students, and make easier the transfer of students from school to school if we could bring about a uniformity in the sequence of subjects taught, and I recommend that we take this matter into consideration.

FOURTH-YEAR ELECTIVE COURSE RECOMMENDED.

I think we all realize that the professional education necessary for a dentist today cannot well be met in a three years' course, and that a fourth year is most desirable.

I do not feel that the time is ripe for an obligatory fourth year, but I do think and recommend that we offer at once a fourth-year elective course. Such a course, if well planned, would prove attractive not only to our students, but to practitioners, who would be glad to avail themselves of the opportunity such a course would offer.

Certificates of various grades might be granted for attendance upon such a course, depending upon the courses taken, the time spent in such courses, etc.

Our profession has not done, nor is it now doing what it should in the way of scientific research and preventive dentistry, and steps should at once be taken to bring about inter-school action to foster a spirit of research among our student body.

RESEARCH SOCIETIES URGED.

Such steps have already been taken in the Harvard School, where some two years ago a students' society for dental research was formed, and named after Mrs. Harriet N. Lowell, whose generous gift to the school made the formation of the society possible. This society is under the management of a research committee appointed by the administrative board, and is made up of men who are giving a portion of their time to research work, and who are also interesting young students in scientific work.

It would be highly advantageous if similar societies could be formed in our several schools, thus bringing about an inter-school society of dental research, and, through such co-operation, an exchange of scientific endeavor.

RATING OF STUDENTS FROM FOREIGN SCHOOLS.

We are still lacking the knowledge necessary to properly rate students coming from foreign schools, and in order that there be a clear understanding in regard to these schools, I recommend that a special committee be appointed to investigate the matter thoroughly and report at our next meeting.

RELATIONSHIP WITH THE NATIONAL BOARD OF EXAMINERS.

There has always been, and there appears still to be, somewhat of a reciprocal alliance between the National Board of Examiners and the National Association of Dental Faculties, and, if in the judgment of the society such co-operation is to the benefit of higher dental education, steps should be taken to bring about a similar arrangement between our association and the National Board of Dental Examiners.

CARNEGIE FOUNDATION.

In the last report of the president of the Carnegie Foundation mention is made of the intention of the Foundation to investigate the standards of the dental schools.

This is a hopeful sign and if carried out will prove, I believe, to be as great a service to dental education as the Foundation's investigation of the medical schools has been to medical education.

In this connection I would recommend that we send to the Carnegie Foundation our appreciation of its intention to investigate the method of dental education in America, and to express our hope that the investigation will be made at an early date.

Dr. KIRK moved that the report be received, and that time be set apart for discussing the special recommendations made in the report. [Motion carried.]

Dr. Smith then resumed the chair.

The next order of business was the report of the secretary, Dr. EDWARD C. KIRK, as follows:

REPORT OF THE SECRETARY-TREASURER.

Mr. President and Members of the Dental Faculties Association of American Universities,—I have to submit for your consideration certain communications of an official character which have been received through the secretary's office since the last meeting of our association.

The first is a letter from Dr. M. Chiwaki, dean of the Tokyo Dental College, inquiring as to what action, if any, had been taken upon the application made by him on behalf of the Tokyo Dental College for admission of graduates of his institution on advanced standing to the senior year in schools of our association. As this question has been debated at two preceding meetings, it seems only right and proper that this official inquiry should receive an official reply. This matter of the official recognition of the Tokyo Dental College was, I believe, referred to the committee of which Dr. Owre is chairman, and I understand that the committee will be able to make a definite report on their findings at this meeting.

I have also to submit for your consideration a letter from Dr. Newill Sill Jenkins of Dresden, Germany, relative to a suggested interchange of professors between German university dental schools and the schools of this association.

I have to present the formal application of the Washington University Dental School for membership in the Dental Faculties Association of American Universities; also a letter from Dean Hosford of the Dental Department of the University of Iowa, transmitting the report of the consolidation of the dental departments of Drake University and the University of Iowa.

I have to report also that, following the instructions of this body, I officially transmitted to the administration of the Carnegie Foundation the text of the resolution of our association suggesting that the Carnegie Foundation investigate and report upon the conditions of education in the dental schools holding membership in this body. The text of the secretary's letter, together with the acknowledgment of its receipt by the Carnegie Foundation, are herewith submitted for your information.

Your secretary has received a communication from Dean Hoff relative to the status which may be accorded in the Dental Department of the University of Michigan to a graduate of the Nippon Dental College; likewise an inquiry from Dean Hoff with respect to the status of an applicant from the dental school in Odessa, Russia, and a similar inquiry from Dean Owre relative to the status of graduates of American dental schools settling in the British colonies, all of which, with the replies thereto, are herewith submitted.

The secretary has received the printed report of the Educational Council foı 1912, which is also herewith submitted for your information and consideration.

The authorities of the Panama-Pacific Exposition Company have transmitted, through your secretary, an invitation to this association to hold its annual meeting in San Francisco in 1915 during the holding of the Panama-Pacific Exposition.

The financial condition of our association is set forth in the treasurer's report, containing a detailed exhibit of receipts and expenditures, and is herewith submitted.

The secretary would call attention to the fact that the Sixth International Dental Congress will be held in London during August of 1914, and although no official invitation from the Committee of Organization has been received inviting this body officially to participate, it would seem that the occasion is one which should enlist the interest and co-operation of all who are related in any way to the advancement of our professional interests, and it might be well that we should, if only in an informal way, endeavor to further the interests of dental education with which all of us are concerned not only in a national but an international way, and to do our part toward advancing the interests of dental education, particularly at the time of the holding of the congress.

All of which is respectfully submitted,

EDWARD C. KIRK,
Secretary-Treasurer.

The next order of business was the report of the Executive Committee. Dr. Hoff, chairman, reported that nothing had been referred to the Executive Committee during the year to be acted upon, and therefore there was no report to make.

Dr. KIRK suggested that the application of the Washington University Dental School be referred to the Executive Committee.

Dr. SMITH suggested that it would probably be best to refer this application to the Educational Committee.

Dr. KIRK moved, and Dr. Owre seconded, that the question of the application of the Washington University Dental School be referred to the Executive Committee, with full power to act thereon. [Motion carried.]

Dr. KIRK asked for final action by the association on the status of graduates coming from the Tokyo Dental College and asking for admission into any school of this association.

Dr. OWRE reported that the Educational Committee had had considerable difficulty in finding out the status of such students, but from such information as the committee had been able to obtain, he did not think they should be admitted to senior advanced standing.

After considerable discussion of the question Dr. KIRK moved and Dr. Owre seconded that the standing resolution governing the admission of students of schools not members of this association to advanced standing in schools of this association be applied to the case of the students from the Tokyo Dental College as it applies to students from other schools. [Motion carried.]

Dr. Kirk asked for instructions on informing Dr. Chiwaki with regard to this tentative disposition of the matter, until we have further details regarding the Tokyo School; also that he might instruct him with regard to the desire of the association to grant unconditional admission to advanced standing only in relation to university schools; that we do not understand his school to be a university school, and could not treat him any better than our own people.

Dr. Owre moved that the secretary be so instructed. [Motion carried.]

After further consideration of the Nippon School, it was the sense of the association that this resolution also apply to the Nippon School.

Dr. Kirk then asked for final action on the proposition contained in the letter from Dr. Jenkins with regard to the interchange of professorships with the German universities. Dr. Kirk read again the letter from Dr. Jenkins making this proposition.

Dr. Kirk then presented the following resolution:

Resolved, That it is the sense of this meeting that the faculties represented in the Dental Faculties Association of American Universities view with sympathetic favor the suggestion for an interchange of teachers with the German university dental schools.

Dr. Hoff seconded the resolution, which was carried.

Dr. Smith then declared the meeting adjourned until the afternoon session.

Second Session.

The meeting was called to order at 3 o'clock by the president, Dr. Smith.

The Secretary then presented to the association the communication from Dr. Hosford regarding the consolidation of the Drake University Dental School with the University of Iowa, College of Dentistry.

Dr. Hosford explained that it was the wish of the University of Iowa to have this action ratified by the Dental Faculties Association of American Universities.

Dr. Kirk moved and Dr. Hoff seconded that this action be ratified. [Motion carried.]

The Secretary next presented a letter from Dr. Hoff regarding application for admission by a student from Odessa, Russia, asking what standing should be given such a student.

The subject was discussed by Drs. Hoff, Smith, Kirk, and Owre, after which Dr. Hoff moved that the association accept credentials from dental schools in Russia, not to exceed advanced standing in time only of more than one year, and this only when the applicant has shown by such credentials or examination that he is entitled to this amount of credit.

Dr. Sharp seconded the motion, which was carried.

Dr. Kirk then presented to the association an invitation from the Panama-Pacific Exposition Company to the association to hold the 1915 meeting in San Francisco during the time of the exposition. This invitation was supplemented by an invitation to the same effect from the University of California.

Dr. Hoff moved that the association accept the invitation of the University of California and of the Panama-Pacific Exposition Company to meet in San Francisco in 1915. [Motion carried.]

The question of the time and place of the next annual meeting was next considered. Dr. Kirk invited the association to meet next year in Philadelphia, at some time to be agreed on later.

Dr. Sharp moved that Dr. Kirk's invitation to meet in Philadelphia in 1914, at a time convenient to the association, be accepted. [Motion carried.]

Dr. KIRK then presented the Treasurer's Report, as follows:

TREASURER'S REPORT.

Receipts:		
Balance from 1911-12	$97.49	
Receipts for dues 1912-13 ...	300.00	
Total receipts		$397.49
Expenditures:		
Jan. 1, 1913. Printing Transactions	$59.00	
Jan. 1, 1913. Clerical services	100.00	
Nov. 1, 1912. Stationery ...	5.25	
April 18, 1913. Postage and envelopes	3.33	
Total expenditures		$167.58
Balance 1912-13		$229.91

Dr. HOSFORD moved that the report of the Treasurer be accepted. [Motion carried.]

Dr. SHARP moved that one member of the Executive Committee be delegated as a committee of one to inspect the Washington University Dental School, in order that the Executive Committee could more intelligently pass upon the application for membership in the association.

The motion was seconded by Dr. Owre, and passed.

Dr. KIRK moved that the Executive Committee select one member of the committee to do this at the expense of the association. [Motion carried.]

The Executive Committee announced Dr. Hosford as its selection for this work, and Dr. Smith suggested that Dr. Hosford be equipped with proper credentials by the secretary.

Dr. SHARP spoke of an effort being made to establish a dental department in connection with the University of Illinois, and after some discussion of the question, offered the following resolution:

Whereas, The members of this association have learned that it is the intention to establish a dental school in connection with the University of Illinois; therefore be it

RESOLVED, That this body views with great satisfaction this movement toward the placing of dental education in the state of Illinois upon a university basis, it being the belief of the association that the interests of dental education will be best conserved by such a relationship, and that the final outcome of dental educational progress must be determined through the fostering care of the universities constituting the higher institutions of learning of this country; and be it further

RESOLVED, That a copy of this resolution be forwarded to the president of the University of Illinois as an official expression of the interest of this association in the proposed plan of creating a dental school as an integral part of the educational system of the University of Illinois.

Dr. KIRK moved the adoption of the resolution. [Motion carried.]

Dr. SHARP asked advice with regard to what to do with an application from a student from the University of Texas, stating that he had the B.S. degree and had taken two years in dentistry, and asked if he could be allowed credit for two years.

It was the sense of the meeting that this applicant could be allowed one year time-credit, but should be required to take two years in dentistry.

Dr. KIRK raised the question as to giving undergraduates in medicine any allowance for time in the dental course.

Dr. HOFF suggested that it would be fair to give such men credit for one year in dentistry when they have taken two years in medicine. After further discussion of the subject,

Dr. KIRK moved that Dr. Hoff be appointed a special committee to bring in a report at the next meeting of the association on the question of granting advance standing to undergraduate medical students in the dental course—that is, undergraduates from medical departments of universities. [Motion carried.]

Dr. SHARP suggested that consideration of the President's address be made the first order of business for the morning session.

The association then adjourned until Wednesday morning at 10 o'clock.

Third Session.

The meeting was called to order at 10 o'clock Wednesday morning by the president, Dr. Smith.

Dr. Sharp brought up the question of considering a course in oral hygiene and dental economics, and asked the consensus of opinion as to the advisability of giving this as a regular course, and giving specified time to the subject. The question was discussed by Drs. Smith, Kirk, Owre, and Sharp, but no action was taken on the matter.

Dr. Smith submitted the application for advanced standing of a student from the North Pacific Dental College who had matriculated at the Harvard school, but whose credentials were not up to the standard. Dr. Smith said this student had not been allowed to continue his second year because of his not satisfying the educational requirements, which were difficult to establish.

The sense of the meeting was that this man be not allowed to continue his course until he meets the preliminary educational requirements.

The next order of business was the consideration of the recommendations in the President's address.

The first question to be considered was with regard to the differences of the members of the association with regard to obligatory subjects in the curriculum. Considerable discussion of the subject was entered into by Drs. Smith, Owre, Kirk, and Hoff, after which,

Dr. Kirk moved that each member of the society be requested to express his views on the subject and forward them to the chairman of the Educational Committee, and let him, from that, systematize a report that will give a definite record as to how near the different college curricula are together, and formulate from that a plan that would tend to unification; this to be discussed at the next meeting of the association.

Dr. Hosford seconded the motion, which was carried.

The next recommendation in the President's address was that in regard to the standardizing of the curriculum.

Dr. Hosford suggested that a minimum requirement of hours for each subject be made standard in the schools.

Dr. Owre suggested that each member of the association send each year a member of the clinical staff of the institution, that they might become conversant with the views of the association in regard to educational matters, clinical work, etc.

Dr. Sharp moved that this question be referred to the Educational Committee, to make a report and recommendation. [Motion carried.]

The next question considered was that of a fourth-year elective dental course.

Dr. Owre moved that that question be referred to the Educational Committee.

Dr. Owre moved that the recommendation in the President's address, to the effect that the secretary be instructed to write to the Carnegie Foundation and express the appreciation of this association of their intention to investigate the methods of dental education in America, and to voice the hope that the investigation be made at an early date, be adopted. [Motion carried.]

The next order of business was the election of officers for the ensuing year.

Dr. Sharp moved that the present officers be re-elected to their present positions. [Motion carried.]

Dr. Hoff moved that Dr. Hosford be re-elected to the Executive Committee for two years. [Motion carried.]

Dr. Hoff moved that Dr. J. G. Sharp be re-elected to the Educational Committee for three years. [Motion carried.]

The final reading of the minutes for approval was, on motion, dispensed with.

Dr. Sharp moved that the association extend its thanks to the president of the association, also to the Harvard Dental School, to the Harvard Odontological Society, and to Mr. Forsyth, of the Forsyth Dental Infirmary, for courtesies extended to the association during the meeting. [Motion carried.]

Motion made and carried to adjourn, subject to the call of the president.

EDITORIAL DEPARTMENT.

CONCERNING EDUCATIONAL STANDARDS.

WE have from time to time directed the attention of our readers to the question of educational preparation for the professional practice of dentistry as a matter of prime importance in relation to our position and future advancement as a profession. We have felt called upon to keep the educational issue prominently in view, because in the very nature of the case it is education in the literal sense of the term upon which all fitness for intelligent dental practice depends. While the general truthfulness of the foregoing proposition is doubtless conceded by all, it too often happens that narrow-minded or partial definitions of the meaning and scope of the phrase "educational preparation" tend to interfere with its efficient and practical application.

The annual sessions of our professional schools are now ended; classes have been graduated, and preparations are now in progress for the enrollment of a goodly aggregate number of new recruits fresh from the preparatory schools into the ranks of dental college students. This transitional stage or period of readjustment in the cycle of dental college activities affords excellent opportunity for those in touch with the work to observe with some particularity the character and grade of educational fitness that has been attained by these novitiates both as the result of their preparatory school training and of their dental college curriculum as well.

The experience of dental teachers in dealing with the product of the preparatory schools for the past fifteen years or more has developed a concurrence of opinion as to the need for better educational preparation for the clear understanding of the specialized subjects of the dental curriculum, and this opinion has had its practical expression in the general and insistent demand for a higher standard of entrance requirement for our dental colleges, so that the unfit may be effectively separated in the beginning from those qualified to enter upon the dental professional course of training. In response to the demand for higher entrance qualifications the matriculation standards for our dental schools have been progressively raised from the indefinite plane called "a competent common school education" to "satisfactory evidence of the completion of four years of standard high-school preparation," with the result that even yet the matriculants who are the product of four years of completed high-school training do not in an average sense manifest that grade of educational efficiency which they should possess in order to intelligently proceed with the studies of the professional course. The medical schools, or at least a goodly number of them, have demanded two years of special collegiate preparation in addition to the four years of high-school work as a matriculation requirement, and one, if not more, in the endeavor to secure properly prepared medical students, demanded for a time the attainment of a bachelor's qualification in arts or science as a matriculation standard for admission to the medical course, which standard was later abandoned because of the limited number of applications for admission that followed its adoption. It will thus be seen that there has been a constant effort to secure a better qualified class of students by the device of demanding a longer period of preparatory study, and that when this plan was carried to its ultimate expression it was found to be self-limiting, that is to say, when the limit of collegiate preparation was finally reached at the baccalaureate there were no students to be had by the medical schools. The analogy between this plan and the unrestrained application of the axiom of "extension for prevention" is too obvious to need elucidation.

The evil of insufficient preparatory training still exists; the device of more time in preparation has not cured the evil, and as we have indicated is self-limiting in its action—What, then, is to be done about it? We have on former occasions pointed out that mere quantity or bulk of education is not the end to be attained in preparation for entrance upon the professional course of study, nor indeed should it be an end of the professional course itself; what is of far greater importance as an educational ideal is kind and character or quality of education and it is when measured in these terms that the American high-school education manifests its inherent weakness and inefficiency as a system of preparation for entrance upon our courses of dental professional instruction. Any dental college teacher having a background of experience that would render him competent to express a trustworthy opinion on the subject would be able to testify that in the vital essential of language training the American high-school graduate is, generally speaking, much below the grade of efficiency that he should be considering his average age and the time he has spent in acquiring a working knowledge of his mother tongue, Moreover, he is less efficient than he should be in reasoning power, in precise methods of critical analysis, and the ability to comprehensively grasp the meaning and relationships of the problems that ordinarily confront him in his professional course. He has a superficial smattering of a considerable number of studies, and rarely knows any one of them well enough to put his knowledge to effective use. It is just this state of intellectual inefficiency that has constituted the *raison d'être* of the demand for higher matriculation standards, a demand that we have attempted to satisfy by asking for more and more of an inherently defective thing in the way of preparatory education.

Comparison of the systems in vogue in Europe with the American preparatory school system is to the very evident disadvantage of our own. Europe has found that an intensive method of training whereby the student is progressively drilled in a well selected but limited group of studies is productive of the best educational results. Our American system is too diffuse, superficial, and lacking in intensiveness, and in our anxiety lest we debilitate the mental machinery of our on-coming population by inducing brain fag in the rising generation, we are eliminating the drudgery of study, the mental exercise of work, and substituting predigested information in sugar-coated tabloid form for real education.

It is time that we re-defined the meaning of the phrase "higher standards" as applied to education and more clearly recognize that it is the factor of quality rather than quantity that counts in education as well as in all other things that deserve the designation good as descriptive of their character. But it may be asked, What has the dental profession to do with the business of preparatory school training, the answer to which is that inasmuch as the preparatory school training is the foundation upon which the dental college training is built, the efficiency of the professional course of instruction is in a large degree dependent upon the integrity and thoroughness with which the foundation is laid. So self-evident does the proposition appear to be that until the professional schools concentrate their energies upon the correction of the present defects of our system of preparatory school training, any material progress in the elevation of entrance standards and likewise in the standards of educational efficiency of the graduates of our professional schools of both medicine and dentistry will be impossible.

Any manufacturing industry that had continuously delivered at its doors raw material relatively as defective for its purposes as that which the preparatory schools are furnishing to the dental and medical colleges to be turned out ultimately as professional men, would either improve its system of inspection or establish such relations with the producers as to bring about extensive improvement in the character, quality, and fitness of the raw material. The connection between the professional and the preparatory school is a vital one, therefore a sound professional education can never be built upon a defective preparatory educational foundation, nor can an intelligent practitioner be made out of an uneducated schoolboy. It is exactly the case of the silken purse and the aural appendage of the *sus scrofa feminina.*

Anatomy and Histology of the Mouth and Teeth. By I. Norman Broomell, D.D.S., Dean and Professor of Prosthetic Dentistry, Dental Anatomy and Histology, Dental Department, Medico-Chirurgical College of Philadelphia, and Phillipp Fischelis, M.D., Associate Professor of Histology and Demonstrator in Embryology, Medico-Chirurgical College of Philadelphia. Fourth Edition, revised, with 368 illustrations. 469 pages. Philadelphia: P. Blakiston's Son & Co., 1913. Price, $3.00 net.

The present fourth edition of this work, which in the review of its forerunner we have elected to our "Five-foot Dental Library" (see review of third edition, April 1910 Cosmos, p. 492), marks another step in advance in a subject the fundamental importance of which, in the more modern specialties of dentistry, especially orthodontia, local anesthesia, root resection, pyorrhea and vaccine treatment, is being more fully recognized. While what has been said before in these columns about the quality of the text and the illustrative material offered by the authors continues to hold good, new valuable additions have been made in the present edition, chief of which are a comprehensive description of the present status of our knowledge of blood and lymph, of the structure of the circulatory apparatus, and the structure of the various forms of glands. The subject-matter of the various chapters has been rearranged, and some novel illustrations have been incorporated. The value of this book to the dental student, and even more so to the graduate of dentistry, whose memory in regard to details of this important subject is only too often allowed to remain without refostering and restocking, much to the detriment of his progress in efficiency, needs no emphasis. The authors' appeal, published in the preface to the third edition, so fitly expresses a present need of the dental profession that it bears repeating: "It has been justly brought forward within recent years that there is a lack of interest and enthusiasm for collateral reading, special studies, and original investigation, not only among students but also among graduates in dentistry. The experience gained in teaching has suggested to the authors that this is due to the fact that dental students use to a great extent text-books on anatomy, histology, and embryology, chiefly intended for medical students, and they generally believe that most of the matter which is contained in these books is not intended for them, having no practical application. Their attention is therefore limited to those chapters which seem of importance to them, and thus an intelligent understanding of the subject is not obtained. Recognizing this fact, it seemed advisable to include in this dental text-book a description pertaining to general cytology, general embryology, and histogenesis, and a further presentation of the significance of the facts thus gained for an intelligent understanding of the formation of the organs of the mouth." This statement is in direct line with the contention that is being so loudly voiced at present in regard to the indifference of a large contingent of the dental profession to advanced reading, and with the efforts being made in dental schools, societies, and notably by the National Dental Association, to induce dentists to engage in original research.

The mechanical execution of the book, especially that of the new illustrations, is excellent, though some of the cuts, especially those in the original chapters on the anatomy of the individual teeth, would bear freshening up.

How to Collect a Doctor Bill. By Frank P. Davis, M.D., Secretary Oklahoma State Board of Medical Examiners, 1908–11; Superintendent Oklahoma State Institution for Feeble Minded, 1910–11, etc. 93 pages and index. Price $1.00. Enid, Okla.: Frank P. Davis, 1913.

A great deal has lately been said and written about the business side of dentistry, so much so that in some quarters the consideration of the theoretical requirements of dental practice proper has been unduly neglected, and the dentist's profession has been discussed in much the same way as a horse deal or a gold-mining enterprise. There is no doubt that the average professional man needs to study more intimately the business side of life, and this little book, though it was written mainly for the medical profession, applies equally as well to the dentist. The topics discussed, such as attitude toward debtors, proper time to collect, books and bookkeeping, letters and forms, statutes of limitations, and exemption laws and their application, are treated briefly and to the point, without the verbose, tiresome prolificacy usually encountered in discussions of this subject. The extracts from exemption laws as valid in every state of the Union is a specially valuable feature. If the methods advised in these pages will aid every reader to collect over ninety per cent. of his accounts, as the author claims them to have done for him, the purchase of this book will be a first-class investment.

Kulturgeschichte der Zahnheilkunde in Einzeldarstellungen. Herausgegeben von Curt Proskauer. (I) Der Zahnstocher und Seine Geschicte. Eine Kulturgeschichtlich - Kunstgewerbliche Studie. [Cultural History of Dentistry in Monographs. Edited by C. P. Proskauer. (I) The Tooth-pick and Its History. A Study in Cultural History and Applied Art.] By Dr. Hans Sachs. With 86 illustrations and one colored plate. Pp. 52. Berlin: H. Meusser. Subscription price *M*. 5.00 and 6.00. Single copy *M*. 6.00 and 7.00.

Since the National Dental Association published Dr. V. Guerini's History of Dentistry in 1909, the interest in the past of our profession, which theretofore was confined to a very small circle of dental bibliophiles, has been considerably enlivened in this country, and a great many interesting facts regarding the beginnings of dental practice in America have been brought to light. This is not surprising, for every progressive science has the desire to establish its historical foundations, and to contribute to this end is the aim of the present series of monographs on the cultural history of dentistry. The first monograph that has so far appeared, from the pen of Dr. Hans Sachs, certainly makes him who finds recreation in cultural history, art, and applied art anxious for the promised forthcoming issues on such subjects as "The Legend of Sainte Apollonia," "The Dentist in Art," "The History of Extracting Instruments," etc. The wealth of information regarding such an apparently prosaic instrument as the tooth-pick as offered by Dr. Sachs, who has traced its origin from the ancient and through its various metamorphoses to our own times, is as surprising as pleasing, and the liberal offer of high-class art illustrations, which have been culled from heretofore inaccessible private collections as well as large and small art museums all over Europe, will surely endear this genuine work of art to the reader. The principle expressed that—"Pictures are the most ideal competitors with words; the more pictures, the more easily art can save words; at all times pictures have been preferred to text, images to ideas"—will make this book valuable and enjoyable even to those who are not well versed in the German language, and if left for the patient's casual perusal in the waiting room, it will favorably reflect upon the owner's good taste. As for the excellence displayed in the art of reproduction, it is no exaggeration to say that the loose, colored plate alone—"The Tooth-pick Seller"—by Smith-Knight, is worth the price of this handsome book.

HOW SHOULD ROOT-CANALS BE FILLED? By Dr. A. Mueller, Vienna.

Mueller makes the following demands upon a good material for root-canal fillings: It must be as nearly permanently antiseptic as possible; it should harden but little, so that it can always be easily removed from the canal if subsequent treatment should become necessary; it should act as a dehydrater, styptic, and mummifier upon the pulp remnants, and should absorb any secretions entering through the apical foramen; it should allow of easy introduction into the narrowest root-canals; it must not produce any discoloration of the tooth; it must not produce mechanical or chemical irritation of the pulp remnants or the pericementum; if forced out through the apical foramen, or into the antrum of Highmore, a fistulous tract, or into an abscess sac, it must not produce any irritation; it must not develop any notable amount of vapors or gases; it must not have a disagreeable odor or taste; it must not decompose in the air; it must be of such consistence that it can be applied without coming in contact with the fingers; it must be applicable in a root-canal that contains a broken broach which cannot be removed. All these requirements can be fulfilled only by an antiseptic soft paste which can be introduced under pressure into the root-canals. The paste employed by the author is of the following consistence: Xeroform 5.0; zinc oxid 15.0; glycerin enough to make a soft paste; thirty minims of concentrated carbolic acid. The root-canals are enlarged at their entrance by a suitable bur, and the paste is gently inserted with a syringe, all excess to be removed by cotton pellets, and the root-canal entrance to be closed with a sterilized asbestos disk. If desirable, especially after gangrene of the pulp, a small crystal of thymol may be pressed into the paste at the canal entrance.

The writer employs paraffin to which 30

per cent. iodoform has been admixed only in root-canals of teeth the apex of which is to be resected, also in perforated canals, and as a capping material for exposed pulps that have not been injured so as to produce hemorrhage.

[*New York Medical Journal*, New York, March 8, 1913.]

TEETHING AS A CAUSE OF DISEASE IN INFANCY. By Dr. Charles Herrman, New York.

Notwithstanding the remarkable progress that has been made in the science of medicine during the last fifty years, certain traditional beliefs remain as deeply rooted as ever. Not the least noteworthy is the important rôle which teething is supposed to play in the etiology of the diseases of infancy. As Holt says—"The physician who starts out with the idea that in infants dentition may produce all symptoms, usually gets no further than this in his etiological investigations."

The present views with regard to teething are three: First, there are those who believe that very many disturbances may be due to teething; second, those who believe that none are due to teething; and third, those who take a middle course, believing that a few disturbances may be caused by teething. To the first group belong a large part of the laity and some physicians. In a recent paper, Neumann has shown in graphic form that in Berlin, from 1877 to 1910, the number of certificates giving teething as a cause of death in infants has diminished from fourteen to three per 1000. The number of certificates giving teething as a cause of death is an index of the intelligence of the physicians, their knowledge of pediatrics being in inverse proportion to the number of such certificates submitted.

The chief danger in believing that many disturbances are due to teething lies in the fact that valuable time may be lost. For example, in cases of acute gastro-enteritis, the disease, falsely attributed to teething, is allowed to progress, and when the child is dangerously ill, possibly beyond all medical help, it is brought for treatment.

The second view is that "teething produces nothing but teeth," that the eruption of the teeth is a physiological process similar to the growth of hair and nails. This view, expressed by Politzer and Fleischmann forty years ago, and more recently by Kassowitz and others, is not incompatible in a somewhat modified form with the third view. So, modified, it would read, teething produces nothing but teeth in normal, healthy infants. In such individuals the hair and nails are of normal appearance; but just as in certain constitutional diseases, such as syphilis and cretinism, these parts may show changes, so in infants with certain constitutional peculiarities the eruption of teeth may be sometimes associated with certain disturbances. The fact that an infant has such disturbances may be considered a proof that it is not normal.

It must be remembered that during the period of dentition many other changes are taking place; it is a time of rapid development of nearly all the structures of the organism. In this connection it is noteworthy that the manifestations of the exudative and spasmophilic diathesis, called "Zahnpocken" and "Zahnkrämpfe" by the Germans, have a tendency to diminish or disappear as the child grows older. "Outgrowing a disease" is not merely a phrase; in these conditions it actually takes place.

Many of the symptoms attributed to teething are met with in the early months, before the eruption of teeth has begun. Many mothers consider an increased flow of saliva and putting the fingers in the mouth indications of the onset of teething, but countless babies can be observed in which both these symptoms are present quite independently of dentition. The eruption of the permanent teeth is occasionally attended with some disturbance, but how often would one attribute a skin eruption, a diarrhea, or a convulsion in an older child to teething? At a time when teething was considered the cause of a number of infantile disorders, the gums were frequently lanced. Why has this operation been so largely given up? Obviously because it did not meet the indications. It is still done occasionally, and probably often, just as is the cutting of the frenum of the tongue, to ease the mind of the mother.

It is admitted that a few slight disturbances may be caused by teething; that requires no emphasizing. What should be emphasized in the writer's opinion is that, in the presence of a disease in an infant, teething should not be diagnosticated as a cause except as a last resort, after every other possible explanation has been excluded.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, January 1913.]

HISTOLOGICAL INVESTIGATIONS ON THE TOOTH GERM IN THE CONGENITALLY SYPHILITIC. BY L. KOEHLER, DARMSTADT.

Referring to the investigations of Cavallaro and Pasini, Koehler explains the origin of Hutchinson's teeth in the following manner: It is possible that the cells engaged in the formation of epithelial tissues are directly injured by the presence of spirochetes. Still the presence of spirochetes does not necessarily mean a luetic degeneration of tissues, since, apparently, an accumulation of spirochetes is necessary to produce a tissue reaction, the spirochetes being able to exist in rather innocuous symbiosis with tissue cells. On the other hand, the correlation of spirochetes with the parathyroid glands may influence the faulty formation of enamel, since it has been possible to prove the existence of spirochetes in otherwise normal parathyroid glands. While rejecting Pasini's view of a purely local influence of the spirochetes, Koehler assumes that the constitutional effect of syphilis and the toxins formed by the spirochetes produce a general injury to the tissues which is characteristically reflected in the dental tissues.

[*American Journal of the Medical Sciences*, Philadelphia, June 1913.]

A STUDY OF CASES OF ACTINOMYCOSIS. BY F. E. MCKENTY, MONTREAL.

From a study of the clinical histories and subsequent course of the cases of actinomycosis in the Royal Victoria Hospital of Montreal, during the past twelve years, McKenty concludes that this disease is more common than is generally believed, especially in rural communities. It is frequently mistaken for tuberculosis or a newgrowth. There are certain characteristics about the cases from each locality which lead to suspicion of the nature of the disease. The usual situations are the jaw, cheek, appendix, and cecum, with thoracic involvement. Infection cannot occur without a lesion in the skin or mucous membrane. Jaw cases are more frequent in the fall of the year, abdominal and thoracic cases in winter and spring. The onset is often acute. Abdominal actinomycosis shows peculiar liability to fistula formation and tendency to heal at the site of the initial lesion, appearing elsewhere. Abdominal and thoracic forms show high mortality, while in skin and jaw cases the prognosis is satisfactory. Excision is the best method of treatment where possible; otherwise, free incision, curetting, washing with weak iodin solution, packing with iodoform gauze, associated with large doses of potassium iodid internally, should be adopted. The relation between cattle and human actinomycosis is closer than that between human and bovine tuberculosis.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, January 1913.]

ROOT SECTION, AN OPERATIVE METHOD FOR THE REMOVAL OF BROKEN INSTRUMENTS FROM ROOT-CANALS. BY E. SCHUSTER, LEIPZIG.

Recognizing the difficulties of removing the fragment of an instrument from a root-canal—especially if it has become embedded in the apical third—and the inadequacy of the generally advised means for removal, Schuster recommends section of the root, guided by the aim of saving as much tooth structure as possible and impairing the function of the tooth as little as possible. His method of operation consists in turning over a flap of mucous membrane under local anesthesia, and making a window-like opening in the alveolus with the aid of a fine, sharp chisel, the location of this opening to be determined by the X-ray picture. The root thus exposed is opened in its long axis with a fine rosehead bur, the embedded instrument is quickly exposed to view, and pushed out in the direction of the pulp chamber with stout, curved sounds. In order to avoid an oversight or swallowing of the broken instrument, a pellet of cotton has been previously introduced into the pulp chamber in order to engage the fragment upon removal. The incision in the root is then filled with tin-gold or amalgam, the lumen of the canal being preserved by a sound previously introduced into the canal. If the canal has been opened up to the apical foramen, this sound is superfluous, as an hermetic sealing of the canal is desirable. The field of operation is carefully cleansed and sterilized, and the wound in the mucous membrane closed by a suture. This operation is, of course, most favorably indicated in single-rooted teeth. It has the advantage over resection of the root apex as recommended by Williger (see DENTAL COSMOS, November 1912, p. 1289) that the amount of injury inflicted upon the tooth is very small, a slit of 1 mm. breadth being sufficient, and that a very small portion only of alveolar bone need be removed, since the broken instrument is removed by way of the pulp chamber.

[*Le Laboratoire et le Progrès Dentaire*, Paris, March 9, and June 1, 1913.]

THE USES OF RADIUM IN DENTISTRY. BY H. LÉGER-DOREZ.

THE TREATMENT OF PYORRHEA ALVEOLARIS WITH RADIUM. BY PROF. DR. WARNEKROS.

[*Oesterreichisch-Ungarische Vierteljahrsschrift fuer Zahnheilkunde*, Vienna, January 1913.]

THE TREATMENT OF ORAL DISEASES, ESPECIALLY OF PYORRHEA ALVEOLARIS, WITH RADIUM. BY DR. F. TRAUNER, GRAZ.

Despite the difficulties connected with the employment of radium in therapeutics, chief of which is its exorbitant price, a great many experiments have been carried out in an effort to determine its efficiency in dental disease. Léger-Dorez employs an applicator, invented by Danlos in 1905, which consists of a small metal plate, of five square centimeter surface, that bears the radium salts—composed of one centigram of sulfate of pure radium mixed with three centigrams of barium sulfate—and is covered by a coat of specially prepared varnish or rubber sheets to exclude moisture. This applicator develops 50,000 units per 0.04 centimeter square, and is applied to the mouth, the palate, or the lips for about one-half hour. Radium treatment is particularly effective in pulpitis following a filling operation, in reducing the sensitiveness of carious dentin at the neck of a tooth, and in congestion of the gums due to trauma or infection. Artificial dentures which have caused pain by pressure can be tolerated after one application, epulis and benign tumors are favorably influenced, and incipient pyorrhea is radically cured by radium radiation, while in long-standing pyorrhea the mucous membranes are restored to health, and hypersensitive teeth can be scaled without trouble. Léger-Dorez cites ten cases of incipient and fairly advanced cases of pyorrhea alveolaris in which radium brought about a complete cure.

Warnekros, following Trauner's example, recommends radio-active water for rinsing purposes as an effective means for curing pyorrhea alveolaris and preventing dental caries to a great extent. Root-abscess yields to massage with radio-active cocoa-butter pluglets, as the radiograph has proved conclusively. Warnekros also describes an apparatus for the emanation of radium gas, by the means of which this gas can be introduced directly into the root-canal of a tooth, into inaccessible cavities, and areas of suppuration. He advises for his patients the purchase of a radium apparatus which will charge water with the emanations of radium, and ascribes great prophylactic value to the habitual use of this rinsing-water. In pyorrhea patients it is necessary, of course, to have all tartar thoroughly removed, for only then can a complete cure be effected. Radioactive water can also be used for the cleansing of tooth-brushes, sponges, and artificial dentures.

Trauner reports very good success from radium treatment, which he employs in much the same way as Warnekros. He finds that odontalgia, fetor, and suppurations are cured in a remarkably short time. Gingival pockets heal readily, the gums receding only to a small extent, and the formation of tartar seems to be retarded. If concentrated solutions of the rinsing-water are employed, a venous hyperemia of the gingivæ and intermittent hypersensitivity of the teeth are noted in some patients. Trauner warns against too optimistic expectations from radium treatment, which will not regenerate lost tissue or take the place of surgical or other measures, such as the establishment of drainage for pus, or orthodontic procedures in pyorrhea caused by malocclusion.

[*Correspondenz-Blatt fuer Zahnaerzte*, Berlin, April 1913.]

DENTAL CONDITIONS IN NORTH AMERICA. BY DR. K. COHN, BERLIN.

Cohn describes his impressions received during the visit to the United States of the German Association for Medical Study Travel last summer, in which a number of representative practitioners and teachers of dentistry took part. While medicine has been imported from Europe to America, this country is the cradle of dental practice and science, and it is interesting to note how the writer, though sincerely admiring American dental institutions, believes that in some respects the children have outgrown the foster-mother. In regard to preliminary education, he notes a certain laxity, especially a regrettable ignorance of the classic languages. He believes that the practice of obliging men to attend a prescribed annual course of studies is incompatible with the idea of academic freedom that governs German universities, and is detrimental to the development of character and self-reliance in the student. The lack of reciprocity in the license to practice dentistry in the various states is criticized as provincial, undignified, and detrimental to a uniformally high professional standard. The great number of demonstrators in the various institutions is recommended on the one hand; on the other, however, the fear is expressed that the instruction suffers in uniformity. As an illustration, the acknowledged inefficiency of orthodontic treatment is cited, the instructor in orthodontia in one of the leading colleges being alleged to have confessed to the writer that hardly two per cent. of the students have any knowledge of orthodontia upon graduation. The lack of knowledge in the field of local anesthesia, of the surgical treatment of pericemental abscess, or surgical prosthesis, and of X-ray work comes in for a large share of censure. The prevalence of the practice of general anesthesia—usually nitrous oxid and oxygen anesthesia—does not meet with the author's approval, and the lack of interest for surgical prosthesis in cases of fractures and deformities, and for the making of obturators with a view to esthetics and phonetics, appears as startling to the writer as the lack of X-ray apparatus or of efficient appliances for the sterilization of dental instruments in most of the dental schools. These impressions are summarized in the rather left-handed compliment that "If we had come to America twenty-five years ago, before we had our institutions in Germany, the American schools would have made a wonderful impression upon us."

Cohn admires the loyalty of the American patient to his dentist, the practical arrangement of dental offices, and the absence of advertising by ethical practitioners. In regard to the manufacture of dental supplies, he remarks that within the last twenty-five years enormous steps in advance have been made in Germany, so that in a short time the German dentist will no longer be dependent upon the American market. The efforts at public oral hygiene, notwithstanding the Forsyth foundation, seem to be still rudimentary as compared with the institutions established for this purpose in even very small German communities.

All in all, this report is most instructive to the critical and progressive American dentist who is willing to profit from the way in which "others see us," all the more so since the sting of criticism is mitigated by a most charming acknowledgment of the courtesies and hospitality bestowed upon our German colleagues during their sojourn here by federal and municipal authorities, universities, schools, physicians, dentists, and dental dealers and manufacturers.

[*Sud-Est Dentaire*, Marseilles, January 1913.]

A METHOD OF ANESTHESIA OF THE PULP AND DENTIN IN UPPER INCISORS AND CANINES BY TOPICAL APPLICATIONS IN THE NASAL FOSSA. By Th. Raynal.

Rhinologists have often observed that local anesthesia produced for the purpose of nasal operations establishes simultaneous anesthesia of the upper teeth. Profiting from this observation, Raynal deposits on the floor of the nose on the side where the dental operation is to take place a pellet of cotton saturated with the following solution: Cocain hydrochlorid, 1 gram; 60 per cent. alcohol 2 gram; sodium bicarbonate 1 gram; salol 0.05 centigram; freshly boiled distilled water 8 gram. This is allowed to remain from five to ten minutes, when a second application is made, the cotton this time being saturated with the following solution: Menthol crystals, stovain, carbolic acid, āā enough to make 5 centigram; cocain hydrochlorid 0.25 centigram; pure adrenalin 5 milligram. Care is to be exercised in this second application not to use too much of the mixture, as any excess flowing down into the throat produces disagreeable effects. For this reason, the patient's head is inclined forward as in taking a plaster impression. After from five to ten minutes an anesthesia is obtained sufficient for the proper excavation of a sensitive cavity or the extirpation of a pulp. It is important not to introduce the tampon too deeply into the nose, owing to the situation of the anterior superior dental nerve. The patient notices a peculiar sensation of dilatation of the nasal fossa which, however, wears off after a few hours. The author prefers this method to hypodermic injections, but considers it as being contraindicated in highly nervous and asthmatic patients.

Periscope.

Atropin to Relieve Iodism.—Atropin will relieve the symptoms of iodism in a remarkable expeditious manner.—*St. Louis Med. Review*, per *Amer. Journ. Clin. Medicine.*

Removing Plaster from a Denture.—The last particles of plaster which may adhere to the unpolished surface of a vulcanite plate can be entirely removed without any difficulty by placing the plate, when polished, into a solution of lysol. The stronger the solution, the less time required for removal of the last trace.—*Edwards Dental Quarterly.*

Avoiding the Splitting of a Root in Removing a Post.—In removing a post from a root with a post-puller, a piece of German silver is cut to fit over the end of the root and punctured, and the post is allowed to pass through and then removed. This eliminates the possibility of splitting the root in case the end should be uneven.—E. T. Tinker, *Dental Review.*

Postanesthetic Accidents from Chloroform.—Nicloux and Fourquier, after extensive experimentation on animals, have decided that postanesthetic accidents from chloroform are due to profound diminution in the alkalinity of the blood and rapid subtraction of its mineral constituents. Administration of sodium bicarbonate gave negative results, but the authors think they are on the right track.—*Presse Médicale* per *N. Y. Med. Journal.*

An Aid in Burnishing Platinum Matrices for Porcelain Inlays.—In burnishing a matrix for a porcelain inlay cavity, when it is difficult to prevent the platinum from shifting, one part is burnished thoroughly, and slightly warmed temporary stopping is forced into that part of the cavity. This holds the matrix firmly in place and permits the completion of the burnishing without any distortion.—E. S. Best, *Dental Review.*

Holder for Polishing Gold Shell Crowns.—Many crowns are bent out of shape in polishing because they cannot be held firmly. An ordinary clothespin may be used to advantage by pressing the two beaks together and slipping on the crown. The beaks are convex, and conform with the walls of the crown, and serve as an excellent holder. One may have to sharpen the beaks to fit small crowns.—F. F. Schwartz, *Dental Review.*

A Simple Method of Polishing Instruments.—Strips of emery and rouge cloth of the finer grades, one and one-half inch wide, folded once lengthwise, and held securely with one end in a small vise or a close-fitting workbench drawer, provide one of the best means for quickly and effectively polishing all kinds of instruments. A stroke similar to that employed in stropping a razor is used, at the same time turning the instrument between the thumb and finger. These strips last a long time, and improve with use.—G. A. Bowman, *Pacific Dental Gazette.*

Protecting the Skin from X Rays.—Silk fabric impregnated with certain lead salts is impervious to X rays, and may be used to protect portions of the body of the subject or of the operator from the untoward effects of the rays. Silk treated with lead phospho-stannate and other salts contained 68 per cent. of mineral matter, including 34 per cent. of lead oxid, 24 per cent. of tin oxid, 8 per cent. of phosphoric anhydrid, and 2 per cent. of quicklime and other alkalies. Slight discharges of X rays were particularly arrested by two layers of this fabric, while six layers were found ample to protect the skin against the action of an ordinary discharge of medium strength. This fabric had the same protective effect as a sheet of copper 0.044 mm. thick, with the advantage of flexibility even when used in several layers.—*Knowledge* per *Dental Scrap Book.*

Chronology of the Eruption of the Deciduous Teeth.—After examining over 1200 children, Dr. Pont suggests the following chronology for the eruption of the deciduous teeth, which is fairly accurate and easy to remember: Lower central incisors, 8th month; upper central incisors, 10th month; lower lateral incisors, 12th month; upper lateral incisors, 14th month; lower first molars, 16th month; upper first molars, 18th month; lower canines, 20th month; upper canines, 22d month; upper second molars, 24th month; lower second molars, 26th month.—*Le Laboratoire et le Progrès Dentaire.*

Porcelain Molar Crowns.—The root is prepared in the same way as for a Davis or a Logan crown, at least two of the root-canals are enlarged, an S. S. White counter-sunk tooth is ground to fit approximately the end of the root, the pins having been removed, leaving room for a cast base. After fitting the posts, an impression of the root is taken in inlay wax, using the crown to force the wax to place. All surplus wax is carved off, the crown removed, and the wax, with pins attached, invested and cast. The crown is cemented to the finished casting, and a very naturally appearing crown is obtained.—C. L. Haywood, *Dental Summary.*

Cementation of Inlays.—Great care should be exercised in the cementation of inlays. Many inlays are failures because of the fact that the operator used a cement totally unfit for this purpose. The cement should have very fine granules, for there are some cements on the market the granules of which measure about 0.05 of an inch. If, however, a cement of proper consistence is used, and a portion of the cement is smeared in the cavity as well as on the inlay, and the inlay pressed in and held firmly, the margins being thoroughly burnished with a smooth burnisher during the hardening process, we can expect to produce an inlay that is ideal. —T. P. Hinman, *Journal of Allied Societies.*

Setting of Porcelain Crowns or Inlays.—In the setting of porcelain crowns or inlays an assistant should, whenever possible, mix the cement and apply it to the inlay or crown to be inserted, while the operator is drying the tooth or root and covering all of its surfaces with the cement, so that, when the cement is right, no delay or chance of interference by moisture or air-spaces may occur. The patient, too, should be required to remain in position until a sample of the cement that has been retained is completely set. Attention to detail is requisite in porcelain work, and the operator must be prepared to exercise it to the utmost—and he will find himself well repaid for his efforts.—J. J. Moffitt, *Dental Brief.*

Hydrogen Dioxid in Local Anesthesia for Dental Work.—G. Mahé and P. Vanel report the results obtained with an anesthetic mixture consisting of equal parts of five volume hydrogen dioxid solution and one per cent. cocain or four per cent. novocain solution. The chief advantage of such mixtures is avoidance of the untoward effects of epinephrin, while the bloodless operative field and increased anesthetic power of cocain or novocain effected by epinephrin are nevertheless retained. The injections should be made superficially and slowly, with a tepid solution, and stopped as soon as the tissues become pale. The solutions referred to are especially indicated for the extraction of teeth in nervous individuals, children, old persons, diabetics, and pregnant women.—*Presse Médicale* per *N. Y. Med. Journal.*

Bridge Attachment.—If, in posterior bridges, the teeth to be used as abutments are so far out of the parallel as to make construction of the bridge in the ordinary way impossible, a hook is cast to the posterior crown, the upper or bent portion of the hook being set parallel with the anterior abutment. The hook is made with rectangular sides, which converge slightly from below upward. This hook is used as the posterior abutment, being made to lock accurately into the casting which supports Steele's facings, and is attached to the anterior crown. In mounting, the posterior crown with attachment is first cemented into position, the other portion of the bridge being immediately afterward temporarily pressed into position, to insure correct assemblage of the parts. Finally, the anterior portion is firmly cemented to the anterior abutment, and also to the attachment on the molar crown.—P. Parker, *New Zealand Dental Journal.*

Sweating Bands.—The band is cut in the same manner as for soldering, edge-to-edge contact—not a lap joint—clean surfaces, and close adaptation being essential. Very little borax is used, and a thin blowpipe flame is applied until a white heat is obtained. The surface of the metal will melt, and the molten metal will run into the joint of the band. At this point great care must be exercised not to burn the band, because brittleness of the band will result, if too much heat is applied. After a little practice, a band can be sweated as easily as soldered. Sweating is far preferable to soldering, for the following reasons: No seams can be detected in the sweated band; a sweated joint is stronger than a soldered one; in bridge work, no solder will be drawn out of the joint of the band in filling-in the dummies; the scrap gold is not contaminated with solder, and can be used for inlay work; a considerable sum is saved on 22-k. solder.—C. S. CUDEN, *Dental Summary.*

Treatment of Vincent's Angina.—T. H. Halstead states that in his experience the best results were obtained by the use of trichloracetic acid in the mild cases of Vincent's angina. He begins by removing the membrane with hydrogen dioxid solution and wiping off with a cotton swab. A ten per cent. solution of cocain hydrochlorid is then used to anesthetize the ulcer, and a few minutes later the trichloracetic acid is applied. Three or four applications, at intervals of two or three days, are sufficient; in fact, sometimes but one is required. Tincture of iodin is preferable to the acid in the presence of extensive ulceration. An important feature in the treatment is that the general condition of the patient must be improved. The teeth must, in particular, be cared for, as no progress can be expected while caries and the accompanying ulcerations are allowed to remain.—*Lancet-Clinic* per *N. Y. Med. Journal.*

Compensating for the Expansion in Plaster Models.—The inherent tendency of all varieties of plaster is to expand in setting. When confined by the sides of the impression and tray, warpage of the model results, the palatal portion of the latter rising to a slight extent. To obviate this difficulty, the impression is removed as soon as possible after the plaster constituting the model has set. This can usually be done in from ten to fifteen minutes after pouring the impression. Although this method obviates warpage, it does not control expansion, which goes on for twenty-four hours or more. The expansion is compensated for by scraping a shallow, rounded groove around the labial and buccal periphery, and a sloping but definite groove across the disto-palatal portion of the model at the point where the distal margin of the denture will terminate.

Models should be of sufficient thickness to withstand stress exerted in closing the packed flask, viz, they should be usually not less than 8 mm. thick in their thinnest part. —J. H. PROTHERO, *Dental Summary.*

Treatment of Trifacial Neuralgia by Electrolysis.—A. Réthi has obtained excellent results in three obstinate cases of trifacial neuralgia by electrolysis of the infraorbital or supra-orbital nerve. The needle employed, of the thickness of a sewing needle, was covered to within three-quarters to one centimeter of its extremity with a thin layer of insulating material, in order to preserve the skin and deeper healthy tissue from injury. One half-hour before the electrolysis, a subcutaneous injection of 0.01 gram—1.6 grain—of morphin hydrochlorid was given, and fifteen minutes later the skin was asepticized, and a deep injection of morphin into the nerve-canal made in order to insure anesthesia of the nerve. At the expiration of the half-hour, the electrolytic needle, constituting the negative pole, was introduced into the canal, the other electrode, suitably moistened, being applied to the side of the face. A current was then passed, gradually increased to twenty, twenty-five, and thirty milliampères, for a period of fifteen minutes, after which the strength of the current was reduced. The procedure was well borne, and the skin remained quite intact, except for a slight evanescent swelling on the day following.—*Semaine Médicale* per *N. Y. Med. Journal.*

Technique of Root-Amputation.—Having fully determined upon the necessity for a partial root excision—and this presupposes that said root has undergone the proper and necessary preliminary treatment, with a final filling inserted therein—the already established sinus is to be increased in diameter by making a slight lateral incision in opposite directions to the opening, this to be followed with a few packings of gauze, which will usually bring into view very distinctly the end of the root. The amount of tissue to be removed will have some influence in determining as to how it can best be accomplished expeditiously. If only a minute portion of the end of the root is to be removed, it can best be done with a suitably selected stone run by the dental engine; if, however, a greater area is involved, I would first use a diamond-shaped drill, passing it through the root, and succeed this with a fissure bur, cutting both ways until the end is severed from its parent. Final smoothing of the roughened end left by the bur can best be done with a fine Arkansas stone. Thorough flushing of the cavity with a warm, normal salt solution immediately following the operation places the surrounding tissues in a most favorable condition for future recovery. —J. G. REID, *Dental Review.*

Cleanliness of the Cement Slab an Important Factor in Mixing Cements.—The first requisite for a proper mix of cement is a perfectly clean glass slab, from which every trace of cloudiness from previous mixes has been removed. This can best be accomplished by allowing the slab to remain for several hours in water to which a few drops of hydrochloric acid have been added. In order to do this, it will be necessary to have more than one slab, and it will be a great convenience to have a number—say from two to three dozen. These can be used freely, there being always a clean one, and at a convenient time all the used ones can be cleaned at once. I have not found it necessary to use the large, beautiful glass slabs which the demonstrators at clinics use, but cut mine from ordinary window glass. By so doing, expense and bulk need not prevent the dentist from having all the slabs he desires. I keep an acid bath in a glass dish in the laboratory, and from time to time the used slabs are dropped into it, those that have been in the bath being taken out, rinsed and dried, and placed back in the cabinet ready for use.—G. C. Poundstone, *Dental Review.*

Restoring Dry-Cell Batteries.—Numerous methods of restoring to usefulness worn-out dry cells have been given in the semi-scientific journals, especially since the advent of the autocar and autoboat. The idea of restoring an inactive cell, one that has ceased to give out current, is based upon a misunderstanding of the principles underlying the construction of a dry cell. Dry cells, when in good condition, are not dry. The electrolyte is held by an absorbent material, and the cell sealed so that it can be handled freely in any position without leakage. Sometimes the electrolyte is lost by evaporation, the cell becomes "dry," and is then inactive. If when in this condition a new supply of electrolyte is introduced the cell again becomes active, and is said to be "restored," and so it is, to a certain extent. A cell so treated may continue to be useful for an uncertain period, but as its life depends upon the chemical agent whose decomposition supplies the electric energy, and this is not renewed by the treatment, the continued usefulness is a very uncertain quantity. Within the last few years the manufacture of dry cells has been very much improved; they are more reliable, they are better made, and more attention is given to the character and quality of chemicals used. These are now so accurately apportioned in the better grades that standard dry cells have become very much like the famous "one-horse shay"—when they give out they give out all over, and, as they are so inexpensive, they are best restored by installing new ones. Dry cells cannot be recharged like storage cells.—W. H. Trueman, *Pacific Dental Gazette.*

Success and Failure of Vaccine Therapy in Mouth Affections.—Although vaccines are an extremely useful means of treating bacterial disease, and their use in many instances is attended by results not otherwise attainable, yet they are not by any means a universal panacea, and unexpected failures sometimes occur. To what can we attribute these failures?

(1) We must remember that we are endeavoring to induce an active immunity in the patient to the infecting organism, and if we fail to get a vaccine of the correct organism, our attempts to produce this immunity and so cure the patient must also fail; (2) the dose of the vaccine given may be unsuitable, either too small to produce any immunizing response or too large, and with a succession of such large doses no good can result, as instead of producing immunity we are lowering the resisting powers of the patient; (3) although the organism of which the vaccine is made may be correct and the doses admirably adjusted, yet the immune substances in the blood may not properly reach the focus of infection; (4) the patient's tissues may not respond to the stimulus of a correct dose of a suitable vaccine through failure of the immunizing mechanism, and (5) there may be factors of which we are at present completely ignorant.

To get the best results, then, with vaccine therapy, it is essential to have the infecting organism determined as certainly as possible, to have the vaccine carefully and correctly prepared, to give the vaccine in suitable doses at well-adjusted intervals, and finally, to bring the blood and lymph streams rich in immune substances to the focus of infection, where they can come in contact with the bacteria and so aid in overcoming the infection. —Dr. Loveday, *Dental Record.*

Experimental Study of Some Effects of Certain Anesthetics.—The drugs—viz. chloroform, ether, nitrous oxid-oxygen, and cobra venom—used by Yates in his experiments were found capable of instituting degenerative changes in the parenchyma of the heart, liver, and kidney, or of aggravating such changes when already established. These metamorphoses were found to bear a serial relationship of increasing severity from which recovery is not always possible. Anesthetics are regarded by Yates as toxic in their effects, and should, he says, be adminstered with due regard to their most dangerous action as affected by individual conditions. Ideal general anesthesia, pleasant and safe, seems to be impossible until a drug is found which will have a purely selective and benign action on the sensorium. The nearest approach thereto may be the development of methods requiring the minimum of the least injurious drugs (probably the most transitory in action), *i.e.* which will least impair, or may possibly enhance, the efficiency of cardio-vascular, respiratory, or defensive mechanisms.

Discouraging discordant opinions, based on personal experience and clinical observations, and therefore frequently biased, Yates believes, justify the statement that there is no one method of anesthesia, single, combined or sequential, which is so safe as to warrant its invariable application; on the other hand, chloroform may be said to possess no redeeming feature. The observations made by Yates in his series of experiments on unfavorable animals under untoward conditions are in such accord with clinical evidence as to give hope that the experiments now under way, designed to determine the degree of persistence of the lesion caused by drugs and their effects on resistance to infection, may permit of valuable deductions.—*Wisconsin Med. Journal*, per *Journ. Amer. Med. Association.*

Failures With Buckley's Formocresol.—The action of this remedy when sealed in the pulp chamber of a tooth the canal contents of which are putrescent is twofold. On the one hand, it is so powerfully disinfectant that it kills the germs of various kinds which abound there; and on the other, it chemically unites with some of the gases which are byproducts of the putrefactive process, rendering them inert, so that further swelling, pressure, and pain are prevented.

This action is positive and uniform in all cases where a proper technique is observed. This technique begins with the remedy itself, which must be a fairly *fresh* preparation. Formalin is a solution of formaldehyd in water, and like all such solutions, gradually gives off the gas, so that an old mixture of formocresol or even a fresh mixture made up with an old solution of less than 38 per cent. formaldehyd, cannot be expected to give results. This is one cause of failure in the use of this valuable drug, and one easily remedied.

Another cause of failure is neglect to place in the tooth a sufficient quantity of formocresol to produce a prolonged effect upon the bacteria, or enough to supply formaldehyd gas to unite chemically with the gases of putrefaction and render them inert as rapidly as they are formed.

We are frequently confronted with cases where it is impossible to seal in more than the most minute quantity, owing to the great loss of tooth structure. In these cases it is better to resort to solidified formaldehyd. Of this last substance a piece not larger than the head of a brass pin, wrapped in a little cotton, may be gently placed in the mouth of the canal and hermetically sealed and left not longer than twenty-four hours.—C. S. Tuller, *Dental Summary.*

Soldering.—Between hard and soft soldering there is this essential difference: In soft soldering the heat is supplied to the solder; in hard soldering, to do so is to fail. In hard soldering the heat must be applied to the work, otherwise the solder fuses to a ball, and is apt to become slightly oxidized; it then requires skilful management to make a good joint. The tendency is to flow over the joint instead of into it, and while apparently the job is well done, the joint is weak and will give way when subjected to strain. This may be illustrated by taking two pieces of tin plate, joining them together by folding the edges, and lapping them together like the joint down the side of a tin can. Now lay a few fragments of wax along the joint where the two pieces of tin come in contact with each other. Apply heat, and as the wax melts, it will appear to be sucked into the joint as if by capillary attraction, and when hard solder does this, you may be sure that you have an ideal joint. Regarding the matter of heat, insufficient heat is a great cause of a beginner's trouble. What is really required is a surplus of heat, so that you not only get the work hot enough, but get it hot quickly, otherwise oxid forms and makes it almost impossible to get a sound joint. Insufficient heat is a frequent cause of melting or burning the work itself. Strange as it may appear, the more heat you have at your command the less likely is this to happen. It is a small supply of heat which has to be kept up a long time which causes the trouble, as it oxidizes the work and the solder before the solder gets hot enough to run. If you have plenty of heat and do not apply it quickly enough, the same state of affairs sets in, and the work is burned or melted. Burning is a surface fusing accompanied by an oxidation that roughens and weakens the metal. A good soldered joint should be made as doctors speak of a wound healing—"by first intention"—for if you have to start tinkering with it, it generally goes from bad to worse.—*Electrician and Mechanic*, per *Dental Brief.*

Dangers from X Rays to Operators and Patients.—The following may be briefly said to be the danger to which the operator in radiography is exposed: If he will observe strictly the rule to remain behind a lead screen or in a lead cabinet he may work for a period of ten or twelve years in safety. What the dangers of exceeding this time limit are we do not know; perhaps there are none. Perhaps all the older X-ray operators will die of leukemia within the next ten years. Who can say? We are entitled to our opinions, but no one really knows. The pioneers in the work are still in danger; we who follow are comparatively safe.

Though the operator need never expose any part of his body to any except the weak, harmless X rays which fill the room, it is necessary to expose at least that part of the patient being radiographed to the direct rays. The question arises, How long may we expose the patient with perfect safety without any danger whatever of producing acute dermatitis? Authorities are very reluctant to set this time limit.

The very few cases of serious acute dermatitis due to exposure for radiographic work occurred when the outfits used were so small that the time of exposure reached thirty minutes and longer. Compare such exposures with those of today, which range from a fraction of a second to only one minute at most, even with the small suitcase outfits, and the improbability of producing dermatitis will be appreciated.

The first rule regarding the exposure of patients should be—Never expose the patient longer than absolutely necessary. Even with the smallest apparatus, and where a number of exposures are necessary, the aggregate time of exposure need not and should not exceed two minutes. If it is necessary to use this full time, two minutes in one day, then do not expose the same part of the same patient for a week or ten days. Give the skin a chance to recover from any change produced in it, and so guard against a cumulative effect of the X rays. I cannot imagine a case in dental radiography which would require an exposure longer than two minutes. And seldom, indeed, will it be found necessary to expose the patient, even in the aggregate, when several radiographs are made, as long as the time limit set.

Two minutes is a conservative limit—in fact, a five-minute exposure would in all probability prove harmless—but keeping inside of it, we may have the assurance that, except in a case of most extraordinary susceptibility, amounting to positive idiosyncrasy, nothing more than a very slight acute dermatitis, no worse in its effect on the health and happiness of the patient than a mild case of sunburn, could possibly occur. And even this slight acute dermatitis is so extremely unlikely to occur that the careful operator need not expect it. Thus, so far as the patient is concerned, X rays are perfectly harmless, if the operator is careful. The danger to patients from infection by instruments is infinitely greater than the danger from the sensible use of the X rays for radiographic purposes. In the early days of the X rays there was a tendency to attribute X-ray burns, not to the rays themselves, but to some accompanying factor, the exclusion of which would prevent the occurrence of X-ray burns. Thus it was suggested that burns were due to an electrical condition surrounding the tube; to chemical conditions surrounding the tube; to bacteria being carried into the tissues by the X rays; to violet rays, and so on. It is generally conceded today, however, that X-ray burns are the result of a specific action of the X rays themselves on the tissues.—H. R. Roper, *Items of Interest.*

Hints, Queries, and Comments.

IS THERE METABOLISM IN HUMAN DENTIN?

The question whether any metabolic changes take place in human dentin after the tooth is completely formed has for a long time been discussed, and opinions are still greatly divided. Charles Tomes, in his "Manual of Dental Anatomy," says: "In the hard or unvascular dentin, some degree of nutrition is perhaps provided for by the penetration of the whole thickness of the tissue by protoplasmic fibers, the dentinal fibers." Other authorities speak as vaguely about this subject. While some investigators, particularly in America, deny the presence of any metabolism in the completely formed dentin, others as decidedly assume its presence, without giving any conclusive proofs of their hypothesis. The following case that came to my knowledge proves, in my opinion, that a very active metabolism may take place in dentin:

Mr. K., 52 years of age, a healthy man of a strong constitution, slipped two years ago in the street and fell headlong on his face, so that his chin and nose were bruised and bleeding. The four upper incisors were very painful and a little loose. On closer inspection, a few days after the accident, the central incisors displayed reddish spots, which covered almost half of the labial surface and were darkest in the center. The right lateral incisor exhibited the same aspect, only the red spot was smaller. I advised the patient to have the pulps of these four teeth removed and the teeth bleached and properly treated, warning him that the pulps of these four teeth would die, which would give rise to further complications, while the teeth themselves would become still darker. The patient feared that the proposed treatment would cause him great pain, and refused to submit to it, and on his own account painted his gums with tincture of iodin.

My prognosis was partly realized afterward. For some weeks the patient had severe pain in those four incisors, which finally wore off. The reddish spots on the two central and the right lateral incisors had become dark blue, and had almost the color of a so-called blood-blister. Once more I advised the patient to have these teeth properly treated, but without any success. For some time, I did not hear any more about this case.

The patient later communicated to me that those discolored teeth had become white again, which I at first would not believe, but a single look at his teeth convinced me that his assurance was true. On my request, the patient allowed me to ascertain by the aid of the electric current that the pulps of the affected teeth had retained their full vitality. I also noted that the spots which had been dark blue were still faintly distinguished from the rest of the tooth by a yellowish, hardly perceptible tint.

Now, four years later, the sound teeth are still in the same good condition, and the pulps react normally.

It is evident that we have here an extravasation of blood which had penetrated the dentin, was decomposed, and almost entirely resorbed again after some time. In my opinion this case is not to be explained in any other way than by acknowledging the presence of a fairly active metabolism in the dentin.

ALEX MERTENS.

The Hague, Holland.

ELECTRIC DEVICE FOR WORKING MODELING COMPOUND.

MODELING compound is of very great value to the dentist, especially to the specialist in orthodontia. Owing to the prevalent very crude methods of manipulating this material, however, poor results are often obtained. In most cases the compound has been worked either too hot or too cold, and the bad results that most dentists have obtained are entirely due to faulty manipulation.

As an example, the S. S. White modeling compound may be cited. The directions say: Bring the water to the boiling-point, set it off the fire, place the compound in the water, soften, and use immediately. I have proved to my own satisfaction that the S. S. White compound can be worked very much better if put in water that is just tepid, and allowing it to remain until the water is heated to 170°.

The directions for Kerr compound, to cite another example, are very misleading. It is stated: Place the compound in water as hot as the hand can bear. As there is a difference of at least ten degrees in the amount of heat which the hands of different individuals can tolerate, it is readily seen that the temperature one hand can bear would be excessive for a compound, while another individual would underheat it. It has been my experience that the Kerr compound works best at 145°.

The directions given for the Consolidated modeling composition are about the same as those accompanying the Kerr compound. I have found that it works best at 150°.

The electric water-heater, illustrated in Fig. 1, can be purchased in any electric supply shop for $3.50. The appliance for holding the thermometer (see Fig. 2) in the heater can be made by any dentist who has had any experience in bending Jackson wires. The holder, illustrated in Fig. 3, with the desired quantity of compound, which is prevented from adhering to the holder by a piece of cheesecloth laid in it, is placed into the heater, which is filled with water at a temperature of about 60°. The current is then turned on, and the temperature of the water is raised to the point best adapted for manipulating the brand of compound used. If a temperature of 150° is required, the current should be turned off when the thermometer registers 140°, as it will be found that the heat will rise ten degrees higher than the point at which the current was turned off, and the water will remain at that temperature for about five minutes.

FIG. 1.

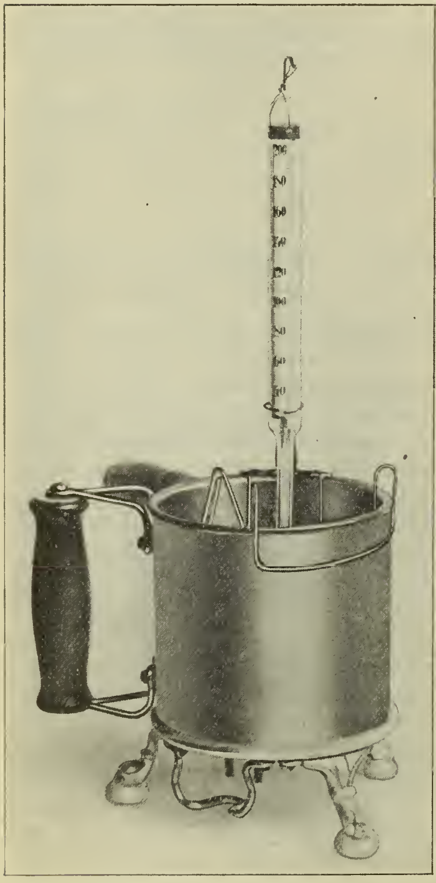

FIG. 2.

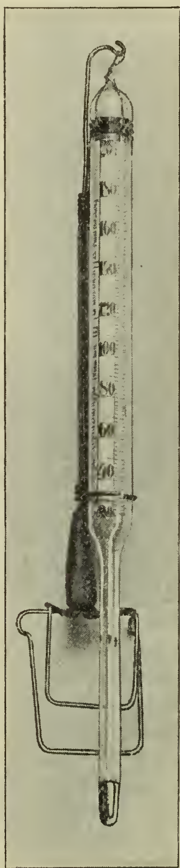

FIG. 3.

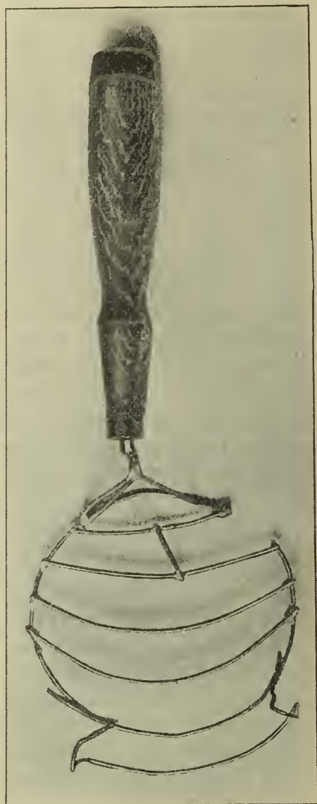

This whole outfit is very inexpensive, and will appeal to those who are striving to obtain the best results possible with modeling composition.

Wilkes-Barre, Pa.

Obituary.

Brief Necrology.

Dr. John C. Wilson of Wichita, Kans., on May 18, 1913.

Dr. Arthur W. Minaker of San Francisco, Cal., on April 25, 1913.

Dr. Robert Burns Gibbs of Harrodsburg, Ky., on June 2, 1912, in his seventy-fourth year. Deceased was a veteran of the civil war.

Dr. Robert McKissik of Philadelphia, Pa., on June 8, 1913. Deceased was a graduate of the Pennsylvania College of Dental Surgery.

Dr. William A. McGiffin of Pittsburgh, Pa., on May 20, 1913, in his sixty-third year. Deceased was a graduate of the Philadelphia Dental College.

Dr. John Muth of New York, N. Y., on May 31, 1913, in his sixty-fifth year. Deceased was a graduate of the New York College of Dentistry.

Dr. Calvin King of Pittsburgh, Pa., on May 8, 1913, in his eighty-fourth year. Deceased was a graduate of the Ohio College of Dental Surgery.

Dr. Andrew Bailey Fonshill of Baltimore, Md., on May 14, 1913. Deceased was a graduate of the Dental Department of the Baltimore Medical College.

Dr. Frank L. DeGour of Reading, Pa., on June 6, 1913, in his seventy-sixth year. Deceased was a graduate of the Pennsylvania College of Dental Surgery.

Dr. Anthony J. Casey of Niagara Falls, N. Y., on May 20, 1913, of paralysis. Deceased was a graduate of the College of Dental Surgery of the University of Michigan.

Dr. William Brayton Mann of Baltimore, Md., on May 23, 1913, of blood-poisoning and pneumonia, in his fifty-eighh year. Deceased was a graduate of the Maryland Dental College.

Dr. John N. Farrar of New York, N. Y., on June 12, 1913, in his seventy-fourth year. Deceased held the degree of M.D., and was a graduate of the Pennsylvania College of Dental Surgery. He was the author of several papers on dental subjects, especially the correction of irregularities of the teeth.

Dental College Commencements.

NORTH PACIFIC COLLEGE.

The annual commencement exercises of the North Pacific College were held on Wednesday evening, May 21, 1913, in Portland, Oregon.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Elmer D. Allen
Ralph O. Appleby
Addison J. Atwater
Ray L. Bathrick
Oran S. Bartlett
John A. Belfils
Lee H. Bequeaith
T. F. Blakemore
Fred G. Bleeg
Fred G. Bunch
John E. Clanahan
Louis Cooperstein
Charles S. Dent
John B. Dye
Clinton L. Foster
Charles E. Gard
Harritt B. Gehr
Theodore Gottlieb
Howard A. Hale
Seiichi Higashida
Alva J. Howard
Arthur Hudson
Roy N. Hunt
Eugene Isdell
Emil Jantz
Otto E. Kinder
Walter J. Larson
Ira D. Latimer
Harley M. Massey
Arthur G. MacDonald
Leo L. McKenna
Philip T. Meaney
Richard G. Moss
John G. Nash
Carl S. Ogsbury
Ralph E. Ostrom
George J. Petersen
Lucien A. Pickens
Francis Quinn
John T. Ryan
H. Arthur Shaeffer
Wenzel M. Skovgard
William H. Springer
Glenn A. Thomas
Arthur F. Weeks
Roy F. West
Benton S. Woods
Keijiro Yamamoto
Guy E. York

THE THOMAS W. EVANS MUSEUM AND DENTAL INSTITUTE SCHOOL OF DENTISTRY UNIVERSITY OF PENNSYLVANIA.

The annual commencement exercises of The Thomas W. Evans Museum and Dental Institute School of Dentistry University of Pennsylvania were held Wednesday, June 18, 1913, at the Metropolitan Opera House, Philadelphia, Pa.

The degree of Doctor of Dental Surgery was conferred by Edgar F. Smith, Ph.D., Sc.D., LL.D., provost, upon the following candidates:

Julio Aleman .... Panama
Otis A. Allen .... Pennsylvania
Clarence J. Appleget .... New Jersey
Assaad J. Attiah .... Egypt
Antonio E. Baca .... Spain
Alvin J. Bagenstose .... Pennsylvania
Jacob B. Balthaser .... Pennsylvania
John R. Barber .... Iowa
Milton D. Barkann .... New Jersey
Albert G. Barrett .... New York
William C. Bauer .... New York
Abram R. Beekman .... New Jersey
Homer R. Bell .... Pennsylvania
Miguel E. Bestard .... Cuba
Louis Blumberg .... Pennsylvania
Gabriel E. Blumer .... New York
Jerome Boley .... New York
Guy H. Brady .... New York
Jacob M. Brille .... France
Malcolm H. Brinton .... Connecticut
Merritt E. Brown, Jr. .... Vermont
John A. Burns .... Massachusetts
Peter A. Callery .... Pennsylvania
Archie A. Campbell .... Nebraska
Ernest G. Caston .... Maine
Ralph R. Chandler .... Pennsylvania
Justus W. Chatterton .... New York
Harvey N. Chichester .... New York
Robert L. Clement .... Pennsylvania
George A. Coleman .... California
Joseph A. Colman .... Pennsylvania
Israel S. Commins .... New York
Juan B. Costa .... Ecuador
Arthur B. Courtemanche ..... Massachusetts
Earl V. Cross .... Pennsylvania
Andrés D. Cruz .... Porto Rico
Charles M. Cuneo .... New York
Arthur J. Cunningham .... New York
Reuben L. Cutler .... New Jersey
Robert T. Daly .... New York
Harry G. Davenny .... Washington
Theodore A. DeRavin .... Australia
Willard F. Detrick .... New York
Juan J. Diaz .... Panama
Livingston W. Doering ...... Michigan
Hugh L. Donnelly .... Massachusetts
John F. Dunfee .... Pennsylvania
John Ells .... Maine
Henry H. Facteau .... New York
Laurence L. Fagan .... Pennsylvania
Austin L. Finan .... New York
William J. Finan .... New York
Walter A. Fitzsimmons ..... Pennsylvania
Edward A. Flanigan .... Pennsylvania
Eldred L. Fraser .... Scotland
André L. Fuchs .... France
Willhenry Fuller .... New York
Lanson F. Gainsway .... New York
Edwin H. Gale .... New York
Eugène L. Gandouin .... France
Henry M. Garrett .... South Carolina
Harry A. Ginsburg ...... Connecticut
Robert R. Gwydir .... New York
Henry S. Hargreaves .... France
Carleton T. Harris ...... New York
Charles M. Harris ...... Bahamas
Leslie B. Hart .... Australia
Terry M. Hart .... Georgia
Chester T. Hatfield ..... Nebraska
William H. Hatfield .... New York
Stanley N. Holt .... New York
Fred H. Housel .... Pennsylvania
Eric G. Ireland .... England
Miguel W. Jackson ..... Georgia
William J. Kelleher ..... New York
Charles H. Kemball ..... Scotland
Andrew J. Leitch .... Scotland
Gaston L. E. Lemaire ... France
Carl E. Levan . ... Pennsylvania
Harry H. Levine .... Virginia
Kenneth Lindsay .... Nebraska
Rae W. Lockwood .... New Jersey
Frank Lodge .... England
Carl W. Lofland .... Pennsylvania
Clyde R. Long .... Pennsylvania
Herbert C. Lyle .... Pennsylvania
Harry F. McCooey ...... Australia
De Witt K. McDonald ... New York
Harold J. McGinn .... Maine
George E. McMahon ..... England
Andrew MacGowan ...... New Jersey
Raymond S. Martin ..... Pennsylvania
Oscar Mattei .... Porto Rico
Andrew S. Mayers ...... Pennsylvania
Edward C. Melville ...... British West Indies
Henry S. H. Moore ..... Germany
Francis D. Morgan ...... Australia
William R. Morris ...... Australia
John A. O'Connor ...... New York
Roger L. Offen .... Connecticut
Walter O'Keefe .... Massachusetts
Albert J. A. Oossterbaan . Holland
Le Roy Owens .... New York
Horace B. Painter .... Pennsylvania
Raymond W. Pearson ... Pennsylvania
Eiffel A. Perras .... New York
James N. Perry, Jr. ..... Pennsylvania
Benjamin L. Protass .... Connecticut
Francis A. Provot .... New York
Edward A. Puderbaugh .. Pennsylvania
Hazimeh S. Rasi .... Syria
Henry J. Rees .... New York
Leon Reisner .... New Jersey
Otto Reiter .... New Jersey

Lloyd C. Robinson	Vermont
José Rodriguez	Central America
Charles J. Ruddy	New York
Donald W. Rupert	New Jersey

Allan K. Yost	New York
Harry C. Zellers	Pennsylvania

Degree conferred (as of the class of 1912) at University Council, December 13, 1912:

Samuel Bogatin John J. Keogh Charles M. P. Valette

DRAKE UNIVERSITY, COLLEGE OF DENTISTRY.

The annual commencement exercises of Drake University, College of Dentistry, were held on Wednesday, June 11, 1913, in Des Moines, Iowa.

The commencement address was delivered by Dr. Cleo M. Chilton, of St. Joseph, Mo.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Harvey A. Anderson	Iowa
Clyde C. Atkins	Iowa
Ed W. Balbridge	Iowa
Horance S. Beemer	Iowa
Robert G. Carper	Iowa
John F. Dwight	Iowa
John C. Gerche	Iowa
Clem W. Grady	Iowa
Charles H. Henshaw	Iowa
Marion E. Irish	Iowa
Clarence W. Johnson	Iowa
Frank A. Maassen	Iowa
Gordon B. Logan	Iowa
Joseph L. Minor	Iowa
Dow A. Rice	Iowa
Ray H. Stringfellow	Iowa

GEORGE WASHINGTON UNIVERSITY, DENTAL DEPARTMENT.

The ninety-second annual commencement exercises of George Washington University, Dental Department, were held in Memorial Continental Hall, Washington, D. C., on June 11, 1913.

An address to the graduating class was delivered by President Stockton.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Edward C. Alley	Kentucky
Elmer E. Briggs	Pennsylvania
Marie G. Brodsky	Russia
Claude Durfee	Illinois
Nathan Eisenstein	Massachusetts
John S. Hardester	District of Columbia
Carl B. Maphis	Virginia
John P. Marstella	Illinois
Charles W. Rich	Pennsylvania
Walter B. Silliman	Pennsylvania
Henry M. Spillan	New York
George E. White	Massachusetts
Edward Williams	Massachusetts

COLLEGE OF DENTAL AND ORAL SURGERY OF NEW YORK.

The annual commencement exercises of the College of Dental and Oral Surgery of New York were held in the auditorium of the Engineering Societies' building, New York, N. Y., on May 26, 1913.

The valedictorian was Harry H. Manville, D.D.S., and an address was delivered by Rev. Loring W. Batten, Ph.D.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Benjamin F. Adles
Jacob J. Alper
Carl G. Anderson
Israel Appleman
David Baumet
Annette Belivan
Zachary Blum
Louis Brach
Samuel M. Cantor
Stanislaw Chalupski
Samuel Colominsky

MEDICO-CHIRURGICAL COLLEGE, DEPARTMENT OF DENTISTRY.

The annual commencement exercises of the Medico-Chirurgical College, Department of Dentistry, were held in the Academy of Music, Philadelphia, Pa., on June 6, 1913.

An address was delivered by Dr. Edwin E. Sparks, president of State College.

The degree of Doctor of Dental Surgery was conferred by Hon. Henry F. Walton, president of the board of trustees, on the following graduates:

Guadalupe Asenjo, Garcia	Nicaragua
Walter A. Borden, Jr.	Pennsylvania
George F. Clarke	New Brunswick
Morris E. Cohen	New Jersey
John F. J. Collier	Pennsylvania
Leopold G. Delgado	Mexico
George M. Edwards	France
William M. Endlich	Pennsylvania
Thomas A. Feeney	Connecticut
Bertram T. Foulkes	New Jersey

Markus H. Weiss	Roumania

Society Notes and Announcements.

"F. D. I."

INTERNATIONAL DENTAL FEDERATION.

General Meeting to be held at The Hague, August 27 and 28, 1913.

The next annual meeting of the International Dental Federation will be held at The Hague, Holland, on August 27 and 28, 1913, in conjunction with a union meeting of the Nederlandsch Tandheelkundig Genootschap and Vereeniging van Nederlandsche Tandartsen, the two Holland dental societies.

Hotel Central, Lange Poten, has been selected as the headquarters.

Dr. C. Van DerHoeven,
43 Celebesstraat, The Hague, Holland.

FOURTH INTERNATIONAL CONGRESS ON SCHOOL HYGIENE.

The most important Health conference that has ever been held in this country is the Fourth International Congress on School Hygiene, which will take place in Buffalo, August 25–30, 1913.

This congress will deal with every phase of school hygiene, and will be attended by the leading hygiene and educational people throughout the world. An entire section has been devoted to Mouth Hygiene, with a large amount of floor and wall space set aside for an exhibit dealing with the same subject. The organization of both the literary program and the exhibit has been placed under the supervision of the National Mouth Hygiene Association. This is the greatest opportunity that has ever been accorded the dental profession to present in an effective manner the important relation that mouth hygiene bears to the general hygiene of the body.

To make a showing in keeping with the importance of this subject it is vital that the members of the organized dental profession throughout the country do their duty both as members of the various organizations and as individuals. A few individuals cannot make an impressive showing. It is therefore imperative that, in addition to a literary program and the presentation of an exhibit, a large number of dentists unite with the congress and attend the meeting, thus establishing the dental profession's interest in and right to participate in the hygiene conferences of the world.

An elaborate literary program has been prepared and an extensive exhibit is being arranged, committees having been appointed representing each state in the Union.

W. G. Ebersole, *Ch'man, Div. Mouth Hyg.*,
200 Schofield Bldg., Cleveland, Ohio.

NORTHERN INDIANA DENTAL SOCIETY.

The twenty-fifth annual meeting of the Northern Indiana Dental Society will be held at the great Steel City of Gary, September 23, 24, and 25, 1913.

W. Leroy Myers, *Sec'y*,
Rensselaer, Ind.

WEST VIRGINIA STATE DENTAL SOCIETY.

The seventh annual meeting of the West Virginia State Dental Society will be held in the assembly room of the Chancellor Hotel, Parkersburg, W. Va., August 13, 14, and 15, 1913. Opening session 2 p.m., Wednesday, August 13th. A cordial invitation is extended to all ethical members of the profession to attend our meeting.

Frank L. Wright, *Sec'y*,
Wheeling, W. Va.

EASTERN DENTAL SOCIETY OF PHILADELPHIA.

A joint meeting of the Eastern Dental Society and the Southeast Branch of the Philadelphia County Medical Society was held May 16, 1913, at the Southwark Branch Free Library of Philadelphia. The program was as follows: M. Weiman, "Relation of Medicine to Dentistry." H. Lowenburg, "The Etiologic Influence of Dentition on Diseases of the Early Years of Life." Chas. B. Schupack, "Importance of Preservation of the First Molar." Aaron Brav, "The Dentist and the Oculist." Lewis Fisher, "The Dentist and the Laryngologist." M. K. Fisher, "Dental Radiography." H. B. Shmookler, "Gastric Disturbances Resulting from Dental Caries."

The annual banquet was held May 15, 1913, the following officers being elected for the Eastern Dental Society: R. Freides, president; M. Schechter, vice-president; H. Golden, financial secretary; J. Coltune, recording secretary; Chas. Schupack, treasurer; Louis Jacobs, librarian; M. Weiman, historian.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending June 14, 1913:

First. Lieut. Robert H. Mills, upon arrival in the United States, will proceed to Fort Riley, Kans., for duty.

For the week ending June 21st:

First Lieut. Alden Carpenter left West Point, N. Y., June 14th, on leave of absence for one month and five days.

W. L. Reesman, ACT.D.S., will proceed to Texas City, Texas, and report to the commanding general, Second division, for duty.

First Lieut. Alden Carpenter is detailed to represent the medical department of the army at the seventeenth annual session of the National Dental Association at Kansas City, Mo., July 8 to 11, 1913.

Paragraph 14, Special Orders No. 60, March 14th, War department, is amended to read as follows:

First Lieut. Minot E. Scott is relieved from duty in the Philippine Department, to take effect on or about September 15th, and will then proceed to the United States; upon arrival will report by telegraph to the Adjutant-general of the army for further orders.

For the week ending June 27th:

First Lieut. George H. Casaday, upon arrival in the United States, will proceed to the Letterman General Hospital, Presidio of San Francisco, Cal., for duty.

W. L. Reesman, ACT.D.S., arrived at Texas City, June 22d, for duty with the Sixth Cavalry.

VOL. LV. SEPTEMBER 1913. No. 9.

ORIGINAL COMMUNICATIONS.

THE RATIONAL TREATMENT OF INFRA-OCCLUSION.

By J. LOWE YOUNG, D.D.S., New York, N. Y.

(Read before the Eastern Association of Graduates of the Angle School of Orthodontia, New York City, April 26, 1913.)

PROBABLY I shall meet with no opposition from the members of this society when I advocate the early treatment of malocclusion of every description. If you agree with this, then I wish to try to impress upon you the necessity of early diagnosis of cases in infra-occlusion.

TERMINOLOGY.

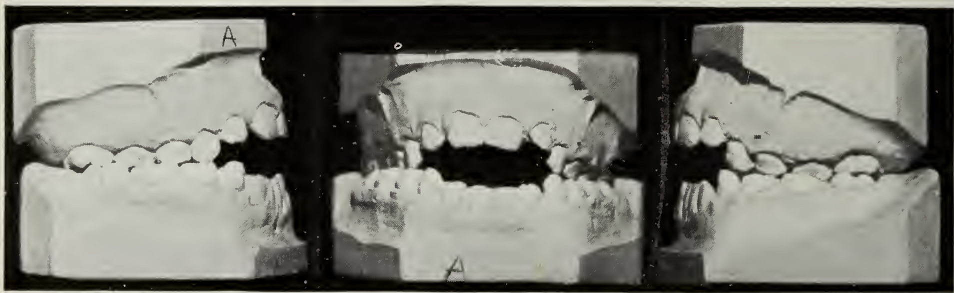
In order that there may be no misunderstanding and wasting of time in a discussion of what constitutes infra-occlusion, I wish to make it very clear what is meant by this term. In the seventh edition of Dr. Angle's book on "Treatment of Malocclusion" this definition is given for the line of occlusion: "The line of occlusion is the line with which, in form and position according to type, the teeth must be in harmony if in normal occlusion." I will therefore apply the term infra-occlusion to all teeth that require elevating in their sockets in order that they be placed in harmony with this ideal line. When the teeth are in harmony with this line, it is impossible for them to be in malocclusion. Consequently, whatever movement of the teeth becomes necessary to bring them into harmony with this line should be carefully considered.

It is possible to have any tooth in infra-occlusion, but for the purpose of this paper we may divide infra-occlusion cases into two classes: (1) Infra-occlusion of the anterior teeth, frequently termed "open-bite" cases, and (2) infra-occlusion of the buccal teeth, frequently termed "closed-bite" cases.

INFRA-OCCLUSION OF ANTERIOR TEETH, OR "OPEN BITE."

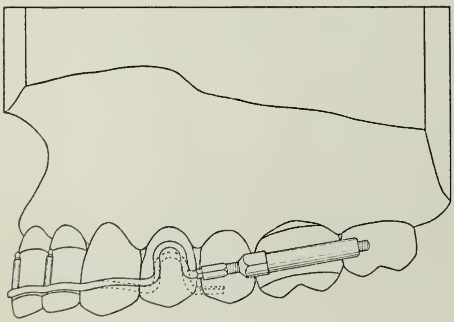
Infra-occlusion of the anterior teeth (Fig. 1) is usually due to habit of some description, and the earlier such a habit is determined, and if possible corrected, the more favorable becomes the prognosis of such cases. These so-called open-bite cases were very annoying to treat, and particularly difficult to retain, previous to the introduction of Dr. Angle's new orthodontic appliances. By means of these new appliances, it is possible to so apply force to these teeth that no slipping or loss of force is possible.

FIG. 1.



Appliance for treatment. In many cases the application of an orthodontic appliance as shown in Fig. 2 will be sufficient to elongate these anterior teeth. If found inadequate, these appliances can be reinforced by intermaxillary rubber bands. When found necessary to employ these, hooks are soldered to the

FIG. 2.



upper expansion arch in the region of the canines, projecting toward the gingiva. Directly under these, similar hooks are soldered to the lower arch, also projecting toward the gingiva. Over these hooks on each side a small rubber ring is worn constantly. If these rubbers give trouble by breaking, it has been found advantageous to use a larger rubber, and carry it back over either the upper or lower attachment on the molar bands, alternating if necessary, thus applying the rubber in a triangular way, but with the short side of the triangle in the region of the canines, which is the reverse of what will be shown in the treatment of cases where the molars are to be elongated. After such teeth have been elongated by using the intermaxillary rubbers, it is no longer necessary to continue their use, as the appliance of itself will hold these teeth in proper position, if the habit has been corrected.

INFRA-OCCLUSION OF BUCCAL TEETH, OR "CLOSED BITE."

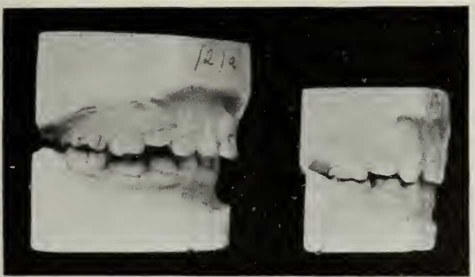
Infra-occlusion of the buccal teeth is due to lack of vertical development in this region. The causes of this maldevelopment in very young patients are obscure in many cases. When the buccal teeth are in distal occlusion, it is most logical to assume that the mandible has slipped back in the glenoid cavity. This is possible owing to the incomplete formation of the temporo-mandibular articulation, as has been shown by Dr. S. Merrill Weeks.* In the paper referred to, we read as follows: "It will be noticed that the condyle in normal cases does not rest as we might expect it to, in the deepest portion of the glenoid fossa, but at some point along the incline toward the eminentia articularis, the

* See *Items of Interest* for August 1909, vol. xxxi, p. 583.

point doubtless being determined by such features as the occlusion, condition of the ligaments, and muscles."

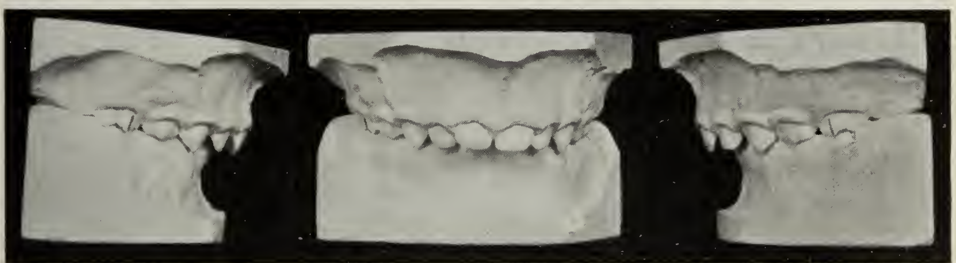
Lack of normal lateral growth of the upper dental arch, particularly in the canine region, I am convinced, is largely responsible for this distal position of the

FIG. 3.



mandible in many young patients. A careful examination of the models of our class II cases of eight years of age and under will show that, when the buccal teeth are placed correctly mesio-distally, the upper arch is too narrow to accommodate the lower teeth. In class II, division 2 cases, the retruding upper incisors prevent the molars from being so placed, but accurate measurements of the models in the canine region will show that lack of lateral development of the upper dental arch precedes the retrusion of the upper incisors. This distal position of the mandible tends to prevent normal development in the deciduous molar region.

FIG. 4.



During normal development, it is obvious that there must be considerable lengthening of the face and also vertical development of the dental arches. That this vertical development sometimes takes place during the eruption of the first permanent molars, Fig. 3 will serve to prove. How often these first permanent molars develop to a higher plane than that previously occupied by the deciduous molars it is impossible to judge from this specimen, as, in my opinion, the deciduous molars as a rule increase in vertical development during the time the first permanent molars are erupting. My observations have caused me to believe that there is always an increase in vertical development in the deciduous molar region in the period intervening between the eruption of the full deciduous denture and the eruption of the first permanent molars, in normal cases. This gradual vertical increase of the deciduous dental arches is responsible for the lengthening of the face so noticeable when we compare the face of a child of three years to that of the child from seven to nine years.

Suggestions as to treatment. I am impressed with the idea that it is impractical to depress the upper and lower incisors in their sockets, unless for some reason they have been mechanically elongated, and further, that in order to put the teeth and facial lines in harmony, it is not necessary to depress these teeth in their sockets in our young patients. If this be true, then it necessarily follows that our efforts must be confined to the lengthening of the molars and premolars, sometimes of the upper dental arch, sometimes of the lower dental arch, and more often of both upper and lower dental arches.

Practical cases. Fig. 4 shows models of the denture of a child at three and one-half years of age, with the deciduous lower incisors striking on the palate at least one-eighth of an inch distally to the upper incisors. This is evidently a case of class II, division 1, and a careful study of these models would show that,

Fig. 5.

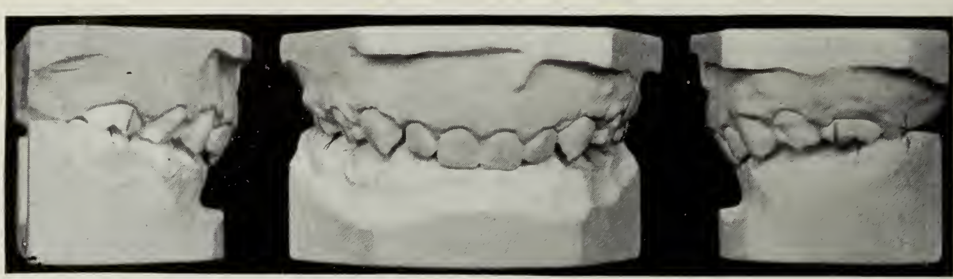


Fig. 6.

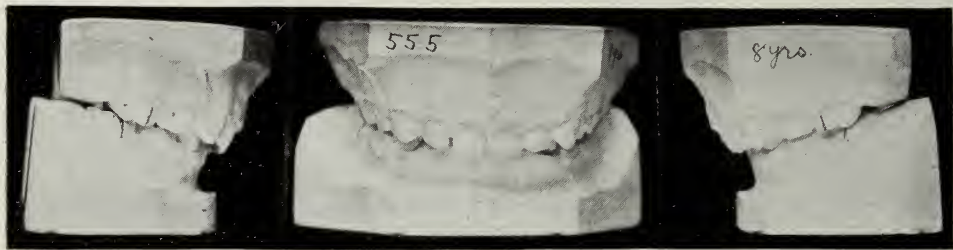

Fig. 7.

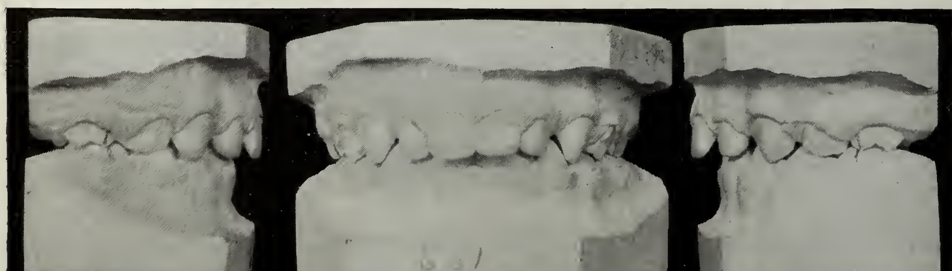

for some reason, the deciduous molars are far from being fully erupted. In fact, the gums, just distal to the second deciduous molars, are on a level with the occlusal surface of these teeth.

Fig. 5 shows models of the denture of a child four years and five months of age, with the lower incisors completely hidden by the upper ones. On the left side, in this case, the deciduous molars are in complete lingual occlusion, and it will be observed that it is a subdivision of class II, division 2, not complete, but rapidly drifting that way. Like the previous case, the gums, just distally to the second deciduous molars, are on a level with the occlusal surface of these teeth.

Fig. 6 is made from models of a child of eight years of age, with the lower incisors completely hidden. Examination of the models of this case reveals a groove across the palate, just distal to the upper deciduous teeth, in which the lower incisors rest. This is a complete case of class II, division 2, and, like the previous one, the occlusal surface of the second deciduous molars is just level with the gums, distally to them. The only permanent teeth in this case are the lower central incisors. Many more cases like this could be shown to prove

Fig. 8.

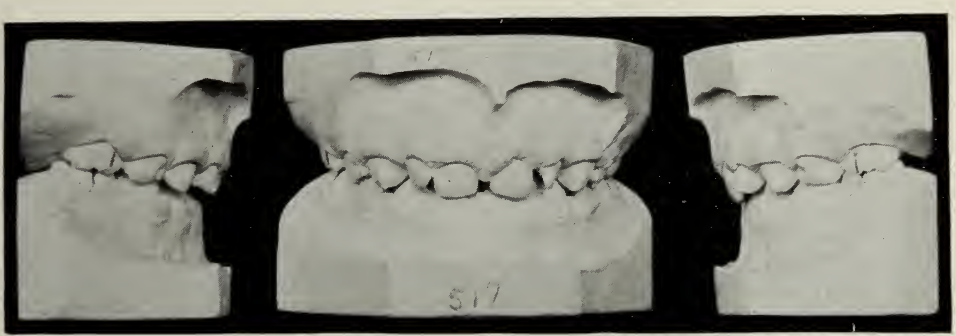

Fig. 9.

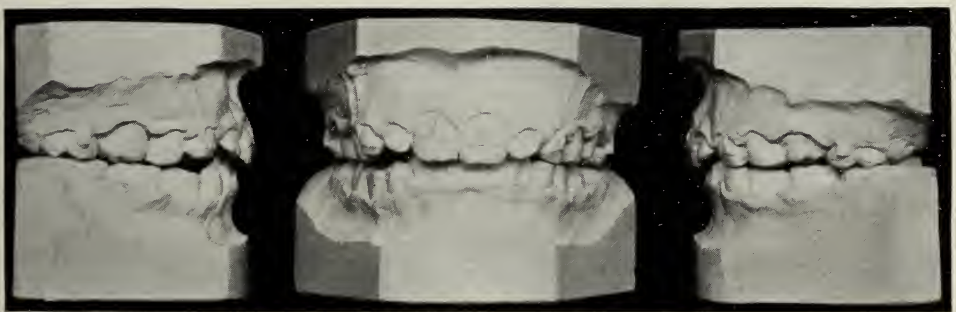

Fig. 10.

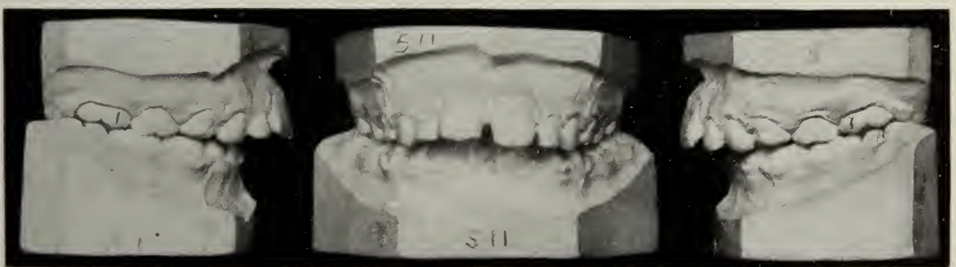
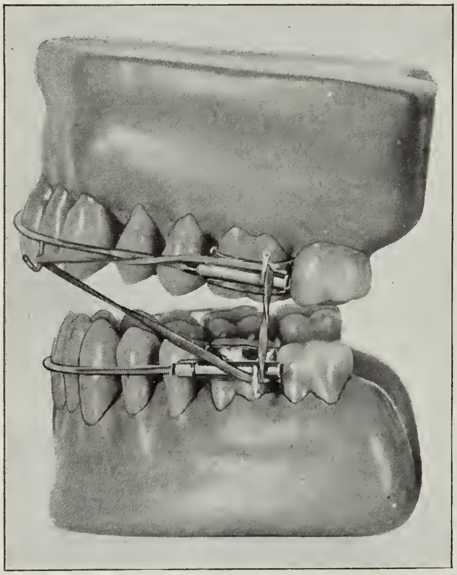


that infra-occlusion begins at a very early age.

The importance of mastication. This distal occlusion, in turn, interferes with

FIG. 11.



the proper mastication of food, and causes further lack of development owing to perverted muscular action, lack of stimulation, and insufficient blood supply to the surrounding tissues. If this is true, then what can be more logical than that these deciduous dental arches be so treated that the patient can masticate food? I am of the opinion that lack of mastication for generations is one of the great causes of early maldevelopment.

The mother or nurse, or both, should be carefully instructed as to the necessity of proper mastication and, more important still, of proper foods to necessitate mastication. In cases where the physician has advised foods that do not require mastication, systematic exercise, as biting on rubber rope, should be insisted on as advocated by Dr. H. C. Ferris. The liberal use of chewing-gum —not the ordinary kind, but good old spruce or tamarac gum, that becomes harder the longer it is used, so that it fairly makes the muscles ache when chewed for a specified time—is thought to be beneficial.

In order to dispel the belief that this condition is always due to a distal occlusion of some sort, a careful study of Fig. 7 is urged. This is made from the models of the denture of a child three and one-half years of age, and it will be observed that the mesio-distal relation of the molars is correct. The lower incisors strike on the palate just distally to the upper ones; and again, the gums, just distally to the second deciduous molars, are on a level with the occlusal surface of these teeth.

FIG. 12.

Fig. 8 shows another case of class I in a similar condition to that described in Fig. 7.

When we compare the last two cases with these [exhibiting several models of normal deciduous arches] we can readily see wherein they are deficient.

Author's method of treatment. About four years ago, the writer became impressed with the necessity of treating cases of infra-occlusion of the buccal teeth, prior to the eruption of the first permanent molars.

Owing to the fact that children do not take kindly to a removable appliance of any description and because they are more liable to carry it somewhere other than where the orthodontist wishes it to be, the following method has been employed, and has proved very satisfactory in all cases when used previous to the eruption of the first permanent molars. The deciduous molars were elongated by eight cast gold tips or gold caps made quite thick on the occlusal surfaces, and securely cemented to these surfaces as shown in Fig. 9. These cases have been watched with a great deal of interest in order to see what effect these appliances might have on the underlying premolars, but so far there have been no ill effects from their use.

FIG. 13.

Shows right and left views of a set of models before treatment.

FIG. 14.

After treatment.

An extreme case, and its treatment. Fig. 10 shows an extreme case of infra-occlusion in which a rather peculiar experience was encountered. At the beginning of treatment all eight deciduous molars were built up with gold caps made heavy on the occlusal surface so as to separate the first permanent molars. D bands were fitted to all first permanent molars, and upper and lower arches adjusted. By means of intermaxillary rub-

Fig. 15.

Shows profile and front view of face before treatment.

Fig. 16.

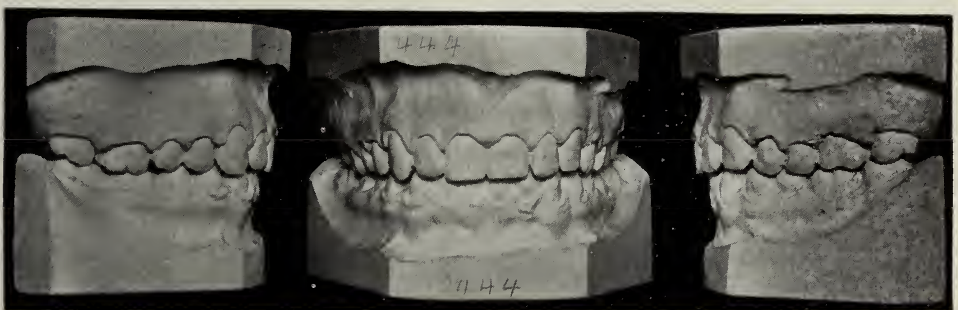
After treatment.

bers worn in the triangular way, as shown in Fig. 11, these teeth were forcibly elongated as shown in Fig. 12. Three years subsequently, the deciduous molars were lost, thus allowing the strain of the muscles of mastication to act on the first permanent molars, and they were found to settle in their sockets and permit the lower incisors to strike on the palate again. This child is now wearing individual bite-planes on the four upper incisors, so as to allow the premolars to erupt fully before they come in contact.

Fig. 17.

Shows both side views and front view of models before treatment.

Fig. 18.



After treatment.

Periods most favorable for treatment. In fact, it seems that, when teeth have come in contact and have stopped their vertical development, it is much more difficult to stimulate bone-growth to support them than when this is done during the active eruptive period. It therefore follows that the two periods most favorable for treating cases in infra-occlusion are previous to or at the eruption of the first permanent molars, and during the eruption of the bicuspids.

That the buccal teeth fail to erupt to their full vertical height, an examination of the class II cases will conclusively prove.

My observations have convinced me that failure to elongate the molars and bicuspids in these class II cases is almost sure to result in the failure to maintain the mesio-distal relation, regardless of how accurately the dental arches have been shaped to fit each other.

Bite-planes and their various modifications. Bite-planes of various shapes, securely attached to bands on the anterior teeth, have been found most satisfactory in the treatment of these cases. The shape of the plane found most useful for this purpose is the one described in the *Items of Interest*

FIG. 19.

FIG. 20.

After treatment.

for January 1911,* in an article by Dr. Alfred P. Rogers. As he has carefully gone into the technique of making this appliance, it is not necessary for me to do so at this time. My main objection to this form of appliance is that four bands firmly united together have to be cemented at one time. To obviate this, I have used tubes on the lingual side of the molar bands, close to the gingival margin, to fit over the wire soldered to the bite-plane. This permits the cementing of the front section of the appliance first, and then the individual cementing of each molar band. This is done by slipping the tube over the wire, having the band lingual to the molar which it is to encircle, and then the band is tipped buccally, forced to place, and clamped. The screw, of course, should be on the buccal side.

Individual planes attached to bands on the upper anterior teeth have been tried in a few cases in conjunction with Dr. Angle's new appliance, and so far have proved very satisfactory. Considerable care is required in making these planes in such a way that no one tooth has to bear all the strain, but, when this is done, a great sense of security is derived from knowing that, if a band *does* loosen, this is very readily detected, which is not true when the bite-plane is firmly soldered to two bands.

Intermaxillary rubber bands. In conjunction with all these bite-planes, it is necessary to wear the intermaxillary rubber bands. The position of these rubber bands can be varied according to the teeth that are to be operated upon. If it is found desirable to elongate the lower molars only, then the intermaxillary rubbers should be worn from hooks on the upper appliance in the canine region to hooks on the buccal surface of the lower molar bands. If it is desirable to elongate both upper and lower molars, the intermaxillary rubbers should be worn in a triangular way, as shown in Fig. 11. In case it is desirable to elongate the upper molars only and not the lower ones, the rubbers would be worn as in the treatment of class III conditions. This application of the intermaxillary rubbers would not be practical in a class II condition, but I have never seen a case where I thought it advisable to elongate only the upper buccal teeth in this class.

Special precautions. It is of the utmost importance, in treating these cases, particularly older patients, to make sure that the intermaxillary rubbers are sufficiently strong to keep the lower incisors in the proper position in the bite-plane during the periods of sleep, for, if the patient is able to get the molars and bicuspids in contact when sleeping, there is no possibility of elongating these teeth. I recall one case where the mandible would drop distally during the periods of sleep, to such an extent that the lower incisors would pass lingually to the bite-plane. To prevent this, the upper canines were banded, each having a plane soldered to its lingual side in such a position that in order to close his teeth the patient had to protrude his mandible so that the lower incisors rested on the bite-plane as they should. In a few months after this appliance was installed, the molars had elongated so that they came in contact.

Practical cases and results of treatment. I will now show slides of cases before and after treatment, in which these methods were employed. (See Figs. 13–16, and Figs. 17–20.)

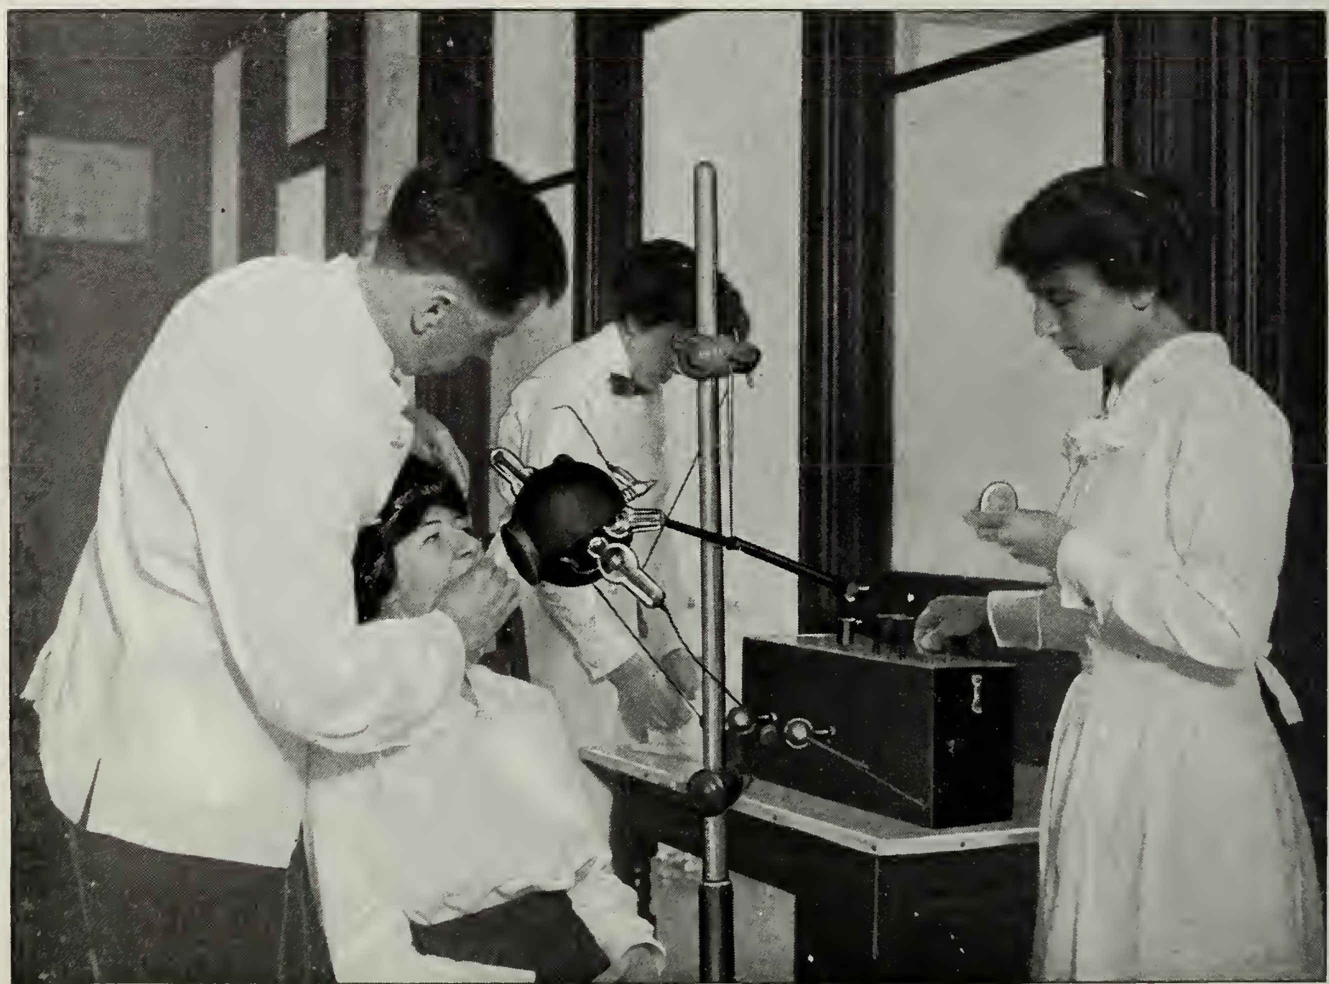
NOTES ON DENTAL RADIOGRAPHY.

By J. J. MOFFITT, D.D.S., Harrisburg, Pa.

(From exhibits held before the Luzerne and Lackawanna and the Harrisburg Dental Societies.)

THE value of the use of radiographs increases as the dental operator overcomes the difficulties involved in making the pictures, and also as he becomes familiar with reading the films or prints. As he begins to rely on their disclosures for guidance in his work, they become absolutely invaluable, and he soon wonders, as we have all done in regard to telephones and taxicabs, how he ever got along without them. The dangers, as far as dental work is concerned, are practically eliminated by covering the entire tube—with the exception of the area over the tooth (see Fig. 1)—with a prepared rubber shield.

Fig. 1.



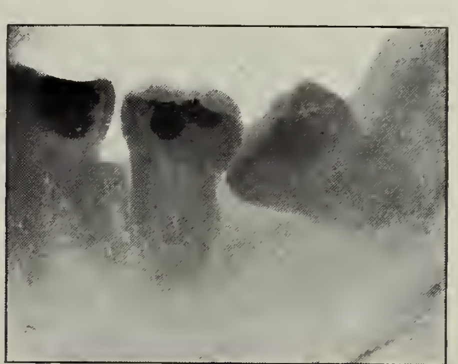
VALUE OF THE X-RAY IN DAILY DENTAL PRACTICE.

An experienced operator, it is true, can get along fairly well without radiographs nine times out of ten, and the tenth case, to him, seems to be the incurable one. These tenth cases are the ones that are of the greatest importance in a dentist's daily activities—to the one who wants to excel his competitors, because these are the cases in which the competitor has failed, and to the dentist who wants to bestow the utmost of his ability upon his patients, because of the satisfaction of curing them and retaining them in his *clientèle*. For these conditions the X-ray apparatus is indispensable. There are a great many other cases in daily general practice in which the X ray is helpful, such as filling roots, treating abscesses, correcting impending irregularities, amputating apices, disclosing causes of neuralgia, etc. Besides, the X ray is a great timesaver to a busy dentist, and a great saver of a patient's feelings in furnishing diagnoses at once without the experiments otherwise necessary, while a comfortable sense of security is derived from a knowledge of what is going on beneath the gingival line. The cases shown are just such as occur in general daily practice.

IMPACTED THIRD MOLAR.

The first case (Fig. 2) is one of an impacted third molar, in which the pic-

Fig. 2.



ture shows its size, location of its roots, and the manner in which it is held by the bone and the adjoining tooth. The gum, which does not appear, almost covers it. To remove this tooth successfully it would be best to cut away the bone over the posterior root, so that the tooth could be tilted back from beneath the overhanging part of the second molar, before force is applied with the forceps. The picture also discloses, in the second molar, the kind of anterior root that is frequently punctured when the operator is unaware of the peculiar curve of its canal.

ABSCESS.

Fig. 3 shows an abscess in the apex of a first bicuspid under a gold crown.

Fig. 3.

There are three crowns, one porcelain and two shell gold crowns, adjoining each other, with a fistulous opening leading from one of them which the radiograph shows at once to be the first bicuspid, thus rendering experiments with the other two teeth unnecessary. Such a diagnosis can be made in five minutes in a dental office.

DIAGNOSIS PREVIOUS TO BRIDGE WORK.

Fig. 4 shows a molar root which has sufficient bone between its anterior and posterior portions to make it reliable as a support for a bridge. It also shows the length and direction of the roots and their extreme narrowness, enabling the operator to avoid puncture of the sides, or protrusion through the apex.

Fig. 5 illustrates a very loose root carrying an old-fashioned Richmond crown. The X ray shows inflammatory conditions of the pericementum due to pressure of the band. The alveolar socket is in good condition, and the tooth is capable of becoming firm again under correct treatment, if the root-

Fig. 4.

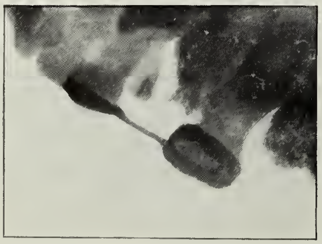
Fig. 5.

canal is properly filled and an anatomically correct crown is inserted.

ERUPTING TEETH.

Fig. 6 shows a platinum brace applied upon the deciduous teeth to prevent the

Fig. 6.



second deciduous molar from being pushed forward by the first molar, which is about to erupt. The bicuspids can be seen in their places, but will not erupt for several years. The first deciduous molar was lost, owing to conditions that are apt to occur in any child whose deciduous teeth are not given as careful attention as the permanent ones. In this case, under a carelessly placed filling, caries penetrated to the pulp, causing an abscess and subsequent destruction of the tooth. With the chief object in view of keeping the first permanent molar back in its place during eruption, a brace was made, and no loss of space will result.

ROOT-FILLINGS.

Fig. 7 was made for the purpose of examination of the apical conditions of

Fig. 7.

roots that had been previously filled by another operator, when it was necessary to crown the tooth. The solid condition around the apices of these roots shows that the tooth may be safely crowned without disturbing the root-fillings.

ORTHODONTIA.

Fig. 8 shows a congestion of the permanent lower anterior teeth, and the necessity of regulating the deciduous teeth in order to prevent serious irregularity of the permanent ones. In this case a very fine platinum appliance was put upon the deciduous canines, and these teeth are being gradually separated, so that the four incisors will assume their proper relations. The canines are chosen as abutments because they remain in position longer than the other teeth. The permanent four anterior and the three deciduous teeth are shown in the picture, one permanent

Fig. 8.

tooth being erupted. The other three have been retarded in growth owing to lack of sufficient room.

ROOT PUNCTURE.

Fig. 9 shows a case in which a bridge bearing a central and a lateral incisor was attached to the root of a central incisor, which could not be retained on account of soreness. The X-ray examination showed that the root had been punctured and that the pin and filling

Fig. 9.

were protruding into the maxilla. This root was saved and subsequently rendered serviceable.

REVELATION OF VARIOUS UNSUSPECTED CONDITIONS.

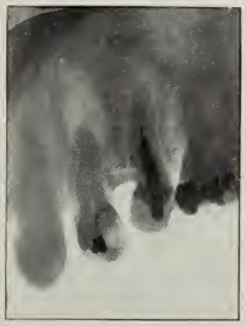
Fig. 10 (from a patient of Dr. Trout's, Red Lion, Pa.) illustrates a case in which an abscess has progressed to such an extent that the tooth cannot be saved except by amputation of the root, which is projecting into the abscess; the apical

Fig. 10.

opening is enlarged and disintegration of the tooth itself has begun.

Fig. 11 shows a case in which the abscess has not affected the apical area to such an extent that it cannot be cured

Fig. 11.



by treatment; it also shows that the root is extremely short and curved.

Fig. 12 (from a patient of Dr. Longenecker's, Mt. Joy, Pa.) is a picture of an amputated lateral root.

Fig. 13 (from a patient of Dr. Behney's, Harrisburg, Pa.) is a picture which was taken to seek the cause of pain and the location of covered roots. The remains of the roots of a second molar that were covered up by gum tissue are shown, also caries in the posterior surface of the first molar under an old amalgam filling, and unsuspected ex-

Fig. 12.

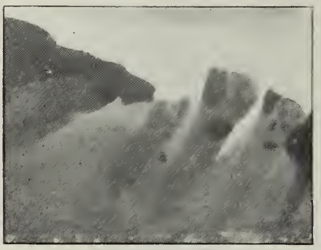
posure of the pulp, causing continuous irritation.

Fig. 14, A, is a picture of a root that had been punctured owing to a misjudg-

Fig. 14, A.

ment of the direction of the canal, which had been previously filled with cement. An attempt was made to crown it without the use of the radiograph. Fig. 14, B, is the same root undergoing treatment. The spot in the bone between the teeth is

Fig. 14, B.



a piece of protruding filling not yet removed.

Fig. 15 shows a punctured pulp-

Fig. 15.

chamber, and also a blind abscess at the apex of a crowned bicuspid.

FRACTURE OF TEETH.

Fig. 16 (from a patient of Dr. Smith's, Lancaster, Pa.) illustrates a case in which the patient, by a severe fall, had loosened several teeth. There were no diagnostic symptoms indicating extraction, so a brace was made to support the loose teeth until they had become permanently fixed in their sockets. After six weeks pus appeared, the condition remaining unimproved. An X-ray examination was made, which showed that the teeth had sustained fractures above the alveolar process in the solid part of the bone, the bone itself remaining unbroken. The patient had reached for an article, standing on a chair, which tilted, allowing the feet to fly out and the face to strike with great force on the back of the

FIG. 16.

chair, bringing about this unusual form of fracture.

IMPERFECT ROOT-CANAL FILLINGS.

Fig. 17 was made from a case of several abscesses below two gold crowns, the

FIG. 17.

roots having been imperfectly filled and the crowns poorly adjusted to them. The radiograph shows at a glance the cause of the trouble and the possibility of curing both teeth. The pulps having been destroyed, there was absolutely no excuse for making shell crowns.

FAILURE OF ERUPTION.

Fig. 18 was made in search of an unerupted central in a child nearly eight years of age. The film showed the root of the deciduous tooth only half absorbed, the other half extending along the crown of the permanent tooth and preventing it from erupting. After extraction of the deciduous tooth, another picture, which was taken several weeks

FIG. 18.

later, showed the permanent tooth one-eighth of an inch farther advanced.

ABSORPTION OF ALVEOLAR PROCESS.

Fig. 19 was made in a case of absorption of the alveolar process with a pus tract surrounding the root. The tooth carried a gold crown which extended underneath the gum fully three-sixteenths

FIG. 19.

of an inch on the lingual side. The root was very loose, the occlusion faulty, the gum swollen and very much congested. The crown was removed, the cement thoroughly scaled off the root, and prophylactic treatment begun, which soon tightened the tooth. When the bone has filled-in around the root, a proper crown will be made that will restore the original shape of the tooth.

DETERMINING EXACT LENGTH OF A ROOT.

Fig. 20 shows a method devised by the writer for determining the exact length of a root when the film has been held at an angle to the perpendicular, and the picture is either longer or shorter than the natural root. The wire

Fig. 20.

is a piece of thick regulating wire, sterilized, inserted as nearly as possible to the apex by means of a former radiograph, held in position with temporary gutta-percha, and clipped off or bent over at the occlusal end of the tooth. By comparing this wire with its length in the picture afterward, the exact elongation or foreshortening of the root is shown.

Fig. 21 (from a patient of Dr. Kirsch's, York, Pa.) shows elongation in the image of roots owing to the film being held at an incorrect angle to the direction of the rays. The picture was made in search of a missing molar as a probable cause of pain.

THE AID OF AN ASSISTANT.

Thus the X-ray picture, while always interesting, often discloses unsuspected conditions, and helps in preventing impending troubles. Every dentist who employs an assistant in his office should have an X-ray apparatus, as the only difficulty about making radiographs to

Fig. 21.

which his personal attention must be given lies in holding the film properly, and at the same time preventing the patient from getting a spark, which takes but a few minutes of adjusting. The assistant can learn to mix the developing solutions, have them in readiness, and can then develop the films in five or six minutes after an exposure is made. As there are two films to each exposure, one is used wet for making the diagnosis and the other one is dried for preservation.

The Roentgen rays will penetrate several thicknesses of films, manifolding the impression on them all.

THE SIGNIFICANCE OF NORMAL OCCLUSION.

By MILO HELLMAN, D.D.S., New York, N. Y.

(Read at the fourth annual meeting of the Eastern Association of Graduates of the Angle School of Orthodontia, New York, N. Y., April 1913.)

NORMAL occlusion of the teeth is one of the phenomena the recognition of which has placed our profession upon a definite scientific foundation. It is the basis of the science of dentistry, and the unqualified condition upon which the efficiency of a denture depends. By a clear conception of the normal relations of the anatomical units of a denture and by a thorough appreciation of their physiological significance, we are enabled to understand the rôle played by the masticatory apparatus in phylogenetic as well as in ontogenetic development; and in proportion as we are able to grasp and interpret the ideas implied by the term "normal occlusion," we shall conceive how remarkable and far-reaching are its effects.

ANGLE'S STUDIES OF OCCLUSION.

Although numerous authors have from time immemorial written on alignment, articulation, mechanical relation, and occlusion of the teeth, it was not until Dr. Edward H. Angle (1) gave us his conception of this phenomenon that the profession obtained a clear understanding of what it really means. While Dr. Black (2) and Dr. Muehlreiter (3) long ago informed us that the teeth do not merely interlock or interdigitate, and definitely described the manner in which it is accomplished, Angle not only observed the minutiæ of these interrelations, but also enumerated the forces that bring them about and upon which these relations depend. To him the profession owes a debt of gratitude which can only be repaid by the recognition of his achievements, and the acceptance of, and adherence to, his teachings. His conception of the *line of occlusion* and his *law of normal occlusion,* to which I shall refer later, are but natural outgrowths of his profound insight into the problem of occlusion.

SCOPE OF PRESENT INVESTIGATION.

To convey, then, a comprehensive idea of normal occlusion and its significance from a scientific viewpoint, it will be necessary to treat the subject in a manner that will not only portray the mechanical interrelation of the teeth, but also bring into the perspective the factors concerned in the establishment of these relations, as well as the effects produced by the normally functionating masticatory apparatus upon its closely associated structures. It is, consequently, necessary to divide the subject-matter into the following topics:

(1) The development of the structures concerned in the establishment and maintenance of normal occlusion ("the forces of occlusion," Angle).

(2) The development of the deciduous and the permanent dentures and coincident development of the face.

(3) The fundamentals of occlusion of the teeth.

(4) The effect of normally occluding teeth upon the alveolar process and its intimately related structures.

(1) DEVELOPMENT OF THE STRUCTURES CONCERNED IN THE ESTABLISHMENT AND MAINTENANCE OF NORMAL OCCLUSION.

It will be of interest to consider briefly the early embryonic processes involved in the development of the masticatory apparatus, and note the sequence of their occurrence in relation to their functional importance. At the beginning of development of the external form, the embryo initiates those changes in the head region which ultimately result in the oral cavity and its contained organs. Thus, about the third week of embryonic life, the oral fossa makes its appearance. The manner in which these morphological changes occur I shall not touch upon, as it is mainly a matter of embryologic detail, and is described minutely in works that treat of this subject in a general[4], comparative[5], special[6], and experimental[7] way—to which the student may be referred for reference. What we are particularly interested in at present are the results brought about by these changes. Thus, before the maxillary, mandibular, and fronto-nasal processes have united to form the oral fossa, in embryos of about 3 mm., there may be seen in the median line of the floor of the stomodeum, between the ventral ends of the first and second branchial arches, a small, rounded elevation which has been termed the *tuberculum impar* (Fig. 1, *t*). In later stages (Fig. 2, A) this becomes larger, and reaches its greatest development in embryos of about 8 mm.; at the same time there appears on each side of the floor of the mouth a longitudinal groove—the alveolo-lingual groove—each of which, at its anterior end, bends medially toward its fellow. By these alveolo-lingual grooves an area is marked out in the floor of the mouth which gradually becomes more and more prominent and rounded upon its oral surface, and forms the anterior portion of the tongue (Fig. 2 B, t^1). This median elevation is bounded at the sides and almost to the median line in front by the alveolo-lingual grooves, and posteriorly it is separated from the anterior edge of the

FIG. 1.

second branchial arches by a distinct V-shaped groove.

The posterior portion of the tongue arises as thickenings of the ventral ends of the second branchial arches, and is consequently a V-shaped structure, into the angle of which the posterior part of the anterior portion of the tongue fits (Fig. 3). The two portions, anterior and posterior, eventually fuse, but the groove which originally separated them remains more or less clearly distinguishable, the vallate papillæ developing immediately anteriorly to it.

As to the muscular character of this organ, there is no need of special mention, since it consists partly of fibers derived from its own substance, the lingual muscle, and from a number of extrinsic muscles—the hyoglossi, genioglossi, styloglossi, palatoglossi, and chondroglossi—it is evident that its influence is highly effective and that in subsequent development it becomes a factor of vast importance.

After the formation of the oral sinus, at about the fifth week, an ingrowth of epithelium into the substance of both the maxillary and fronto-nasal processes above and the mandibular processes below takes place, and the surface of the ingrowth becomes marked by a deepening groove (Fig. 4, *Lg*), which separates an anterior and lateral fold, the lip and

cheek, from the alveolar process. Medially, from the maxillary portions of the upper jaw, shelf-like ridges then begin to develop (Fig. 4, *Pp*).

When, however, these ridges or shelves, which become the palatal plates, are first formed, about the fifth or sixth week, they have an almost vertical direction, projecting downward and somewhat inward between the sides of the tongue and the alveolar process (Fig. 5*) (8). The tongue, at this stage, completely fills the primitive oral cavity, the stomodeum, its dorsum being in contact with the base of the skull (Fig. 6). Later, the lower jaw, which at first is considerably shorter than the upper, increases in length and at the same time in breadth, and assumes a more horizontal position. The tongue, as may readily be seen in Fig. 7, A, forms first the core for the developing and shaping of the jaw-bones, and later constitutes the most important structure for the molding of the roof of the mouth; for, as the tongue sinks downward between the Meckelian cartilages, the palatal ridges bend dorsally over it, so as to assume a horizontal position (Fig. 7, B), and through further growth, up to about the third

* Figs. 5, 6, 7, 8, and 9 were taken from Michio Inouye's work: see bibliography.

month, their union in the median line takes place to form the palate (Fig. 8). for it now devolves upon the structures thus far formed, *i.e.* the tongue, the lips,

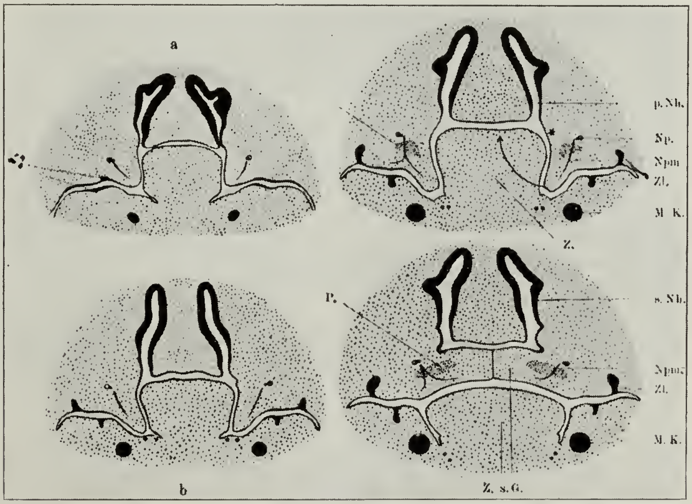
These processes in development having taken place, the first and most important condition of normal occlusion is fulfilled, and the cheeks—to maintain the normal relation between the two jaws until the eruption and proper locking of the teeth has occurred. Even more, the correct placing and locking of the teeth themselves depends upon the normal development of these structures. The effect of their powerful influence will readily be appreciated, if the force exerted by the tongue, lips and cheeks during their functional activity be carefully measured. The highly efficient suction-pump that these organs constitute in the healthy nursing infant is corroborative evidence of their effectiveness.

(2) DEVELOPMENT OF THE DECIDUOUS AND PERMANENT DENTURES AND COINCIDENT DEVELOPMENT OF THE FACE.

The beginning of the development of the teeth in the embryo takes place at about the seventh week, *i.e.* shortly after the formation of the palate and the differentiation of the lips and cheeks from the jaw itself has taken place. (Fig. 9.) The formation of the dental shelf or lamina, and its further development into the required number of tooth germs, the dental papilla, and enamel organ, I shall not dwell upon. What I do want to emphasize at this moment is the fact that, at this early period in the history of the development of the dental apparatus, the definite shapes, the forms, and sizes of the teeth in their respective crypts are designed, and when the time arrives for them to take their position in the arches, they form, individually and collectively, when normal, a complete and harmonious whole. With what particular purpose this process takes place can only be appreciated when we realize the accuracy necessary for the establishment of the inter-relationship between the individual members of a denture, when the organ as a whole reaches its adult normal type. How truly remarkable to think that every sulcus, groove, fossa, ridge, inclined plane, etc., formed at this early period, will play an important rôle in the integrity of the masticatory apparatus as a whole, years later on! Synchronously with the process of the developing teeth, the growth of the muscles within and of those surrounding the oral cavity is taking place. Combining, therefore, the influence exerted by the muscles of mastication, respiration, deglutition, speech, and expression, with the developing and eruptive force of

FIG. 9.



Frontal sections through oral and nasal cavities, showing relative development of the palate and dental lamina. *Zl*, Dental lamina. *Z*, Tongue. *s.G*, Palatal process. *M.K.*, Meckel's cartilage. *p.Nh*, Primitive nasal cavity. *s.Nh*, Secondary nasal cavity. (Inouye.)

the teeth, a powerful stimulus is given to further the growth of the developing bones of the face. Thus, at the time when the eruptive force of the deciduous teeth is carrying them occlusally, the alveolar process grows around them. This process of growth, according to Noyes(9), brings about an increase in the size of the jaw-bones in three dimensions of space. He says:

For, as the teeth erupt, they and the alveolar process grow downward, forward, and outward in the upper jaw, increasing the distance from the floor of the nares and the floor of the orbit to the alveolar border and the occlusal edges of the teeth. In the lower jaw, this movement is upward, forward, and outward, increasing the size of the arch and the distance from the symphysis to the mental foramen.

But, after the deciduous teeth have taken their position, the developing permanent teeth in their crypts continue the influence upon the development of the jaws and the face. "With the continuing growth of these teeth prior to their eruption, there is an accompanying pushing downward, forward, and outward of the deciduous teeth, process and all, increasing the size of the arch from canine to canine, causing the deciduous teeth to stand wide apart, and finally, when the roots and the alveolar process of the deciduous teeth are absorbed, they are pushed from the gum." (Noyes.) If three skulls be compared, that of the toothless infant (Fig. 10), that of the child with the deciduous dentition (Fig. 11), and that of the adult with the permanent denture (Fig. 12), it will readily be seen to what extent the changes in growth have influenced the transformation of the bones of the infant face to those of the adult.

The influence of the developing teeth upon the growth of the face may be observed from the standpoint of the changes in the facial expression. As Schwalbe(10) says:

Thus the most striking change in the head taking place from birth until the end of childhood is found in the face. Even to those who observe these phenomena not from a medical point of view, this change is the most significant of the entire body. The face reflects intellectual life; the development of intellectual life finds expression in the facial change.

The first change in the nursing infant gives the countenance a greater fulness, and produces the characteristic appearance of the infant face. At birth, the forms are less full, while in healthy children during the middle of the first year, their round face, with their round cushionlike cheeks and large eyes, is normal. Furthermore, the growth of the facial portion of the head is more rapid than that of the brain portion, especially after the first year; above all, the erupting teeth and the accompanying enlargement of

Fig. 10.

Skull of infant at birth. (Noyes.)

the jaw-bones give the face a different expression. As the facial expression is decidedly influenced in infancy by the eruption of the deciduous teeth, so it is again in childhood the transition from the deciduous to the permanent dentition that produces a change in the facial expression. Of course, this is a slower change, taking place more gradually than that first described.

A similar view is expressed by Stratz (11) in the following manner:

Just as the growing of the milk teeth enlarges the jaw-bones and with them the lower part of the face, producing the first fulness from the typically toothless nursing infant, in a similar manner but in a higher degree the features are markedly longer, more definite, and stronger. The lower jaw becomes more powerful, its angles are more definitely marked, the round soft mouth is lengthened, the nose becomes more prominent, the cheeks assume no more the position of small globes

FIG. 11.

Skull of child, showing deciduous dentition in position, and development of permanent dentition. (Cryer.)

FIG. 12.

Adult skull showing completed permanent dentition. (Cryer.)

below the eyes, but disappear gradually, and flatten out about the increasing width and length of the chin and mouth portion. As the growth of the brain-case and eyes is much slower than that of the face, the eyes are apparently continually rising, and the head seems to diminish in size as compared with the face. Besides this, and owing to the lateral gain in the jaw portion, the eyes seem to approach each other more and more. Also this difference is only apparent, for the distance between the pupils changes very little during the entire life. . . . Although the transformation of the child's face to that of the typical girl or boy is very gradual, there is during the change of the dentitions a marked exacerbation in this process.

(3) THE FUNDAMENTALS OF OCCLUSION OF THE TEETH.

In order to realize the accuracy with which such a masticatory apparatus as presented in Fig. 12 is perfected, and at the same time appreciate the degree of its efficiency, it is necessary to review in a general way some of the salient points pertaining to its anatomical construction. As Angle expressed it—"The shapes of the cusps, crowns, roots, and even the very structural material of the teeth and their attachments, are all designed for the purpose of making occlusion the one great object." In proportion, therefore, as we are familiar with the minutest details pertaining to the occluding surfaces of the teeth, shall we respect the integrity of the smallest portion that enters into the formation of the masticatory apparatus. Just as in the case of an extremely complicated machine, the efficiency of its mechanism may depend upon a single insignificant cog of one of its numerous wheels, so, in the masticatory apparatus, the integrity of the whole depends upon the presence and normal functionating of every one of the inclined planes of the cusps of a tooth.

This is the problem that perplexes every student and baffles every practitioner. But while no orthodontist can begin the treatment of a case without a thorough knowledge of occlusion, it is most surprising to note how little cognizance is taken of this by the majority of the general practitioners in dentistry. As upon the normal locking of the occlusal inclined planes of the teeth depends in a great measure the ultimate result of normal development, it follows that upon it depends the permanence of all orthodontic operations, as well as the success of all dental restorations.

A careful examination of a normal denture in reference to occlusion will reveal a number of factors which vary from the simplest to the most complex, depending upon the anatomical character of the different teeth in the dental series. Thus, while the occlusion of the incisors is quite a simple matter, the labial surface of the lower and lingual surfaces of the upper alone coming into relation, this condition is immediately complicated when the occlusion of the canines is studied. The plain labial and lingual surfaces of the incisors are here divided by the lingual and labial ridges, resulting in labial, buccal, mesio-lingual and disto-lingual surfaces. The canines, consequently, present four surfaces, instead of merely one cusp which must be correctly placed, if the normal is to be obtained. Furthermore, as we reach the multicuspidate teeth, the designation becomes still more complex. For instance, taking up the study of the occlusion of one cusp—the buccal cusp of a premolar—we remember from our anatomical knowledge that leading from the point of that cusp there are four ridges, the mesio-incisal, the disto-incisal, the central buccal, and the triangular. These ridges transform the cusp into a pyramid, so to speak, with four surfaces, or rather inclined planes, two of which point to the lingual and two to the buccal. But since each of these present either mesially or distally, they are termed as above, mesio-buccal and disto-buccal, mesio-lingual and disto-lingual. It is evident, therefore, that the premolars occlude by means of eight inclined planes, and not by means of two cusps or points.

In the molar series, on the other hand, each tooth contributes sixteen inclined planes, and not merely four points, toward the process of triturating food. This is further complicated when we remember that each cusp in turn is antagonized by four inclined planes, from four different cusps. Thus, for instance, if the occlusion of the mesio-lingual cusp of the upper first molar be analyzed, it will be found to come into relation by its mesio-buccal inclined plane with the disto-lingual inclined plane of the mesio-buccal cusp of the lower first molar; by its disto-buccal plane with the mesio-lingual plane of the disto-buccal cusp of its lower namesake; by its mesio-lingual plane with the disto-buccal plane of the mesio-lingual cusp of the lower first molar; and by its disto-lingual plane with the mesio-buccal plane of the disto-lingual cusp of the lower first molar.

What confuses the majority of the dental profession in regard to the anatomical make-up of the occlusal surfaces of the teeth is that too much stress is placed upon the elevations and insufficient attention is given to the depressions of those parts. If the grooves, sulci, and fossæ that divide the various elevations of the occlusal surfaces of the premolars and molars were taken more into consideration, better results would be obtained in restorative operations in general. A splendid paper on this subject was read by Dr. J. L. Young in Toronto, in 1912(12). A cusp can never be properly restored if the depressions outlining it are not perfectly reproduced. And if the fact that each cusp is composed of four inclined planes were constantly kept in mind, instead of its being merely a point, there is no doubt that operative procedures would reach a higher degree of excellence, and mutilated cases of malocclusion would be rarer. I cannot emphasize too strongly the urgent necessity of an exhaustive knowledge of the minutest anatomical make-up of the tooth surfaces, as upon it rest the ideal results in dentistry as well as in orthodontia.

As suggested by Dr. H. C. Ferris(13), the mechanical index of a denture depends upon the number of inclined planes that participate in the performance of the function of mastication. We can, therefore, easily determine the degree of efficiency of a given denture, if the number of teeth, cusps, and inclined planes that perform their normal function be computed.

The problem of the efficiency of the masticatory apparatus may be approached from another direction. If its make-up as a whole be examined, we shall appreciate the truth of Weigert's hypothesis (1896) that "physiological structure and function depend upon the *equilibrium of the tissues* maintained by virtue of *mutual restraint* between its components." Or, as Angle expressed it:

> The sizes, forms, interdigitating surfaces and positions of the teeth in the arches are such as to give one another, singly and collectively, the greatest possible support in all directions. Each tooth is not only in harmonious relation with every other tooth, but helps to maintain every other tooth in these relations, *for the cusps interlock and each inclined plane serves to prevent each tooth from sliding out of position, and further to wedge it into position if slightly malposed;* that is, if not beyond the normal influence of the inclined planes.

In any normal skull it can be observed how in mastication the overbite of the incisors would prevent the lower jaw from shifting forward, how the temporo-mandibular joint prevents it from shifting backward, how both joints and the external locking of the upper teeth would prevent the lower jaw from shifting laterally. Furthermore, the action and reaction of the molars and premolars of the opposing series, due to their positions, is such as to mutually restrain each other. It should be noted how the entire weight of the upper molars falls on the distal two-thirds of the lower molars and impels them forward. But also the reaction thereof should be observed, namely, that the distal two-thirds of the lower molars antagonizing the mesial two-thirds of the upper, exerts a restraining influence upon them.

The horizontal arrangement of the teeth in their respective arches differs in individuals. In a general way it may be said that both dental arches, the upper as well as the lower, form a semi-ellipse, the long axis of which passes between the central incisors. In the curve of this ellipse the canines stand a little prominent, giving fulness to the corners of the mouth. While the teeth of the lower arch are arranged similarly to those of the upper, they stand in a smaller curve, so that the line of the ellipse which falls on the buccal cusps of the upper premolars and molars will fall upon the buccal surfaces near the gum on the lower teeth. Furthermore, while the incisors of the upper arch are arranged so as to describe a curve from canine to canine, the deviation of their long axis from the vertical is such as to place the apices of their roots in a smaller arch. In the lower this condition is different; the apical arch may be of the same dimensions as that of the incisal edges, or even larger. However, the marked variability in outline of the dental arches may readily be seen in Figs. 13 and 14.

Referring to the observations made by Prof. Raymond C. Osburn([14]), a dental arch in a given type of man will be found to exhibit "a definite relation to the skull." Prof. Henry Fairfield Osborn, in 1902, demonstrated the existence of a correlation of the teeth with thirty-seven skull characters in lower animals. But whether the form of the skull or the correlated thirty-seven skull characters have any direct influence upon, or in any way affect the shape of, the dental arch, or *vice versa,* these authorities do not state. From what I shall show presently, it is probable that the form of the skull and its characters may directly be influenced by the masti-

(Osburn.)

catory apparatus, although both these conditions are possibly the expression of more profound causes. Thus, asserts Professor Patten (15):

> Prominent differences in men arise from the contrasting effects of upland and lowland climates. An upland race, if in a dry region, has a purer and more bracing atmosphere, and hence does not need so much lung power. It must develop greater vigor and endurance, partly because of the cold, and partly because of the game it chases and cattle it herds. Its food is dryer, harder, and more condensed; hence a better development of the jaw and its muscles results; along with this come smaller stomachs, better digestion, and fresher blood. A tall, narrow-chested man comes into being, who is in marked contrast with the short, broad man of the lowland region. These typical differences are accompanied by minor traits, not always found in all of a given race, but often enough to indicate that they have the same general causes. Long heads and round heads represent dynamic changes, even if we cannot trace back to given climatic origins. Some races and persons have a marked development of the lower face, with prominent jaws and strong facial muscles. These people like hard foods, enjoy chewing their food, and, if possible, keep something in their mouth, gum or tobacco, or the like, to exercise their jaws. It indicates a surplus of energy and strong muscular development. It is equally plain that those with a weak lower jaw and muscles take readily to soft, sweet foods, that they suck or gulp down rather than chew. This means a better muscular development of the throat. A snake, for example, sucks down its food, while a tiger chews his. In men the sweets and the meats are causes that brings out this difference between the chewers and suckers. Another like contrast is between the mouth-breathers and the nose-breathers. We speak of breathing as a habit, and yet different habits would not tend to be formed if muscular differences did not exist. Each activity is the outlet of energy, which tends to express itself through bodily mechanisms. The strong grows at the expense of the weak; each difference in bodily powers *tends to develop a type.*

The vertical plane of the human denture may vary from that of a straight line to a marked curve with its convexity downward. The meaning of this surface outline has been guessed at by several authors, but, so far, no real significance has been attributed to it. It needs no great amount of argument to conclude that the arrangement of the teeth, individually and collectively, both vertically and horizontally, in their respective arches, is dependent upon their structural form and their environment, and that in no other position could there be that definite, positive, and effective relationship, as in the one where the forces controlling them have been instrumental in placing them.

(4) THE EFFECT OF NORMALLY OCCLUDING TEETH UPON THE ALVEOLAR PROCESS AND ITS INTIMATELY RELATED STRUCTURES.

The alveolar process, being that part of the jaw-bone which develops with the denture and atrophies after the loss of the teeth, demands our immediate attention. To describe this process minutely would necessitate the writing of a voluminous essay. Suffice it, therefore, to say that in its general anatomical make-up it is as remarkable a structure as would do justice to the functions it is called upon to perform. Its architectural construction is such as not only to give support to the teeth during their physiological activity, but also to dissipate the force of mastication exerted upon the teeth, and to transmit it to neighboring parts that are by nature more resistant than itself. To fulfil adequately such requirements, it is expected that this process should be constructed accordingly. Thus the facial and oral cortical plate of compact bone, with the intervening spicules of cancellous tissue of which it is formed, is powerful enough to withstand the enormous pressure produced during the act of mastication. But as this force is not alike in all, and not alike in the different regions of the mouth in the same individual, there is a great variability in the relative quantity of the two forms of bone in homologous regions of different individuals, and in different regions of the same individual. In Figs. 15 to 22 the proportions of the cancellous and compact bone may be observed;* the variability

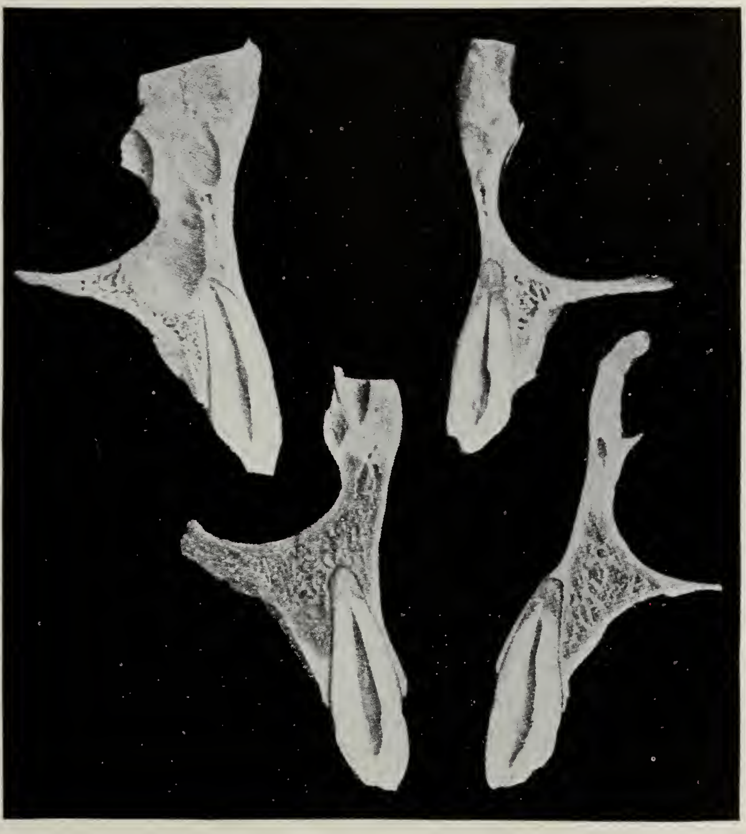
in the relation to the palatal process and that of the root-apices to the various superposed air-spaces; the different curves described by the palatal process toward the alveolar process, and the length of the alveolar process in the various specimens. Also, wherever greater strain is exerted upon the alveolar process than it is alone able to withstand, those parts are enforced by buttresses for additional support, as in the premolar and molar regions by the malar process and its articulating bones, the malar and zygoma. The main point, however, in connection with these sections is the evidence of the manner in which the force produced by the act of mastication is transmitted by this process to the other bones of the face and the skull. Before analyzing more critically the dissipation of this force, it is important to remember the direction of the long axis of each tooth; and it can readily be observed that, if the roots of the incisors would be extended, they would strike the pyriform opening of the nasal chamber; the extension of the direction of the canine points to the frontal process, while that of the premolar and molar roots points to the floor of the antrum. Thus, according to Loos([16]), the forces of the lower jaw actuated by the muscles of mastication is transmitted to the upper teeth, and from there on upward, following well-established rules. According to the laws governing the one-armed

Fig. 17.



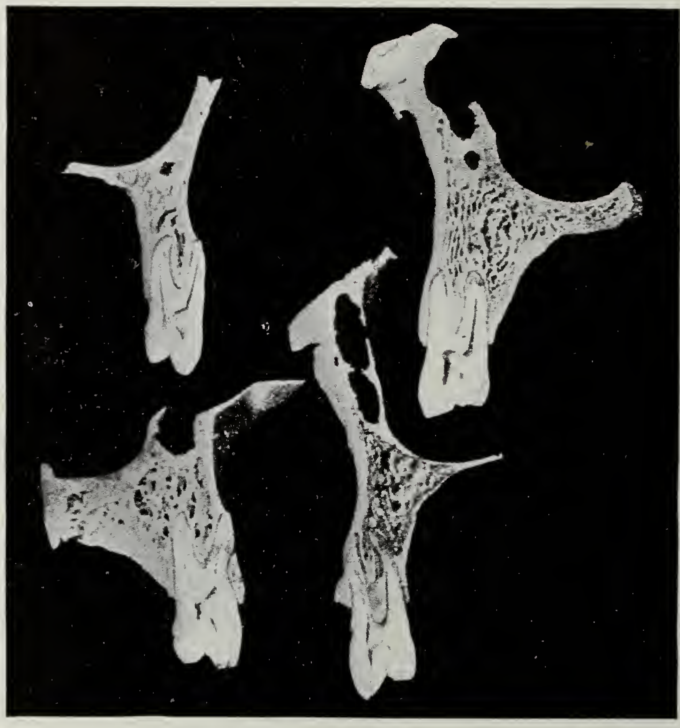
Upper canines. (Loos.)

lever, which the mandible with its dental arch represents, the various teeth are subjected to different degrees of stress, depending upon their distance from the temporo-mandibular joint—the fulcrum.

Molars. As the molars are nearest that point, the stress received by them is greatest, and we shall consider them first. The force received by the molars is transmitted directly on the facial as well as on the oral wall. The spongiosa, situated between the free alveolar plates, transmits the force exerted upon the alveoli to the compact plates of the alveolar process. Owing to the maximum pressure of mastication in the molar region, and the like resistance rendered by both the facial and oral walls of the alveolar process, there is developed a system of buttresses for reinforcement in this position. We have here the strong malar process of the maxilla, into which the facial wall extends. This in turn is reinforced by the malar bone and the zygomatic process of the temporal. The malar bone, again, articulating with the frontal bone, gains thereby still more resistance. By this manner of reinforcement, it will be seen how the force is finally transmitted to a great portion of the brain-case.

The oral wall of the alveolar process in the molar region is situated at the junction of the lateral nasal wall and the floor of the nose, that is, a point on a convex wall. The force exerted by the palatal root must therefore divide into two components, the one of which falls on the lateral nasal wall, while the other is received by the palatal process. The lateral nasal wall in turn reaches the brain-case by the median orbital wall. The components upon the palatal process derived from both maxillæ are received

Fig. 18.



Upper first premolars. (Loos.)

at the median suture, and similarly transmitted to the brain-case via the septum of the nose. The third portion of the pressure received by the alveoli is taken up by the spongiosa, and through its numerous spicules is dissipated toward both cortical plates of the alveolar process and partly also toward the floor of the antrum—again a convex bony wall. The floor of the antrum in turn transmits this force facially to the malar process, orally to the lateral nasal wall, mesially to the frontal process, and distally to the wings of the sphenoid bone. A union of all these resisting walls of the antrum, and with it also a reinforcement of the whole, is accomplished by the roof of the antrum.

Premolars. The tooth of next importance in the maxilla is the premolar. It is immaterial which of the two we shall take into consideration, both being subjected to similar conditions. The exerted pressure, as in the case of the molars, is directed upon the facial wall of the alveolar process. The transmission of the force orally is only possible through the narrow part which the wall of the alveolar process contributes to the formation of the alveolus as well as to the spongiosa. We have three kinds of buttresses to consider which tend to participate in the resistance of the force exerted on the facial wall. One part of the pressure is exerted directly upon the malar process, another upon the frontal process, and the third upon the convex lower orbital border, which, in turn, transmits it partly to the frontal process and partly to the malar process. The direct force exerted on the oral plate is taken up by the palatal process, and is compensated in an analogous manner, as in the molar region. The pressure re-

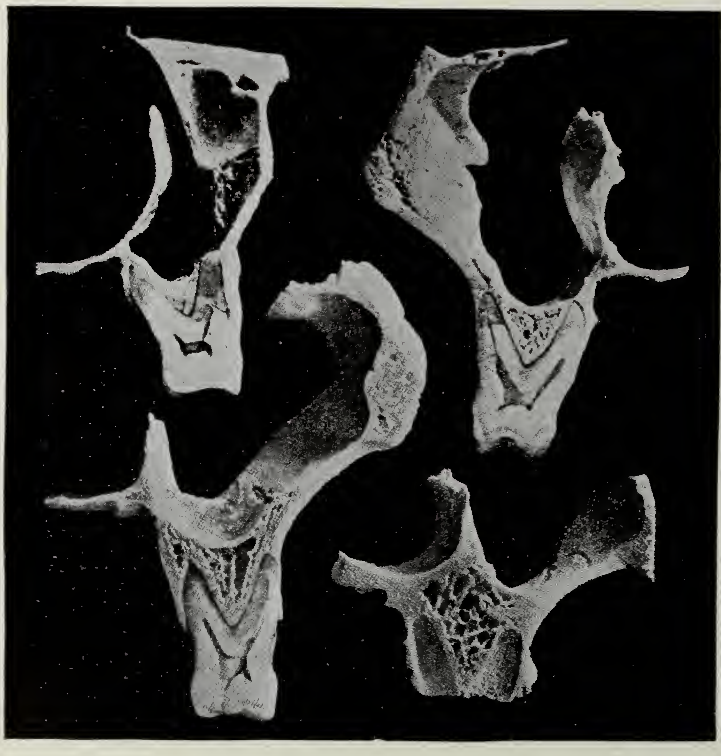
Fig. 19.

Upper second premolars. (Loos.)

ceived by the spongiosa is transmitted partly to the facial wall of the alveolar process and its buttresses, partly to the oral plate of the alveolar process and the palate, and partly to the floor of the antrum and the lateral nasal wall, which, as described above, forms one component directed to the skull and another to the nasal floor, that is in turn compensated by a similar one from the opposite half at the palatine suture.

Anterior teeth. The force that the front teeth, incisors and canines, are exposed to is slight, owing first to the distance from the fulcrum—*i.e.* the length of the lever the mandible represents—and secondly, to the character of the teeth, which are by nature designed to incise but not to triturate the food. The facial wall of the alveolar process is directly burdened, the oral wall very little. The buttress of the facial wall is formed by the frontal process of the maxilla, which is normally placed just over the canine. This process, therefore, receives all the force exerted upon the canine. The incisors transmit the force facially upon the lower border of the *apertura pyriformis,* a downward convex thickening, which in turn transmits it to the frontal process externally and to the palatine suture via the nasal spine medially, where it is counteracted by the components from the other half of the bone. Orally the front teeth exert their force upon the oral wall of the alveolar process, and, through its curved direction, it is transmitted to the palate and compensated at the median suture as above. It may also be said that, although the dissipation of all these forces is best analyzed in the permanent dentition, it

Fig. 20.



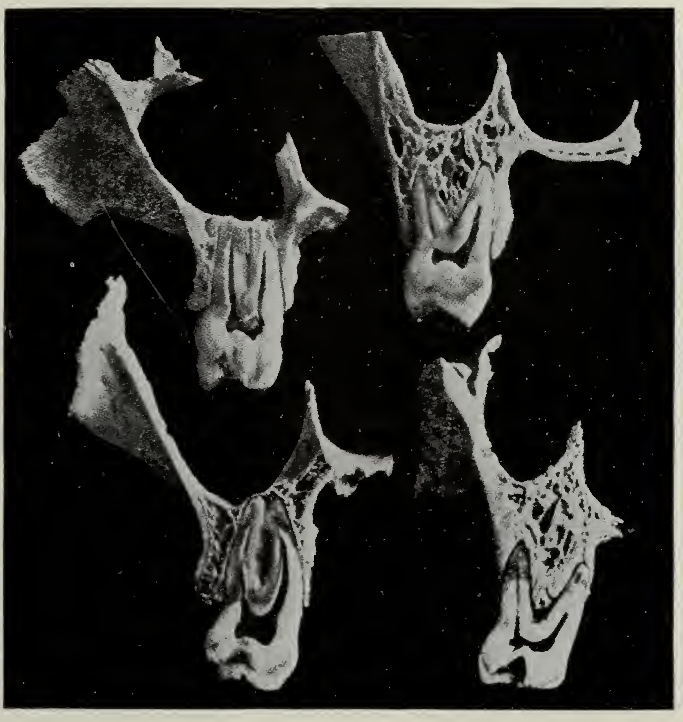
Upper first molars. (Loos.)

similarly occurs in the deciduous teeth, and its effectiveness is just as marked in the healthy toothless nursling.

We see, then, that the force exerted by the muscles of mastication upon the teeth is ultimately invariably transmitted to the brain-case. Another powerful force received by the cranium directly is that derived through the condyles of the mandible, as they articulate in the glenoid fossæ of the temporal bones. Thus, if the mandible, as stated above, represents a lever of the third class, and the weight upon the teeth during the act of mastication represents hundreds of pounds of pressure, this will be manifolded at the other extremity of the lever, in proportion as the power—the muscles—proximates the fulcrum. We would, consequently, not go so very far astray by assuming that, in the establishment of the cephalic index, the masticatory apparatus is a very important factor.

And finally, tracing the effect of all these forces upon the paths themselves, it is quite evident in what manner the face and upper air-passages are influenced. We are therefore led to agree with Prof. Raymond C. Osburn that—"When the teeth are present in the proper number and in normal occlusion, the facial outline, as far as it is affected by the teeth, will be normal for the individual, whatever particular 'cast of countenance' nature designed him to have." In other words, as Angle formulated it in his law of normal occlusion: "It is that the best balance, the best harmony, the best proportions of the mouth, in its relation to the other features, require that there shall be *the full complement of the teeth, and that each tooth shall be made to occupy its normal position—normal occlusion.*"

Fig. 21.



Upper second molars. (Loos.)

Of course, the position of the human masticatory apparatus as such in relation to the face and head, producing conditions of prognathism and orthognathism, is of great significance; for it may vary in the different races of man, as it varies in the different species of animals from the lowest to the highest form without the slightest deviation from the normal. Depending upon the inclination, form, and position of the alveolar process and its contained teeth, in relation to the face and head, we may have the

different gnathic types, which is true of lower animals as well as of man. This character of the two different types of jaw of the Titanotheres, an extinct animal, has been distinctly described by Prof. Henry Fairfield Osborn(17). The different types of dentitions of the teeth should be noted in the monkeys (Fig. 23), and finally the different gnathic types of man (Figs. 24, 25, and 26).

SUMMARY.

To recapitulate, we may say:

(1) That, as the late Prof. John Ryder, of the University of Pennsylvania, contended, the soft parts are not determined by the hard parts, the reverse being true. The bony structures are the consequence of the activity of the soft parts, and are laid down later. Those parts in which metabolism is modified, so that the solid ingredients of the blood are deposited there, become solid and unyielding. Bony structures thus come into being and seem a part of heredity, when in reality they are a consequence and not a cause.

Fig. 26.

Models of normal dentitions of three orthognathic Europeans, showing variability in the inclination of the alveolar process and teeth. (M. H.)

(2) That, therefore, the first requisite of normal occlusion is the normal development of the structures concerned in the establishment and maintenance of this condition ("Forces of Occlusion," Angle).

(3) That the forces of occlusion develop in order of their importance; first the tongue, next the lips and cheeks, then the jaws, and lastly, the teeth and the dental arches.

(4) That the normal activity of the dental apparatus is functionally concerned in mastication and speech; but the interrelation of the teeth themselves depends, besides their occlusal inclined planes, upon the normal development and normal activity of the structures named under 3.

(5) That the effect of normal occlusion is not limited to the mouth alone, but influences the development of the respiratory passages and the face and head, in the establishment of type.

(6) And finally, the line of occlusion —"the line with which in form and position, according to type, the teeth must be in harmony if in normal occlusion" (Angle)—can only be thoroughly comprehended upon the keenest appreciation of the *true* significance of normal occlusion in the broadest possible manner.

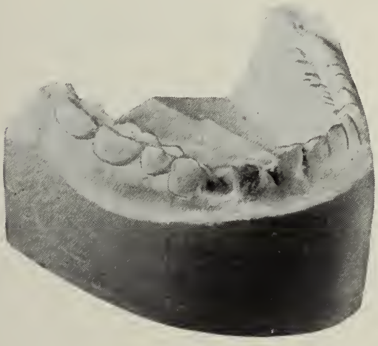
FORCED ERUPTION AND REGULATION OF A RETAINED LOWER RIGHT CANINE.

By ALEX MERTENS, The Hague, Holland.

ABOUT five years ago, a lady brought her daughter of about seventeen years of age to my office, the latter's lower right canine having failed to erupt. In the place where this canine should have been there was an open space, while the lower right lateral incisor was somewhat out of proper alignment distally, as may be seen on the accompanying reproduction of the model of the lower jaw. (Fig. 1.)

FIG. 1.



HISTORY OF CASE.

Besides, there was an ugly scar on the cheek almost corresponding with the place of the alveolus of the lower right canine. On further inquiry I learned from the mother the following history of the case: From her eighth to her ninth year the patient had violent neuralgic pains along the mandibular nerve on the right side. (The family was then living in the Indies.) Continually there appeared on the cheek, following the course of the nerve, herpes blisters, which the mother, upon the advice of a physician, opened by means of a needle passed through a flame. After about a year an ulceration, as the mother called it, was formed at the site of the present scar. There was a liberal secretion of pus, and after some time the sore, and with it all pain, disappeared. The mother was of the opinion that the needle with which she had pierced the herpes blisters the last time had not been sufficiently sterilized, and had caused the sore and consequently the ugly scar, which to her was, and remained, a continuous source of grief. I heard, too, that about three or four years ago the lower right canine had been extracted because it was loose and caused pain; but whether this was a deciduous or permanent tooth, neither the mother nor the daughter could tell.

DIAGNOSIS.

My diagnosis was retention of the lower right canine. The pressure on the pulp, in all probability, had caused the neuralgic pain which persisted during the patient's eighth year. I surmised that after a year the pulp had died, causing an abscess which broke out on the face. This, too, explained the sudden relief from the neuralgic pain. Since

FIG. 2.

palpation did not reveal a retained tooth, I proposed that a radiograph be made. In this radiograph (Fig. 2) the retained tooth can be clearly seen lying in an almost horizontal position, labially from the other teeth, and entirely surrounded by bone, the crown reaching to the apex of the lower right central and the apex to the root of the lower right second bicuspid.

TREATMENT.

I then proposed to try and bring this retained tooth in its proper position, which was agreed to. First, by elastic rings, the lower right lateral was moved in a mesial direction, thus closing the space between the lateral and central. Then at the level of the retained tooth, an incision in the gums was made up to the bone and the mucous membrane pushed aside by small cotton tampons. An opening was then drilled through the jaw-bone and widened to 0.5 sq. cm. A thick, tough membrane of connective tissue was reached, making me think, at first, that I had struck the pericementum of the retained tooth, but I was soon convinced, upon using a sharp probe, that there was enamel under the membrane. The little wound was then dressed with a bit of iodoform gauze, and the patient was dismissed till the next day. A small hole was then drilled into the crown, and by means of cement a little hook was fixed in it. At the same time it was noted that there was no pulpal reaction to an electric test. The lower right teeth, from the central to the first molar, were then capped, and the caps were connected by a little bar. To this little bar an elastic ring was fastened, which was connected with the other end to the little hook in the retained tooth. By fastening the elastic ring to the horizontal bar more mesially or distally, it was possible to induce the crown of the canine to erupt in the desired place. After some weeks the crown had entirely come out of the gingiva; the incisal edge of the crown was, however, turned still too much in a mesial, the apex too much in a distal direction. In order to give the tooth a more vertical position, a second hook was fastened to the mesial side of the crown, but lower than the hook on the distal side. By effecting an upward mesial traction, while the distal hook was firmly held in its place by being fastened to the horizontal bar by a wire ligature, the tooth was placed in a more vertical position. After a lapse of five months, the tooth was fairly well in place. I then proposed to treat the root-canal and to bring the tooth still more into its proper place, but the patient thought the result quite sufficient, and declined any further treatment.

FIG. 3.

FIG. 4.

In Fig. 3 the result obtained may be seen. The position of the tooth in its socket is very solid. Another radiograph (Fig. 4), which was taken on April 10, 1909, was not very successful, yet close examination, nevertheless, shows that the regulated canine has a long root bent convexly in a mesial direction, and pretty well occupies its proper position.

THE FUNDAMENTAL PRINCIPLES OF ROOT PREPARATION.

By FORREST H. ORTON, D.D.S., St. Paul, Minn.

(Read before the North Dakota Dental Association, at its eighth annual meeting, Fargo, N. D., May 16, 1913.)

THE literature describing methods for replacing natural with artificial crowns is voluminous and abundant, and the technique of construction is, as a rule, presented graphically and in detail. Nevertheless, it must be clear to anyone who will consider the matter carefully that neither mere ingenuity nor even the greatest amount of mechanical skill in execution can at all compensate for an improper preparation of the root. Yet on this subject the literature is so slight as to be insignificant. This most difficult as well as most important feature of the work is usually dismissed with a brief and utterly inadequate caution to make the axial walls of the root parallel.

From this curt dismissal of the subject one would be inclined to infer that the preparation of the root was of secondary importance. Nevertheless, I am convinced that more crown failures can be traced to a lack of thoroughness at this stage of the work than to any other cause.

It may be true that the character of this work is such as does not lend itself readily to description by means of the written word; there can be no doubt that a better understanding of the technique and instrumentation employed may be gained by watching a clinical demonstration than by reading a verbal description. This is true of most of our work; we learn best by seeing an operation done. Most dentists have therefore come to have the type of mind known as the visual mind. One of the most difficult problems of the spoken or written word, the successful solution of which requires the master hand, is to render a description which makes the hearer or reader see the thing as it actually is—*i.e.* gives him a correct and full visual image of it. Yet, in spite of this difficulty, I see no reason why the principles which should guide this operation may not be as clearly presented as, for example, the principles of cavity preparation.

COMPARISON BETWEEN CAVITY PREPARATION AND ROOT PREPARATION.

We may draw an instructive parallel between cavity preparation and the preparation of the root for the reception of a crown. An intimate knowledge of the surface anatomy of the tooth is prerequisite to a proper understanding of the principles of modern cavity preparation. In the case of the preparation of the root, likewise, we are dependent upon our knowledge of dental anatomy, and that to an even greater extent. When we stop to consider the firmness of the attachment between the enamel and the dentin, together with the fact that a certain part of the field of operation is concealed from view by a very delicate membrane, which will usually react unfavorably to the slightest injury, we can readily understand that this work cannot be performed in a perfunctory manner. Other things being equal, it is certain that he who depends upon a sense of touch alone in this work will do more damage to the surrounding tissues than he who is aided also by a clear knowledge of the character and shape of the structure upon which he is working.

ANATOMIC CONSIDERATIONS IN ROOT PREPARATION.

The subject of dental anatomy, in so far as it has important bearing upon operative dentistry, may be conceded to have been exhaustively treated in the two able and authoritative text-books upon the subject published by Drs. Black and Broomell. But the making of a crown introduces new problems, and makes new and searching demands upon our knowledge. We are confronted with the necessity of understanding the relation of the dentin and the enamel to the contour of the tooth, *i.e.* the proportion of the tooth occupied by each tissue; we need to know the shape of the dentin when denuded of its enamel, and especially is it important to know the form of the enamel as it approaches the cementum, the amount of variation of the gingival line, and the average length of the free gum margin. The length of the free gum margin can be made a very important diagnostic sign. This feature may be decisive as to when it might not be best to employ the banded crown, for where the gum line is normal, a condition frequently found in youth, we might safely infer that the peridental attachment is normal, *i.e.* the peridental fibers are attached as far crownwise as the gingival line. Under these conditions, it would be impossible to remove the enamel without doing a serious injury to the fibrous attachment which holds the free gum margin tightly against the gingival margin. An injury to the attachment would cause a recession of the gum and progressive loss of gum contour. While the gum recedes normally as age advances, I am convinced that it is bad practice to deliberately hasten this recession.

I simply mention the foregoing supposition in passing, as it is far from being the average condition, and is chiefly to be expected in youth and adolescence. But when a tooth has been subjected to such an unfavorable environment as to require a crown, either through extensive destruction by caries or loss of structure by poorly placed fillings, the interdental space will have been lost, with more or less injury to the peridental attachment, in which case the situation admits of a banded crown. But even then we may still have from 1½ to 2 mm. from the gingival line to the free margin of the gum.

THE PROBLEM OF REMOVAL OF ENAMEL.

It is generally conceded that the ferrule should extend rootwise as far as the gingival line, and as the gingival line is the most constricted portion of the tooth, if we are to have a ferrule in close contiguity around the entire gingival circumference, the tooth must be scaled down at least as far as this constricted gingival line. How are we to be sure when we have scaled the tooth sufficiently to obtain this necessary condition? Will the removal of the enamel be sufficient to give us parallel walls, or does the dentin make up part of the gingival contour?

MERE EMPIRICISM OF LITTLE VALUE.

I have asked this question of a great many dentists, and have been strongly impressed with the want of a standard of criticism. Dentists generally seem to agree that experience and judgment are the only guides possible in this work. Each individual who accomplishes anything in this direction laboriously works out for himself by a trial-and-error method his own theory and practice, and when he passes away, his art perishes with him. I need not insist on the loss of effort caused by this method of working, nor upon what the profession loses as a whole by the fact that one man cannot begin where another leaves off.

I do not in the least underrate the value of clinical experience. But we cannot build a science on this alone. Scientific inquirers give the name of empirical laws to uniformities which observation has shown to exist in a definite number of cases, but on which they hesitate to rely in cases varying much from those actually observed. Such a law seems to hold as a matter of fact, but it is impossible to see any reason why such a law should exist. Therefore, however useful empirical knowledge may be, it is not to be compared in value with that well-connected and perfectly explained body of knowledge which constitutes an advanced and systematic science. It is in proportion as a science becomes systematic and enables us more and more to grasp apparently unconnected facts under the same law, that it becomes perfect. He who knows exactly why a phenomenon happens, will also know exactly in what case it will happen and what difference in the circumstances will prevent it from happening. Keeping in mind, therefore, these general considerations, let us see if we can discover any such principle in connection with the matter before us.

EVOLUTION AS INFLUENCING THE SHAPE OF THE TEETH OF MODERN MAN.

Let us consider the tendency shown in the evolution of the jaws of civilized man. It is generally admitted that the jaws are growing smaller. No better proof of this can be given than the changing shape of the teeth. In the higher anthropoid apes the teeth are short, broad, and extremely bell-shaped, with large interdental spaces, owing, no doubt, to the existence of plenty of room for their development. In these teeth the dentin makes up part of the contour of the crown. The teeth of primitive man, while not quite so large, have the same general type, and, as might be expected, the dentin makes up part of the contour of the crown. In the deciduous teeth of today also, the dentin makes up part of the contour of the crown.

Now, let us look at teeth of the extreme opposite type. In the highly complex nervous organization which is becoming so common in the overcrowded civilized centers today, the jaws are smaller and narrower, and as a consequence the teeth are longer and crowded more closely together; the cusps are bunched together, and the teeth are less bell-shaped. In these teeth the dentin, instead of making up the contour of the crown, presents axial walls which tend to approach each other, so that in extreme cases, when the enamel is stripped from the crown, we have a veritable peg-shape left. I would not be misunderstood as advocating that we build our theory and practice on extreme cases. If we are to have a scientific standard of criticism, we must know the anatomy of the average tooth of today; then, having possession of the general principles noted above, when we meet with extreme types the principle will tell us how and why to vary our operative procedure.

The removal of the enamel from the dentin for a space of upward of 2 mm. underneath the gum tissue, without doing injury to the gum tissue and the peridental attachment, requires so high a degree of surgical skill and is so laborious an operation, burdensome alike to the patient and the operator, that we would like to be quite sure of its necessity before insisting upon it as a normal procedure.

RELATIVE DISTRIBUTION OF VARIOUS TISSUES IN TEETH.

A description of the relative proportion of the tooth occupied by each tissue will, I think, be convincing on this point. The contour of the tooth is made up almost entirely by the enamel. Beginning at the gingival line by a beveled edge, it gradually increases in thickness, until the points of the cusps are reached; here we shall find the thickest enamel. The enamel will also be thickest underneath any ridges or elevations on the various surfaces, this thickness being formed by the increased convexity of the outer surface. The dento-enamel junction—or axial wall of dentin—passes toward the occlusal surface with little or no convexity, but only with a slight inclination toward the axial line of the tooth. If this anatomical description is accurate, the entire removal of the enamel seems to be an obvious necessity if we are to have the crown in close contiguity with the entire gingival circumference.

While the anatomy just described will not be found in any published work upon this subject, Dr. Daymon, the dental anatomist at the University of Minnesota, has thought this matter of such fundamental importance as to warrant the undertaking of a large task in grinding specimens, taking measurements, and making charts. It is hoped that a practical application of these findings will tend materially to advance crown work to a high rank among modern prosthetic dental procedures.

DIFFERENCES IN TOOTH FORM AT THE FREE MARGIN OF THE GUM AND AT THE GINGIVAL MARGIN.

In order that dentists may have a more accurate perception of the difference between the form of the tooth at the free margin of the gum and at the gingival margin, we will study these portions of a lower first molar somewhat in detail. A difference is noted in the outline form of the dento-enamel junction and that of the periphery of the crown at this point. The measurement of the outline form of the dento-enamel junction at this point is practically the same as the measurement of the outline form at the gingival line. We can easily verify this by taking an extracted tooth, obtaining the shape at the gingival margin by shaping a brass ligature wire around it at this point, and then grinding down the occlusal surface until we have reached the free margin of the gum. The discoloration and etching of the enamel will aid us in determining it on the buccal and lingual surfaces and the points of proximate contact on the approximal surface. When subsequently the outline form of the gingival margin, which has been obtained with the wire ligature, is placed over the dento-enamel junction at the free margin, it will be found almost identical.

SCALING OF ENAMEL IN DIFFERENT TEETH.

Thus, if we are to obtain a perfect adaptation of the band at the gingival margin, the removal of all the enamel at this point is obviously necessary. In scaling the enamel, we should always bear in mind the points at which we should expect to find it thickest. Our sections and drawings [demonstrating] show a thicker deposit upon the mesial and distal than upon the buccal and lingual surfaces, and again a thicker deposit upon the distal than the mesial surface. One of the most difficult points to scale is the disto-lingual angle point, and here we will find the thickest enamel. This we might expect, as the mesial root has two canals, and is wider bucco-lingually than the distal root, which has only one canal, while the measurement of the periphery of the crown is the same on the distal as on the mesial surface.

In the upper molars there is usually found a thickening of the enamel upon the mesio-lingual and disto-lingual angle points which is especially difficult to scale. This thickening is probably due to the lessened mesio-distal diameter of the lingual root over that of the two buccal roots, while the mesio-distal diameter of the crown upon the lingual root remains about the same as that of the buccal roots.

A point to note in this upper left first molar [demonstrating], from which the distal convexity has been cut off, is that the enamel passes higher gingivally on the lingual than upon the buccal surface, and in a buccal view at the point of approximal contact it may be observed that it passes higher on the distal than the mesial surface. This is an important anatomical point to remember in scaling the root, as well as in trimming and festooning the band.

SERIOUSNESS OF INJURY TO THE GINGIVAL MARGIN.

From the want of care taken to avoid lacerating the gingival margin, one would be inclined to think that a great many dentists do not fully appreciate the importance of maintaining a healthy free gum margin. I doubt if a traumatic injury to this tissue may ever be fully repaired.

The free border of the gum is covered with a moderately thick, dense coating of epithelium, but the portion that folds in and lies next to the neck of the tooth is composed of softer and more delicate cells than other portions. The lymphatic glands are larger and more numerous in this neighborhood than in other portions of the membrane. These glands lie very close to the gingival aperture. That portion of the connective tissue in close conjunction with the tooth is not covered by the epithelium—in other words, there is no attachment of the epithelium to the root of the tooth, and—"It seems to be through this space that the cells, so-called salivary corpuscles, found under the free border of the gingiva, pass, and their number is augmented with every irritation of the membrane." (Black.)

THE DENTAL LIGAMENT.

Bundles of fibers emanating from the cementum at the neck of the tooth turn up into, support, and hold the free gum margin tightly against the gingival margin. These bundles of fibers have been termed the dental ligament; anything which interferes with their attachment will cause the gum margin to recede.

TECHNIQUE OF REMOVAL OF ENAMEL IN ROOT PREPARATION.

While the dental profession has shown a wonderful productiveness in the invention of instruments suitable for accomplishing the various operations incident to operative dentistry, the same degree of ingenuity does not seem to have been directed toward the invention of instruments for the removal of the enamel. Furthermore, while the average dentist will supply himself with from one to three dozen burs and as many chisels, he will limit himself to three or four scalers, notwithstanding the fact that these instruments are subjected to the most severe strain of any in his equipment, and need to be resharpened after each operation.

Your committee has requested me to outline the technique as taught at the University of Minnesota. While each tooth, owing to its position in the mouth, will require some variation of instrumentation, it has been thought best—in order to avoid stretching this paper to an inordinate length—to limit its scope to those cases in which the conditions are favorable, on the principle that it is best to understand the simple before proceeding to the complex.

INSTRUMENTARIUM.

As the lower first molar is probably the tooth on which a banded crown is most often indicated, we will select this tooth for making our preparation for the reception of the crown. The instruments used are (1) an assortment of thin carborundum disks known under the trade name of "Joe Dandy," (2) the Harper scaler, with good assortment of scalers, and (3) the Johnson scalers. These scalers are selected for the reason that they will slide under the gum margin without injury to the soft tissues.

In order that we may have an intelligent understanding of the contemplated operation, we must know the condition of the tooth. Owing to the unquestionable superiority of even a large mesio-occluso-distal inlay over the most skilfully placed crown, a crown in this region is only indicated when the walls are badly broken down, or only the peripheral enamel remains, or in the event of using a comparatively sound tooth as an abutment in bridge work. As the latter involves a more extensive technique, we will suppose that we are to prepare a comparatively sound tooth.

REMOVING ENAMEL PROJECTING ABOVE THE FREE MARGIN OF THE GUM.

The occlusal one-fourth is first removed by cutting through this portion of the tooth [demonstrating] with a Joe dandy disk held in a right-angle handpiece. No attempt should be made to cut off the entire occlusal surface at once —such an attempt is not an economy, for too many disks will be broken. A cut is made to about 2 mm. of depth, and then this weakened occlusal portion is broken away with a chisel, continuing in this manner until the occlusal fourth is removed.

The mesial and distal approximal surfaces are next in order. The mesial surfaces may be removed by beginning at a point about one-sixteenth of an inch distal to the mesial approximal surface with the disk held in the straight handpiece and cutting at a slight angle until the proximal space is reached.

The buccal enamel may be removed next by cutting, with the same disk, a series of perpendicular cuts through the enamel. The continuity of the enamel is thus broken up, and it may be readily chipped off with a sharp chisel.

The removal of the distal contour presents the same requirements as those described for the mesial aspect, with the following difference: On the mesial surface there is a slight inclination mesially; on the distal surface this inclination must be toward the distal aspect. Owing to the presence of the anterior teeth, it is impossible to accomplish this with the straight handpiece. But this difficulty may be overcome with a Joe dandy disk, held in the right contra-angle handpiece, by reversing the handpiece—*i.e.* by holding the angle part of the handpiece toward the distal surface and beginning at a point one-sixteenth of an inch mesially to the disto-proximal surface, cutting at a slight angle toward the distal surface until the approximal space is reached.

The continuity of the enamel on the lingual surface is broken up in much the same manner as on the buccal surface, but with the difference that the perpendicular cuts are made with the disk held in a contra-angle reversed in the same manner as described in removing the distal contour. As the requirements, especially for a molar, will not allow of a chisel being used for chipping off the broken-up enamel, a heavy enamel cleaver, held in a right-angle handle and known as the Harper scaler, may be employed.

We have now removed the enamel from that portion of the tooth which projects above the free gum margin.

REMOVING ENAMEL FROM THE NECK OF THE TOOTH.

But we still have a rim of enamel encircling that portion of the tooth from the gingival line to the free gum margin known as the gingival margin, which, as I have said, will usually be from one and a half to two millimeters in extent. The rods are shortest, and therefore the enamel is thinnest, at this portion of the tooth, and for this reason it would be easier to remove were it not for its inaccessible location, as in demonstrating this technique on a freshly extracted tooth, this gingival ring of enamel is the easiest to remove.

In considering the instrumentation, then, we will have to select instruments that will slide up under the free gum margin without doing injury. I have been most successful with the Johnson scalers on the buccal and distal, and the Harper scalers on the mesial and lingual surfaces. These instruments should be modified by grinding off the convex surplus on the end, as this surplus end only takes up space without adding to the strength of the blade.

SHARPENING ENAMEL SCALERS.

It is best to have an assortment of these instruments, at least six of each kind, and it is important that they be kept sufficiently sharp to enable them to bite into the tissue without the necessity of exerting much force, for if the operator attempts to remove this enamel by main strength, he will be sure to slip and lacerate the gums, or else break off the blade of the scaler. The difficulty and time required in sharpening these blades by hand without rounding or making several different bevels on the same blade is no doubt the reason why so many operators are discouraged, and give up trying to keep their instruments sharp. With the sharpener [demonstrating] invented by Dr. Chas. Wiethoff of Minneapolis, a true bevel and sharp edge may be quickly and easily obtained; in fact, an office assistant, after a few lessons, can put on as true a bevel as the instrument had when it was purchased from the manufacturer. This sharpener is thoroughly practical, and I do not hesitate to recommend it as one of those instruments which are indispensable in a dental equipment. While frequent sharpening wears down the blade, this is an advantage, as it gives the operator an assortment of blades of different thicknesses. For example, the Johnson scaler as it comes from the manufacturers is, in some instances, too thick to allow of its being inserted between the lateral and central incisor, especially if these teeth come very closely together at the gum margin. Blades that have been worn down by frequent sharpening may be inserted without injury to the soft tissue, whereas the newer blades may be used on the buccal and lingual surfaces, where there is sufficient room to allow of their being inserted beneath the gum cuff without injury. But even when the interdental space on the four incisors is normal, owing to the thinness of the gingival enamel on the incisors a very much thinner blade would be indicated than that required for the removal of the much heavier enamel which is usually found on molars.

Having selected the proper instruments for the removal of the enamel at the gingival margin, we will be guided in our method of approach by recalling a mental picture of the shape of the gingival margin, so that, instead of pushing the scaler in a direction parallel to the long axis of the tooth, we introduce it at an angle which allows it to follow the enamel bevel. When the condition is at all favorable, the scaling of the enamel may be done without traumatic injury to the soft tissues, and when pain is experienced other than that which may be due to the pressure of the instrument, it must be attributed to faulty technique.

We have presented toward us the base or thickest part of the enamel rim, which, for illustrative purposes, may be likened to a ledge under which we are to introduce our scaler, and—except in those cases where the pulp has been devitalized for several years, in which case the attachment to the dentin will have weakened—it is not best to force the scalers up as far as the gingival line at first; but by first removing the widest part of the rim, measuring about one-half mm. all around, we will obtain more room, and then we may continue in this fashion, until the enamel is entirely removed.

Convenience will teach the operator when to use the palm grasp and when the pen grasp. This depends upon the position of the tooth in the arch and other favorable conditions, such as loss of interdental space or the tipping forward of the tooth into adjacent spaces.

CONCLUSION.

In conclusion, I would like to say that, if I have succeeded in emphasizing the importance of a more thorough study of dental anatomy, I shall feel gratified. For an intimate knowledge of the anatomy of the teeth and their surrounding structures is as important to the dentist as general anatomy is to the surgeon; in spite of which fact that part of dental anatomy which has a special bearing upon crown and bridge work has hitherto been strangely neglected.

SOMNOFORM ANALGESIA AND ANESTHESIA.

By E. L. MORAVEC, D.D.S., Cedar Rapids, Iowa.

(Read before the Cedar Rapids Dental Society, April 7, 1913.)

ANESTHESIA, the greatest boon ever bestowed upon suffering humanity, is the gift of Horace Wells, a dentist, a humanitarian, and a great benefactor. Another dentist, Dr. Morton, discovered the anesthetic properties of sulfuric ether.

Anesthesia has made surgery possible, and dentistry has contributed anesthetics to the sum total of the world's knowledge. That alone should be glory enough to make the dentist proud of his profession.

PAIN A GREAT BARRIER.

The nature of our work is such that we almost constantly inflict pain. Patients under our care suffer both mentally and physically, the one kind of suffering augmenting the other. Were it not for the dread of pain, five times as many dentists as we now have would be required. I have read that in our country only eight per cent. of the population are regular attendants of dental offices, and from forty to fifty per cent. of our people are amply able to pay for such services. *Pain* is the reason. By our continual practice our sensibilities become deadened, and the constant effort to impress upon our patients the fact that "This will not hurt" makes us finally believe that the outcry of the patient is only the result of an imaginary pain. The phrase has been coined—"He lies like a dentist."

REASONS FOR THE USE OF ANALGESIA AND ANESTHESIA.

The reasons why we should employ analgesia and anesthesia are as follows: (1) To prevent pain, thus eliminating fatigue, shock, and collapse. (2) To make possible shorter sittings, a condition certainly more pleasing to both the patient and operator. (3) To enable the operator to make a more thorough operation. (4) To enable the operator to accomplish an increased amount of work in a given time. (5) To elevate dentistry to the dignity of a branch of surgery; also to increase the receipts of our practice, since for such service the people are willing to pay.

PAIN AND SHOCK.

Pain causes exhaustion of the vasomotor centers and shock, rather than structural lesions.

Shock, then, may be defined as a depression produced by exhaustion of the medullary centers controlling respiration and circulation by a too sudden and painful or prolonged stimulation of the afferent nerves, these nerves carrying the impulses from the periphery to the brain.

As a practical illustration take the following condition: The operator applies suddenly the revolving bur to sensitive dentin; the patient turns pale, and breaks out in perspiration. What has happened? Too sudden stimulation of the afferent nerves is exhausting the respiratory and circulatory centers in the medulla, and if it be applied for too long a time, loss of consciousness may result, with cessation of breathing.

Psychical shock is caused by mental impressions, the fear of pain being the etiological factor. I have seen patients faint at the sight of forceps or from watching another patient undergo an operation. Local anesthetics would in these cases be, at best, only partially effective.

ANESTHETICS.

The first known form of anesthetic employed was boiled hemlock applied locally, and vinegar applied subsequently as an antidote or a stimulant. Other anesthetics are as follows: Sulfuric ether, $C_4H_{10}O$. Chloroform, $CHCl_3$. Ethyl chlorid, C_2H_5Cl. Methyl chlorid, C_3H_3Cl. Ethyl bromid, C_2H_5Br. Bromoform, $CHBr_3$. Pental (non-official). Nitrous oxid, N_2O_2. Also a number of others.

For your present consideration I shall take up a combination of ethyl chlorid, methyl chlorid, and ethyl bromid, which combined constitute somnoform.

Somnoform.

The first formulæ for this combination were as follows:

(*a*)

	Per cent.
Ethyl chlorid,	60
Methyl chlorid,	35
Ethyl bromid,	5

(*b*)

	Per cent.
Ethyl chlorid,	83
Methyl chlorid,	16
Ethyl bromid,	1

This (*b*) is now used in 5 cc. and 3 cc. capsules.

The action of each ingredient alone is vastly different from that of the combination. The process of obtaining or the source of each ingredient we need not discuss here.

Ethyl chlorid is used also for internal medication, as a stomachic, a carminative in flatulent dyspepsia, and a cardiac stimulant, besides being a local anesthetic and also, when inhaled, a general anesthetic—although a somewhat dangerous one, therefore seldom employed alone.

Methyl chlorid belongs to the same family as ethyl chlorid, the formula differing but slightly. It is used in medicine for neuralgia. It is a local anesthetic, and also is used as a general anesthetic; it is a very dangerous one.

Ethyl bromid was first introduced into the practice of medicine about 1880, as a quick and agreeable anesthetic, but it proved fatal in a number of cases, and was therefore abandoned. It causes dangerous lesions of the heart, lungs, and kidneys.

In the combination anesthetic, the methyl chlorid secures promptness of action, so that somnoform begins to exert its anesthetic effect within from thirty to forty seconds, or about the time required for the red blood-cells to travel from the lungs to the nerve centers where anesthesia is induced. The ethyl chlorid prolongs the stage of anesthesia, while the ethyl bromid produces the stage of analgesia immediately following the anesthesia, which is of great value in slight operations. This stage is sometimes longer in duration than the period of anesthesia.

PREPARATION OF THE PATIENT.

The preparation of the patient in my office is left to my lady assistant. Success depends largely upon the capability of this assistant, who with female patients must see to the removal of the corset and the loosening of all bands about the waist and neck. While doing this, if competent in her work, she will maintain a light conversation to keep the patient's mind off the operation, mention cases—especially those of patients of her acquaintance if possible—who have undergone such operations successfully. She should laugh with the patient, since there is nothing like a laugh to make one feel at ease. While the operator is administering the anesthetic, the assistant should stand on the left side of the chair. There should be no conversation except quiet, reassuring words from the operator, who should ask questions and request answers from the patient, thereby judging somewhat the stage of anesthesia. No whispering should be tolerated. as the hearing is the last sense to depart and the first to return. When the anesthesia is sufficient to operate, the assistant should watch the condition of the patient. If the patient is in the analgesic state, she must hold the appliance and increase or diminish the amount of air and somnoform as conditions indicate. She must, of course, be thoroughly acquainted with the symptoms of anesthesia. The necessary instruments must be at hand for the operator, a pus basin being kept ready in case of tooth extraction, and the assistant takes general care of the patient following extraction. A third person must always be present, especially if the patient be a young woman.

INDUCTION OF ANALGESIA.

After all is in readiness, the appliance is adjusted in the proper position, and the patient is allowed to breathe air only, for a few inhalations, then the indicator is advanced to about $\frac{1}{8}$—which means that the patient is getting $\frac{1}{8}$ somnoform and $\frac{7}{8}$ air—for four or five inhalations. A quiet, reassuring conversation is kept up; the indicator is advanced to $\frac{1}{4}$, while the operator continues to ask questions requiring answers, thereby judging the progress of the anesthesia. Soon a lazy dropping of the eyelids and slight muscular relaxation will be noticed. At this time an excavator should be applied to the dentin. The operator should proceed slowly at first, ask as to pain, then start slowly with a sharp bur. It will be found that the patient will not mind the bur. The assistant may, at this time, shut off the somnoform, at least in part. If the patient again shows signs of pain, she will advance the indicator. An assistant should be able to judge of the patient's condition as well as the operator, centering her attention upon the patient. By keeping the patient at this stage, the most hypersensitive cavity can be prepared with almost no pain, in a very short space of time.

FULL ANESTHESIA.

If, after preparation of a cavity, a pulp is to be removed or an extraction to be made at the same sitting, the somnoform is advanced so as to produce a complete anesthesia. The operator should never try to expose a pulp under analgesia, as considerable shock will be produced.

Signs of anesthesia. There are many factors to be kept in mind. Every symptom and detail is important. A lazy drooping of the eyelids and muscular relaxation is generally but not always present; sometimes rigidity takes place instead. In this case an oral operation would be impossible unless a mouth-prop has been placed in position beforehand. Then other guides must be depended upon. The corneal reflex, which is regarded as practically infallible in chloroform or ether, is *not* reliable in early stages of somnoform, although a valuable guide in deep anesthesia. The eyeball will roll upward and become somewhat set, with a noticeable dilatation of the pupil. There is muscular relaxation with rhythmic and automatic breathing, usually marked by snoring. By a study of these symptoms an operator develops an anesthetic sense; this sense is acquired only by experience and very careful study.

CONTRA-INDICATIONS TO ANESTHETICS.

The following contra-indications to the administration of anesthetics must be kept in mind: Diseases of the heart, such as lesion of the valves, cardiac dilatation, or hypertrophy; diseases of the brain, neurasthenia, insanity, or intoxication; diseases of the bloodvessels, as arterio-sclerosis; diseases of the kidneys, as Bright's disease or nephritis, and the status lymphaticus, or enlargement of the thymus glands, as in goiter.

DANGEROUS SYMPTOMS AND ACCIDENTS.

A sudden dilatation of the pupil, without responding reflexes, may be due to paralysis of the contractor muscle fibers, or may represent a stimulation of the dilator centers due to asphyxia.

A sudden concentrated inhalation of vapor may cause heart failure. Heart failure and death may also occur in a slight operation about the mouth under analgesia or incomplete anesthesia, since the nuclei of the trifacial nerve are so near those of the pneumogastric nerve that sudden impulses or shock may be conveyed over the vagus, causing death by inhibition of the heart's action.

Sudden coughing or vomiting may force the diaphram upward, also interfering with the heart's action.

Asphyxia, due to the respiratory centers being affected, may also result, or dropping back of the tongue, causing strangulation.

TREATMENT IN EMERGENCY.

The cessation of respiration always takes place first. Artificial respiration, therefore, should be resorted to by Sylvester's method, the tongue being pulled forward. Inhalation of amyl nitrite, or 1/30 grain of strychnin or 1/100 grain of nitro-glycerin hypodermically may be resorted to, or from eight to ten drops of adrenalin solution be placed in the conjunctival sac of the eye, adrenalin being a strong cardio-vascular stimulant; or cold ether be poured upon the chest to stimulate the reflex by its refrigerant effect. As a last resort, a strong and sudden dilatation of the sphincter ani muscles may be produced, causing irritation. The drugs mentioned should always be at hand, though an operator may hope never to use them.

EFFECT OF ANESTHETIC UPON VARIOUS ORGANS.

The effects of somnoform upon the various organs may be summarized as follows:

(1) *Skin.* Local irritant and refrigerant action.

(2) *Brain.* Depression of the cerebrum, abolishing all its functions, but returning to normal, the cortex being but slightly affected.

(3) *Medulla.* It is affected last of the entire nervous centers, and only in extreme cases of dangerous narcosis and paralysis of the respiratory and vasomotor centers.

(4) *Spinal cord.* All reflexes are abolished; the sensory side is paralyzed first, then the motor.

(5) *Circulation.* Only slightly affected; in deep anesthesia the blood pressure is slightly diminished.

(6) *Capillary area.* A slight dilatation cutaneously occurs, causing flushing of the face.

(7) *Heart.* At first slightly stimulated, but then returning nearly to normal.

(8) *Eye.* Dilatation of the pupil at first, slight rotation upward, and is "set." In deep anesthesia, contraction takes place; in dangerous cases, sudden dilatation. If the anesthesia is still advanced farther, coma results, owing to paralysis of the contractor fibers.

(9) *Respiration.* In analgesia, the respiration may be regular or irregular, depending upon the excitability of the patient; in complete anesthesia, it should be normal or rhythmic, as in natural sleep; in dangerous narcosis, cessation may set in owing to paralysis of the respiratory centers of the medulla.

(10) *Temperature.* Usually slightly reduced.

(11) *Metabolism.* Is but slight and tranquil, as elimination is carried on by the lungs and kidneys. There may be some destruction of proteids, with improper oxidation.

(12) *Blood.* The blood exhibits very slight diminution of the hemoglobin and corpuscles, but no hemolysis is produced as by chloroform and ether.

Following is a table showing the changes noted, by minutes. The figures, of course, may vary in different cases, but the records taken in a number of cases show the results to be practically the same:

	Normal.	1 *m.*	2 *m.*	3 *m.*	4 *m.*	5 *m.*	6 *m.*
Pulse	72	84	76	68	68	68	67
Respiration	16	28	20	19	20	20	19
Blood pressure	120	125	130	135	140	140	140

Dropping back to 110 on awakening.

THE FUTURE OF PORCELAIN IN DENTAL ART.

By F. T. VAN WOERT, D.D.S., Brooklyn, N. Y.

(Read before the Connecticut Dental Association, at its annual meeting, at Waterbury, Conn., April 15, 1913.)

FROM my earliest recollection and knowledge of the science of dentistry, efforts have been made to secure a material for the restoration of lost tooth structure that would possess sufficient strength to withstand the stress of mastication, and sufficient adaptability to secure perfect union or fit, and represent the natural teeth in appearance. The earliest efforts in this field were directed toward cements. This investigation is still going on, and probably will continue until the ideal has been found.

EVOLUTION OF THE PORCELAIN INLAY.

Later, porcelain was used by a few who were expert enough to grind pieces cut from porcelain teeth, to fit a cavity. Some of the manufacturers placed upon the market various shapes and sizes of porcelain buttons for small cavities in the molars and bicuspids, and an English firm presented a variety of shapes for all locations. Following this came the Timme glass inlay, which I think was the first to be fused into a metal matrix that had been shaped and burnished to fit the cavity. But it remained for Dr. N. S. Jenkins of Dresden to perfect medium-fusing porcelain for use in a pure gold matrix; and notwithstanding many contradictions in favor of the high-fusing body, I believe that to be the nearest to the ideal at present. It is true that no operation is perfect, but I defy anyone to show more nearly perfect results with another material than can be obtained with medium-fusing porcelain —if properly manipulated. This qualification may seem presumptuous, but it is true, and very pertinent.

REASONS FOR THE LACK OF POPULARITY OF PORCELAIN WORK.

Why is it that there is so little porcelain inlay work done today? I am told by the manufacturers that there is very little sale for this material, one of the best-known concerns having to abandon its plant and go into the hands of the receiver. It is because the manufacturers do not qualify in their products; they rate the fusing-point of the body too high, the reason for which I do not understand. Then there is not upon the market to my knowledge today an electric furnace which will not overfuse the low-fusing bodies unless very carefully and skilfully handled. Pyrometers are a delusion and a snare, unless perhaps in the hands of a very few. I am convinced that a time-limit and the human eye are the only reliable means of perfectly melting these bodies. The dentists, relying upon the manufacturers for data for the proper manipulation of the material and its accessories, meet with ill success, and both they and their patients become disgusted, and consider the whole method a failure.

CAUSES OF FAILURE.

Let us analyze a few of the causes for these failures: (1) Improper cavity preparation; (2) the direct method of obtaining the matiix; (3) the imperfect investment of the matrix, because of an imperfect investing material; (4) the warping of the matrix, due to the above-named factors; (5) the too rapid heating at too high a temperature, and (6) the imperfect cementation of the inlay in the cavity. These, together with a number of others, such as faulty occlusion, lack of contour, etc., go to make up the goodly number of causes for the present state of unpopularity of porcelain work.

It is not my purpose to deal with the problem of inlay work this evening, but to call attention to the higher branch of the ceramic art as applied to dental science, namely, the hand-carved porcelain crown.

THE LOGAN CROWN, AND SUGGESTED MODIFICATIONS.

The porcelain crown has been considered more from a commercial standpoint than from an esthetic or accurate one. The earliest efforts in this direction, and perhaps the most practical of these, resulted in the Logan crown. The design and mechanical application of this crown is the most practical of any yet known, but unfortunately the manufacturers persist in making this crown with a pure platinum pin, which renders it the most unreliable of all commercial crowns; while, if it were supplied with a pin of the proper rigidity—which could be obtained by the addition of from 10 to 20 per cent. iridium to the platinum, it would be not only the best crown commercially, but the best for scientific attachment to the natural root of the anterior teeth in particular, as it could be fitted with approximate adaptation to the end of the root, and placed in a position through a platinum or pure gold cap, previously fitted to the root. The space between cap and crown may then be filled with any of the standard porcelains, high- or low-fusing, and a perfect union between root and crown is secured, which is a most essential feature. But unfortunately the Logan crowns available today have pure platinum pins, which are so soft that they cannot be depended upon, and as a result we are forced to construct the entire crown from the raw material. This has led to all sorts of schemes for the production of a crown that will fit the root properly, present a natural appearance, and possess the strength for sustaining the stress of mastication.

A PORCELAIN CROWN WITH FACING.

Attention is called to an old method that is employed very much at the present time, and, while it is very much better than any appliance that can be constructed from stock crowns, it has many disadvantages.

The construction of this crown is as follows: A platinum cap is made for the root, with the necessary pins for its retention. A facing of suitable shape and color is selected and ground to fit, and then soldered to the attachment with pure gold, or preferably platinum solder, after which the rest of the crown is made up of a porcelain body fusing at a lower point than the facing.

This crown is very much better than any stock crown, but has a weakness which condemns it, namely, the difference between the high- and the low-fusing body, which prohibits a perfect union between the two, with the result that, after a short time, the lower-fusing body cracks or crazes, and later is disintegrated, so that this part of the crown has to be removed and made over, or a new crown made.

A PORCELAIN CROWN THAT IS ENTIRELY BUILT UP.

Another method consisted in spatulating the porcelain body to a putty-like mass and building up the crown upon similar foundations as described, without the facing, and carving it to shape. This crown has many disadvantages, the principal one being that the shrinkage is very difficult to provide for. Again, this crown requires perhaps three or more bakings, each of which invites inaccuracies.

THE BUELL CROWN.

Another method, which I consider really the most practical for all-round purposes, is that devised by Dr. Buell of Buffalo, N. Y. I have styled it "the Buell method." The principle is old, but the technique pursued by Dr. Buell is certainly original and practical. For fear of misrepresenting this method and its details, I shall quote verbatim from Dr. Buell:

There are two methods of attachment, (1) by an iridio-platinum post entering the root, and (2) the crown is made in the form of a porcelain shell covering a stump of the tooth, which may be applied to either vital or devitalized teeth.

The tooth is excised, and the surface end of the root ground so as to form two inclined planes, the periphery of which shall be under the free margin of the gum. The root may be so decayed that this form can be only partially obtained. Whatever the form, some provision must be made to lessen the tendency of the crown to revolve upon the root. The root-canal is opened for the reception of a square iridio-platinum post of from No. 14 to No. 16 gage, which is fitted to the root, so that it can be easily removed, then marked where it protrudes from the root. A piece of soft platinum plate from two to three thousandths of an inch in thickness, according to the size of the root to be crowned. is laid upon a lead bar, and the post driven through it. This method punctures the plate in such a manner that it makes perfect contact with the post on all sides. The post is forced through the plate until the mark, where it protruded from the root, is reached; then it is soldered with platinum solder.

The plate and post are placed upon the root, and the post driven to position. The periphery of the root is then outlined by the use of a small pine stick and mallet, after which the plate is trimmed to within one-sixteenth of an inch of this line. Placed upon the root once more, this excess is carefully burnished over the periphery. Should the root be badly broken down, it is best to pack with temporary stopping for a few days before making the cap. The periphery of the root must be well outlined through the plate, and the angle formed at this point should be sharp and well defined. For a final adaptation of the cap, a pad of vulcanite is placed between the teeth over the cap, and the patient is requested to close upon it, thus swaging the cap to perfect adaptation.

A modeling compound impression and bite is now taken. If the cap and post is not removed with the compound, it should be carefully removed and placed in its proper position in the impression. The part of the post that is exposed and the inner surface of the cap are coated with a thin film of wax, then the outer surface of the band is coated with a thick covering of wax. A plaster model and antagonizing model are poured, attaching them to a crown articulator that has a joint permitting a lateral movement.

While the plaster is setting, the shade is selected. I find the best method, in my experience, is to select, with a shade guide, a tooth that is of the proper shade. For convenience, let us assume that No. 38 S. S. W. is the shade desired.

By covering the sample tooth with the finger, so that the cervical portion only is exposed, we find that S. S. W. high-fusing porcelain, shade No. 1, matches this portion; then, covering the cervical portion and exposing the incisal half, we find that shade E matches this portion.

The plaster having set and the compound having been removed, the adjacent teeth are carved away so that the space is widened one-sixth, to allow for the shrinkage of the porcelain, and the articulator is set so that it is held open one-sixth of the length of the crown to be made. The post and cap are now warmed over the burner, and removed from the model. The wax is completely burned off and, when cold, new wax is placed upon the root side of the post, and upon the inside of the band and plate. A button of plaster about one inch in diameter in all directions is placed upon a glass slab, and the post and cap are placed, with the wax side down, into it. When set, the plaster is carved into the shape of a cone, the length of the cone determining the diameter of the tooth to be carved. The post and cap is heated and removed from the cone, all the wax is burned off, then it is chilled in water, and replaced upon the cone. A piece of glazed note-paper, about two by three inches, is wound around the cone of plaster and folded over at the bottom, forming a cornucopia the length of which, above the cap, determines the length of the tooth, and should be in excess of the required length, so that there may be plenty of porcelain to work upon. The porcelain that is to form the cervical portion of the crown is mixed to a thick creamy consistence and the cornucopia is filled with it, then jarred down by drawing the serrated handle of the carver across the paper over the plaster cone. The moisture is driven to the top and absorbed with a napkin. This is repeated until no moisture comes to the surface; the paper is then removed. The porcelain is carved away, exposing the band, and then a thin instrument is forced under the band to the post, and the cap, post, and porcelain are carefully removed from the cone of plaster.

Carve the porcelain so that it will fit into the space on the model. Carve away on the labial side to the height desired for the cervical color, leaving the lingual side intact in incisors and canines. For molars and bicuspids carve away both buccal and lingual sides, in each case carving at an angle, so that the gray porcelain will overlap, causing a blending of the shades. Remove from the model and place upon the plaster cone again. Wrap the paper around the same as before. Add the other shade of porcelain, a little thinner than the previous mix; add quickly in generous portions, so that it may run down between the paper and the dry porcelain, before it absorbs the moisture from the new porcelain. Jar slightly at first, and remove moisture as soon as it shows, repeating until it is all absorbed. Remove from plaster cone as before and trim, so that it will again go into place upon the model. Carve labial side to desired contour, then lingual side in the same manner, using the adjacent teeth and the antagonizing model as a guide. It is always best to make the anterior teeth a line or two too long, as they can be easily ground off. The tooth having been blocked out, remove it from the model and complete the carving, holding the post in a broach-holder. The surface is smoothed with the ball of the finger, thus removing all traces of the carver. The chips and powder are brushed away with a large camel's-hair brush. The surface is now all gone over with an S. S. W. porcelain burnisher, to iron down the surface and make it smoother. The biscuit bake should be made in not less than seven minutes. Try the crown upon the root, and re-adapt the platinum to the surface end of the root, fill in the space thus formed with new porcelain, and, should there be any discrepancy upon the sides or incisal end, it may be remedied by the addition of more porcelain at this time. Bake to a glaze, taking at least ten minutes for same. Try in the mouth, and, if satisfactory, cut the platinum plate away from the post with a No. 1 round bur; wet the crown and carefully peel the platinum away. Should there be any further edges around the periphery of the base of the crown, these may be removed with an Arkansas stone. The crown is then ready for cementation.

I have some specimens of the work done by Dr. Buell, which I shall be pleased to pass around for examination, and I am sure that they will be found to be very beautifully executed, and a proof of the practicability of what he says. But it has one principal disadvantage that all previous methods have—that is the great amount of shrinkage, about one-sixth, and the crown must be fired twice, and sometimes three times.

CROWN METHOD DESIGNED BY THE AUTHOR.

The last method which I shall present for consideration is one which I think reduces the technique more nearly to an exact science than any other yet devised. Let us take for a basis of these deductions the following qualifications:

The crown desired must be (1) one that possesses the maximum strength; (2) one that can be made to occlude with the opposing teeth normally; (3) one that will harmonize with its neighbors in shape, color, and contour; (4) one that will perfectly fit the end of the root to which it is attached, and (5) one that shrinks the minimum amount. This crown which I am suggesting shrinks one-tenth in every case, and, as a result, has the maximum strength, together with possibilities in blending of color that are limited only by the skill and artistic ability of the individual operator.

DETERMINING SHRINKAGE OF PORCELAIN.

The method employed for determining the percentage of shrinkage is best shown in Fig. 1, which shows a hardened steel mold, 7 mm. in diameter and 10 mm. long. This is made of Stubbs steel, as hard as fire and water will permit, and then ground to the exact size by standard micrometers, shown in Fig. 2. This instrument is seen supported in a stand, to make it rigid, and is capable of measurement to 1/200 millimeter, which is equal to 1/5000 of an inch. In order that this instrument may be made more accurate, it is provided with a ratchet adjustment, so that, in setting it, a fixed amount of resistance or pressure is employed in every case, no matter whether it is manipulated by an expert or a novice. To insure further accuracy, provision is made for the taking-up of all lost motion, and for readjustment to a standard hardened steel gage.

This instrument is of standard make, and is absolutely reliable as to its accuracy. The method of testing consists in, first, the molding of the billet in the mold (Fig. 3) with a fixed proportion of porcelain body and menstruum in a fixed space. These proportions and the formula will be given later. The result is a billet of the required diameter, but of excessive length. It is placed in the hardened steel mold, and one end is filed with a No. 4 Grobert file, so that it is perfectly parallel with one end of the mold. It is then placed upon a glass slide, and the surplus is cut from the top with a fine saw, which leaves a billet of exactly 7 x 10 mm. This is fused, and measured with a micrometer (see Fig. 4), and the resulting piece will be 9 mm. long, with the proportionate diameter. This seems to be the limit of percentage of shrinkage to be obtained with any of the bodies at our command at the present time. Further condensation by subjecting it to a higher pressure makes no discernible difference, even when measured with a 1/10,000th micrometer. Having reduced the shrinkage to so small a percentage, we have minimized the very serious difficulty of providing for such shrinkage, hence a very much more accurate reproduction of the lost part is secured.

The other essentials required for this process are shown in Figs. 5–14 (pp. 925–927)—suitable molds and press, proportionate calipers, a 5 cm. rule, lard or la.d oil, gum tragacanth, paste or jelly, a simple set of scales, and carving and other instruments. The porcelain body should be the same as that used by the manufacturers for stock teeth. I prefer Consolidated or Dentists' Supply Co.'s body, which fuse at about 2700° F., but which can be fused at a very much lower temperature by giving them time—and that is the way in which this body should be fused in order to obtain the best results in color, contour, and strength.

ROOT PREPARATION.

Almost any method of root preparation may be adopted that does not provide for a knife-like edge at the continuity of the root. An impression should be taken of the root with modeling compound, and I have found the best method to consist in making a metal ring or band to conform to the shape of the circumference of the root, but slightly larger—with about ½ mm. space all around it. This is held in position over the root, and the modeling compound, which has previously been formed into the shape of a cone, is made very soft on the pointed end, forced through the band on the end of the root, and cooled or chilled. Upon removal of this compound, it will be found that a very accurate impression of the root end has been obtained. This impression should then be invested in plaster to a sufficient depth to permit the packing of amalgam about 5 mm. thick. The amalgam should be mixed very soft, and the excess of mercury removed by pressure, after the impression is filled in.

MAKING THE BASE, OR CAP.

This will produce a very strong die, upon which a platinum cap can be swaged in a Brewster press or by any of the other methods. This cap is trimmed and shaped to project slightly beyond the margins of the root, when it is placed upon the root itself and adjusted, and such pins or dowels as are to be used are placed in position and attached to the cap with hard sticky-wax. The whole is removed and invested for soldering, and the cap and pin or pins are united with platinum solder. This cap is replaced on the root to ascertain that no change has taken place. The cap is removed and the underside—or that portion which comes in contact with the root—and the pin are painted with a thick, creamy paste of whiting and water. This is done to prevent the low-fusing metal in the plug from adhering to the platinum. The plug is then heated sufficiently to melt the fusible metal, viz, to 430° F.

The platinum cap or base is then placed into position in the metal and allowed to cool. (See Fig. 7.)

Fig. 1.

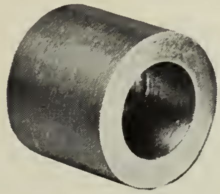


Fig. 2.

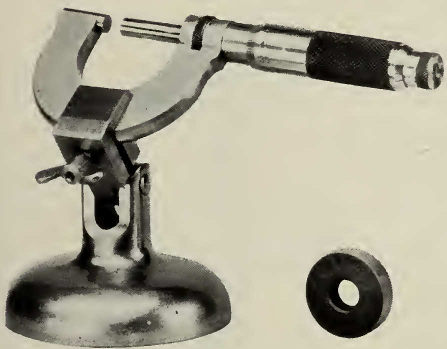

Fig. 3.

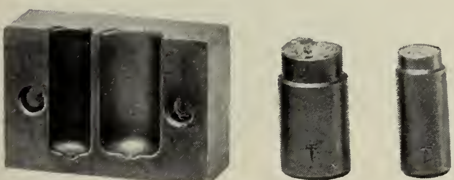

Fig. 4.

BUILDING OF THE PORCELAIN, AND BAKING.

The halves of the mold suitable for the plug are then coated with lard or lard oil, and screwed together, and the porcelains are selected, in the order of their shading, the enamel body first, the foundation second. The amount of

Fig. 5.

porcelain should correspond to the formula upon the mold. (See Fig. 7.) The plug is placed into the mold until it reaches the shoulder, which prevents it from going farther. The press and mold intact is then placed, preferably, at the opening of an electric furnace burning at a low temperature, occasionally turning it until a globule of the low-fusing metal in the plug appears at the union between the plug and mold. It is then removed from the furnace, and while still hot, the mold is taken from the press, and separated by removing the two screws which hold it together. By lightly tapping its side with a small mallet, the mold will be separated, and the porcelain will be found attached to the cap embedded in the plug. By throwing a flame on the end of the plug farthest away from the porcelain, the fusible metal in the plug will then be melted, and the porcelain attached to the platinum cap is easily removed, the result being shown in Fig. 13, A. It should then be trimmed to permit its going to place in the impression, and the general carving may be done after the following manner:

Fig. 6.

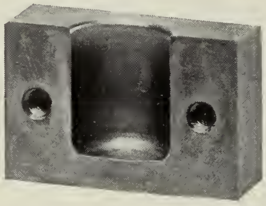

Fig. 7.

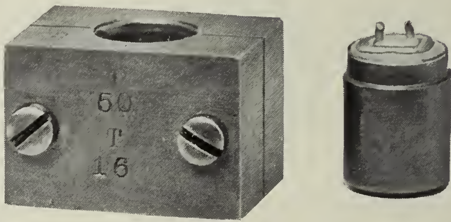

Fig. 8.

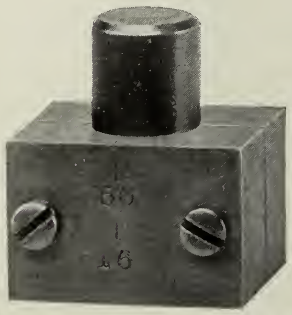
Fig. 9.

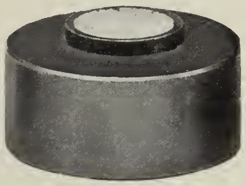
Fig. 10.



CARVING THE CROWN.

Two measurements should be taken directly in the mouth; first, the distance between the two adjoining teeth; second, the distance between the end of the root and the deepest fissure or sulcus. The measurements are taken with the fixed end of the proportionate caliper, and

Fig. 11.



that, in turn, is measured with the 5 cm. rule, and a memorandum is made thereof. The approximal surfaces of the teeth on the plaster impression are carved by resetting the caliper to the required measurement on the fixed end to the dimensions of that on the adjustable or pointed end. This makes allowance for the amount of shrinkage in that direc-

Fig. 13.

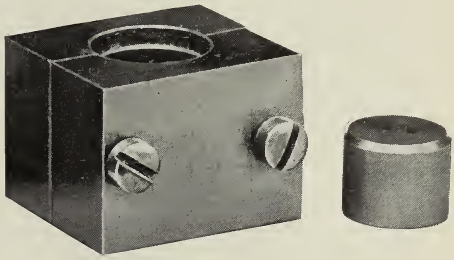
A B

tion. The opposing teeth are then set and locked on the articulator, in accordance with the measurement. The porcelain can now be trimmed and carved, gradually decreasing the length of the crown to a proper occlusion and proper general contour; in other particulars this carving is done "by eye," the result being shown in Fig. 13, B.

ADMIXTURE OF TRAGACANTH JELLY TO THE PORCELAIN.

The tragacanth jelly is difficult to make with pure tragacanth and water only, but if the tragacanth is mixed in alcohol in the proportion of gum tragacanth $\frac{1}{8}$ oz. and alcohol $\frac{1}{2}$ oz., in a small glass beaker, and stirred thoroughly, the tragacanth will seem to be held in suspension, as it is not soluble in alcohol. If $1\frac{1}{2}$ oz. of water be added very

Fig. 12.



rapidly at the same stirring, a smooth, jelly-like mass will be obtained. When a stated amount of this jelly is mixed with the porcelain body, a stiff putty-like mass is obtained, which can be easily packed, molded, etc.

Fig. 14.

CROWN-HOLDER.

Fig. 14 shows an instrument which I have constructed for holding the crown during the process of carving. It has many advantages over the ordinary pin-vise or pliers, in that it can be set up on the table or laboratory bench at any angle, which makes carving very much easier.

CONCLUSION.

In conclusion, I want to express my belief that, in a very short time, porcelain will be as popular, if not more so, than it has ever been; as the success of the silicate cements is far from assured, and our patients will not submit to disfigurement of the anterior teeth, in particular, by the use of gold and other such materials. And if the members of the profession, at least those who have abandoned porcelain, in the probable event of their feeling compelled to take it up again will depend upon their own deductions from systematic experiments, and not upon the statements of the manufacturers, then the value of ceramic art as applied to dental science will be reestablished on a much more secure basis than in the past.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

EDUCATIONAL PUBLICITY—WHY NECESSARY.

By W. G. EBERSOLE, M.D., D.D.S., Cleveland, Ohio,
SECRETARY-TREASURER OF THE NATIONAL MOUTH HYGIENE ASSOCIATION, AND HONORARY VICE-PRESIDENT OF THE FOURTH INTERNATIONAL CONGRESS ON SCHOOL HYGIENE.

(Read before the union meeting of the District of Columbia Dental Association and Maryland State Dental Society, at Washington, D. C., June 13, 1913.)

EDUCATIONAL publicity—why necessary from the dental standpoint? I am given twenty minutes by your committee to answer a question that might be answered in twenty seconds or in twenty words.

Educational publicity is necessary owing to the fact that there are one and one-half million American citizens dying annually, 40 per cent., or 600,000, of whom die from preventable diseases.

Each death, it is estimated, is preceded by two years of invalidism. This means that there are three million people sick in the United States at all times, which entails a tremendous loss to the government and country annually.

It has been estimated by conservative men that six hundred thousand of these deaths, and most of the invalidism of this country, can be averted by the employment of rational and thoroughly practical preventive measures. In the practice of preventive measures, the organ which wields the greatest influence and is most worthy of consideration is the human mouth.

Until within the recent past, both the dental and medical professions have failed to recognize the important rôle that the mouth plays in the health problems of the nation. But today most dentists and many of the leading medical men of the country are awakening to the fact that, without healthy mouths, cared for and used normally, the maximum health, strength, and working efficiency of the individual cannot be attained.

The great majority of the members of the dental profession are inactive or indifferent to the importance that mouth hygiene bears to the general hygiene of the body; almost all of the members of the medical profession are ignoring oral conditions, and the unwarned laity are marching to preventable death at the rate of six hundred thousand annually, all because those who are seeing the light have failed to do their duty, have failed to raise the curtain and let the light shine where it would do humanity the greatest amount of good.

The use of educational publicity of the most effective kind from the dental standpoint is imperative, or dentistry must be held accountable to the charge of criminal neglect.

To know that which we know relative to the important relation that mouth hygiene bears to the general hygiene of the body, but to fail to draw back the curtain and to let the light of mouth hygiene educational publicity shine into the faces of humanity with sufficient brilliancy to catch and hold the attention, is, to my mind, but little less than criminal neglect.

To possess knowledge which will save human life and then not make use of that knowledge in saving the lives of mankind is but little short of manslaughter; and I want to say to the members of the dental profession that the cry which goes up from many of the members of the laity—"Why is it that we have not been told these things before?"—is a just one, and is a criticism which we will have to meet more and more frequently, as humanity comes to know the extent to which it has suffered because of our neglect.

Of the ninety-one million people in the United States, eighty-eight and one-half million are in need of dental care, treatment, or advice. To care for these people, we have forty thousand dentists in the field. In spite of all that these forty thousand dentists have been able to do, the mouths of the human race are passing from bad to worse with such rapidity that those who are familiar with existing conditions stand appalled at the indifference or actual opposition of the dental profession to educational publicity of a kind that would be effective in checking the ravages of dental caries.

It has been estimated that there are not enough dentists in the United States to meet the present needs of the people in New York alone. If this statement is true—and we believe it is—then something is radically wrong with the system of publicity that the dental profession has been employing in bygone years.

Most of you know that I come from that state which has just passed through one of the most disastrous floods in modern times. Millions of dollars' worth of property were destroyed and hundreds of human lives lost, because those whose duty it was to know, and upon whom we relied for the employment of measures which would have prevented such destruction of life and property, failed to prove themselves worthy of the trust placed in them. Today thousands upon thousands of men are struggling, seeking to overcome the devastation and ruin wrought by somebody's failure to see and know his duty.

And so today the human race is suffering from a vast deluge of dental decay and destruction, all because somebody has failed to do his duty by not sounding the warning in such a manner that the people might be led to save themselves from much of the sin, sickness, and death that is ruining the morals, wrecking the health, and sapping the lives of the human family.

We have listened to an eloquent appeal for funds for the establishment of a Bureau of Scientific Research. We have had a vivid word-picture painted of the value and benefit such a bureau would bestow upon mankind. I would not utter a word that would detract one iota from the importance attached to that great movement. We have listened to a very earnest and strong appeal, and I say, All honor to the men who have conceived the plan and are advocating the policy of dental scientific research! We need it—and we need it badly!

But much as we need it, I am here to tell you that we need it alone for corrective measures. I stand here tonight to tell you that, with the knowledge now at command, properly prepared and spread throughout the land, nothing else is needed to arrest the decay and stop the loss of the teeth of mankind.

Years ago Dr. D. D. Smith declared to the world that he could stop dental caries, and arrest and cure mouth lesions by oral prophylaxis. At once he was pronounced a fanatic by fellow members of the dental profession; damned, double damned, and triple damned by some, particularly some men in his own city. But the principles advocated by him were right, and with that knowledge, backed by an indomitable will such as few men possess, that great warrior fought on, until today every fair-minded and honest practitioner of dentistry must concede that Dr. D. D. Smith has rendered the profession and humanity an invaluable service. Today he and his followers are redeeming thousands of mouths that have been considered beyond hope of repair, and are preventing the wrecking of thousands of others.

If these men, and women too, can, by the employment of oral prophylaxis, dental cleanliness, mouth hygiene, redeem the supposedly wrecked and ruined mouths of the people of the land, let me ask what must be the possibilities open to the men and women of the dental profession who have the foresight and the courage to step from the ranks of those who are today devoting their talents and their energies to the employment of corrective measures, and stand at the fountain-head and employ mouth hygiene measures and dental educational publicity.

It is here that the greatest opportunity is offered to the dental profession to benefit humanity. It is only by the employment of the broadest kind of an educational publicity campaign that the dental profession can ever hope to bring the ravages of dental caries under control.

With the inroad that dental caries, the greatest of all destroyers, has made upon the health of mankind, dentistry cannot hope to battle single-handed. She must call to her assistance the greatest educational institutions of the country—the medical profession, the great educational professions, the school teachers of the land, the boards of health, the civic organizations, the churches, the women's clubs, the men's clubs, the boy scouts, the camp-fire girls.

In fact, she must call to her assistance every individual that is interested in the health, strength, and working efficiency of the human race, if she is to do her duty in stemming the tide of preventable disease and unnecessary death. Dentistry has neither the men, the time, nor the money to meet the obligations that are being placed upon her.

Realizing that humanity must be awakened to the necessity of self-protection, a few of the members of the dental profession banded themselves together to form the nucleus of what is now known as the National Mouth Hygiene Association.

The purpose of this organization is to have the people know the frequency with which dental caries occurs; to have them understand the ravages this disease is making upon mankind; to teach the methods and means whereby people can escape from this devastating disease, and to place at the command of those who are able to care for themselves a method and means whereby they may look out for those unable to care for themselves, without placing an additional tax upon the individual, the community, the state, or the nation.

From the time of organization, two years ago, down to the present, the efforts of the association have been directed principally toward interesting the dental profession in its proposed work to an extent which would enable it to go to the public with a charter membership larger than the membership of any dental organization in the country. Today we have almost reached that number, but the labor required to secure that membership has been such that those at the head of the work are forced to acknowledge that the accusation of the general public that "Dentistry is interested in this movement only in so far as the individual will receive benefit from the efforts put forth," seems to be true.

Those who have been in the forefront of this work appreciate, however, that almost one thousand members of the profession have become sufficiently interested in the work to give of their time and money that humanity may come into her own.

We need educational publicity most in educating the dentist, for it is here that we meet with the greatest handicap. Unenlightened, mercenary dentistry is the handicap that is preventing true dentistry from receiving the rank and recognition due her, and humanity from obtaining that which she has a right to expect from the dental profession of this country. We need educational publicity to meet the thirst for knowledge that is being exhibited on every point by educational people and the laity in general.

Members of the dental profession, those of experience in the mouth hygiene field, have been forced to the conviction that the public is far more ready to receive information than are the members of the dental profession to place this information at their command.

I wish to repeat what I have said before, viz, that educational publicity from a dental standpoint only will make it possible to combat successfully the inroads of dental caries. Educational publicity from a dental standpoint has done much, but as yet the surface has not been scratched.

Three years ago last December, the Ohio State Dental Society was the first to place a large amount of money in the hands of its oral hygiene committee for publicity purposes. Then and twice since that time she voted $500 to be expended for this purpose.

Four years ago we went to the governor of Ohio, asking for the appointment of a dental representative on the state board of public health. The politicians, members of the medical profession, and most dentists ridiculed our efforts. But as an instance of what a little money, well spent from an educational publicity standpoint, will accomplish, we beg to inform you that Ohio has today, in the person of Dr. H. C. Brown of Columbus, a man who has received the first appointment from any great state in the Union to sit in the highest council in dealing with the health problems of the commonwealth. Dr. Brown has but recently been appointed a member of the Ohio State Board of Health, with a rank and vote equal to any member of that organization.

As another indication of what can be accomplished by educational publicity, I have to relate that three weeks ago yesterday I traveled to Wilkinsburg, Pa., a suburban village at the outskirts of Pittsburgh, and there visited the schools for the purpose of ascertaining the results obtained by a four months' *oral hygiene campaign* in the public schools.

There I witnessed one of the most remarkable scenes it has ever been my privilege to witness in regard to mouth hygiene. Hundreds of children were paraded before me upon that occasion, representing every walk in life; and as I looked into the mouths of those children, I saw thousands of carious teeth, but not in a single instance did I see a dirty or neglected mouth in so far as a toothbrush or tooth toilet could render a mouth clean and wholesome. The gums were healthy, the mouths clean, and the children seemingly happy.

To one who has traveled far and near inspecting schools, such a revelation was very remarkable indeed. The witnessing of the sight convinced the speaker once for all of the correctness of his theory that cleanliness and use were the only specifics necessary for the prevention of dental caries, or decay of the teeth.

Therefore, let us teach the boys and girls in our schools the proper care and use of the mouth and teeth. Then, a generation later, let us examine the children of those who are children today, instructed and cared for in the homes of the future as advocated today, and we shall produce a generation, hence a race of people, in whose mouths dental caries will be as rare as is the healthy mouth of today.

In conclusion, let me say that the statements uttered here tonight are not based upon fads and fancies, but upon indisputable facts gained from experiences which afforded ample opportunity to study and to know the conditions whereof I speak.

Few men, if any, have had a greater opportunity to study all phases of the question which confronts the mouth hygiene workers of this country. And I repeat that, with the value of oral prophylaxis and mouth hygiene declared and practiced in the light and in the manner now at command, no other means need be employed from a preventive standpoint.

If, with the baby in the cradle, we begin to teach the care and normal use of the mouth, we shall need to have no further concern. In other words, if the child of today and then the child of tomorrow are properly cared for dentally, the child of the future will be as perfect as the child of today is imperfect.

To the skeptic I have but to say that I know whereof I speak. I have seen the light, and my prayer now is that God, in His goodness, will spare me to stand at the helm and steer the bark of publicity until all mankind knows the value of a healthy and perfectly working "gateway" to the human body.

EFFECTS OF DEPRAVED ORAL CONDITIONS UPON NUTRITION.

By RUSSELL W. BUNTING, D.D.Sc., Ann Arbor, Mich.

(Read at the union meeting of the Maryland Dental Association and District of Columbia Dental Society, Washington, D. C., June 13, 1913.)

THIS is an age of social service. Never in all history has the world been so concerned in the welfare of "the other half"; never has there been such a strict inquiry into the life conditions of all peoples; and never has there been such concerted action to relieve suffering and social wrongs, as we see manifested so generally today. Surely the "millenium" is at hand. Well may we say with Riley:

> This world is a curious compound, with its honey and its gall,
> With its tears and bitter crosses, but 'tis a good world after all;
> And a good God must have made it—leastwise that is what I say,
> When a hand is on your shoulder in a friendly sort o' way.

MODERN SOCIAL SERVICE.

Everywhere the hand of social service is being laid upon the shoulder of the poor and unfortunate, the oppressed and the needy, "in a friendly sort o' way." It is a great work, and is enlisting the co-operation of all classes of people. The laymen in his sphere, and the members of the professions, the ministry, medicine, dentistry, engineering, and law are working side by side—each in his sphere—to bring about proper life conditions for all.

CARE OF THE CHILD.

Such a movement as this cannot be without its effect. Who can say what the continuance of this disposition for social service shall mean to the individual and to the nation? Perhaps the greatest results will not be attained in our generation, for it takes time to change customs that are established and to undo the effects of untoward conditions, but our greatest benefit will be realized from the efforts which are rightly directed toward the coming generation. Here we have to deal with virgin territory, that of child life, fresh and moldable, which will quickly respond to whatever change in life conditions we may make. And as we look into the welfare of the adult, we see that a large part of the sickness, suffering, and inefficiency is the result of some physical defect or some life condition which had its inception in childhood, the effects of which have persisted throughout the life of the individual, to handicap or entirely ruin an otherwise promising career. Truly, it is the child that is father of the man—and so it is to the children that we should give our greatest attention.

APPALLING STATISTICS REGARDING DEFECTIVE CHILDREN.

And what of our young American citizenship? Do they need any special attention? The results of investigations of public school children of every state answer emphatically, Yes. Take, for instance, the report of Dr. Leonard P. Ayres of the Russell Sage Foundation, in which he states that upon the examination of over 100,000 school children he found more than 70 per cent. of them defective. And he has tabulated the various defects under the following heads: Enlarged glands, defective vision, defective breathing, defective teeth, hypertrophied tonsils, adenoids, and other defects, the largest of these, by far, being the teeth. Statistics without number, gathered from all quarters, clearly show that the same conditions prevail in every city and community, frequently to an even greater extent.

BACKWARDNESS IN SCHOOL DUE TO PHYSICAL DEFECTS.

At the same time we find that there are far too many children in our schools who are not up to the average in their school work. Many of them are not in good health, are ill-nourished, and suffering from one or more physical defects. We have, by natural inference, come to the conclusion that there is a connection between the physical defects and the nutrition, the health and efficiency of the child, and have felt that, without the physical defect, the child would have better nutrition, better health, and greater efficiency. This belief is shared by a large number of observers as well as educators who have been watching these conditions for many years. There is not a teacher who is not familiar with the ill health and poor mentality of children suffering from physical defects, especially those which occur in the mouth, the nose, and the throat. So notorious has mouth-breathing become in its effect upon the child that teachers almost expect scholars who are suffering from this defect to be below the average in mentality and quickness of perception.

Not that we would say that every defective child is backward, or that all inefficiency may be traced to a physical defect, for, as has been pointed out by both Dr. L. P. Ayers and more recently by Dr. W. S. Cornell, director of medical inspection in Philadelphia, there are many other factors entering into the progress and development of the child which may have as vital an influence as physical defect. Among the most common of these may be cited poor food, poor sanitary conditions in the home, hereditary dulness of mentality, etc., all of which must be taken into consideration. But of this we are very certain, viz, that a large part of the children in our public schools are suffering from physical defects, many of which are preventable, and are growing up with a handicap which is too great for them to carry and at the same time keep up with the average in physical, mental, or moral growth.

UNTOWARD EFFECTS OF DISEASED ORAL CONDITIONS RATHER UNDER- THAN OVER-RATED.

Since so large a part of the physical defects which have been found lie in and about the mouth, we as dentists have been deeply interested, and have carried on many and extensive investigations of the condition of the mouth and teeth alone. In these we have been appalled by the great prevalence of dental disease and deformity, and have had our attention called with great force to the effects of these dental conditions upon the health and welfare of the child. As our knowledge has grown, we have become more and more convinced that the mouth conditions are among the important, if not the most important, of all physical conditions which commonly occur among children. Much has been written by members of our profession in substantiation of this claim, and as a result we have been accused of overrating the mouth conditions beyond their true value and importance. Dr.

Cornell, in his report of 1912, makes the statement that—"Notwithstanding the figures showing the association of defective teeth with poor scholarship, carefully estimated, the evidence of the depressing influence of decayed teeth upon both the general health and scholarship of the *whole number of children is inconclusive.*"

A statement such as this, coming from a man who has had so much experience in school hygiene work, is somewhat of a shock to us at this time. We felt that the observations of the medical inspectors and the school authorities, added to our own, had thoroughly established our position in the matter beyond a reasonable doubt. If our results had all been self-adduced, we might have suspected that we had been influenced by a too high professional zeal, and had unconsciously exaggerated the importance of our own special field; but when we have ample accord and collaboration with the medical profession, some of whom have been broader in their claims of dental importance than we ourselves have been, it gives us the courage of our convictions, and the assurance that our position may be maintained in the light of scientific investigation.

ASSOCIATION OF DEPRAVED ORAL CONDITIONS WITH NOSE AND THROAT DEFECTS.

As the faulty mouth conditions are so frequently associated with nose and throat defects, it is many times difficult to differentiate between the effects of each, and indeed they cannot be separated, for they work hand-in-hand in producing detrimental influences upon the system. In the consideration, then, of the effect of depraved oral conditions upon the general health, they must be considered together with the throat and nose conditions, being of equal importance and closely related. And the results of these oral, pharyngeal, and nasal defects may be traced, directly or indirectly, to their effect upon the nutrition of the body. It is, then, to the nutrition of the child that we must look in the consideration of his health and welfare.

THE PRIME IMPORTANCE OF NUTRITION IN CHILDHOOD.

There is perhaps no time in life when there is so great a demand for good nutrition as in childhood. Not only must metabolism be maintained, but it must be excessive; anabolism must exceed catabolism, in order that new cells and tissues be formed in the normal growth of the child. In order that these demands be fulfilled, the cells need nutritious food from which they may produce energy and a surplus for cell-growth. They also need oxygen for the oxidization of these foods to forms in which they may be utilized. They need, in addition, other proper life conditions to execute this their life-work; they need proper physical conditions, proper innervation, and proper waste removal. And, as I shall presently attempt to show, it is against all of these very desiderata mentioned that the effects of oral conditions operate.

EFFECT OF UNTOWARD ORAL CONDITIONS ON THE INGESTION AND ABSORPTION OF FOODS.

In the consideration of these phases by which untoward oral conditions might operate against nutrition, we should first consider the effect on the ingested foods and their absorption into the body. The function of the mouth in the digestion of food has been a much-debated question. A physiology which has been recently published abroad begins the discussion of digestion with the stomach, stating that the mouth has no part of any importance in the process. But in opposition to this view we have a host of authorities who place considerable importance upon the oral functions. It is interesting to read the views of Beaumont, which he gained from his study of the gastric fistula in Alexis St. Martin, and which are our earliest authentic information upon the subject. I quote: "The use of mastication is to separate the food into small particles, so that the solvent of the stomach may be applied to a greater extent of surface. . . . Mastication is absolutely necessary to healthy digestion. If aliment, in large masses, be introduced into the stomach, though the gastric juice may act upon its surface, chymification will proceed so slowly that other changes will be likely to commence in its substance, before it will be completely dissolved. . . . I therefore consider mastication as one of the most important preliminary steps in the process of digestion." In his inferences he also makes a very pertinent statement when he says that "digestion is facilitated by *minuteness of division* and *tenderness of fiber* and retarded by opposite qualities." Thus we see that Beaumont has been struck with the value of the division of the foods by mastication, but he has failed to notice the part which the saliva plays in the process.

THE FUNCTION OF THE SALIVA IN NUTRITION.

This function of the saliva has been studied and discussed very ably by Chittenden, who may be looked upon today as an authority on nutrition. He dwells at some length upon the enzyme action of the saliva, by which the indigestible starches are converted to simple sugars suitable for absorption. He says: "Need we comment, in view of the natural brevity of this process, upon the desirability, for purely physiological reasons, of prolonging within reasonable limits the interval of time the food and the saliva are commingled in the oral cavity? It seems obvious, in view of the relatively large bulk of starch-containing foods consumed daily, that habits of thorough mastication should be fostered, with the purpose of increasing greatly the digestion of starch at the very gateway of the alimentary tract. It is true that in the small intestine there comes another opportunity for the digestion of starch, but it is unphysiological, as it is undesirable for various reasons, not to take full advantage of the first opportunity which nature gives for the preparation of this important foodstuff for future utilization."

THE CARDINAL IMPORTANCE OF PROPER MASTICATION.

And we find that J. H. Kellogg, as well as Chittenden and many other dieticians and close students of nutrition, has given a great deal of prominence to the part held by the proper function of the oral cavity in the process of digestion. But it remained for a layman to call attention most forcibly to the factor. By close study and perfection of the process of mastication, Horace Fletcher changed his physique from that of a weakling to that of an athlete, and proved conclusively that the mouth had a very important mission to perform which was necessary to complete digestion. So enthused is he in his belief that he has said: "The whole problem of nutrition will be settled within the first three inches of the alimentary canal."

In the light of these opinions upon the necessity of proper mastication for perfect digestion, none of which, by the way, have emanated from the dental profession, how are we to look upon the nutrition of the children who are so largely bereft of normal mastication? When it is reported that from 70 to 95 per cent. of all school children are in need of dental attention, what does it mean? We know that of those who are reported as being defective dentally many have teeth which are irregular and out of occlusion, many have cavities which may be painful enough to put the carious teeth and their neighbors out of commission, and many have lost large portions or the entire crowns of several teeth by caries, so that, instead of a normal functioning articulation capable of performing its office of preparing food for digestion, these children have but a remnant of normal mastication possessing almost no efficiency. With this apparatus the children cannot masticate their food. They can only tear off portions of food, break it up as well as they may and their teeth will allow, and bolt it. Consequently they are acquiring perforce the habit of bolting their food, and are thus introducing into the stomach and intestines large masses of unbroken starch and proteid material. Does it seem reasonable, in the light of the knowledge we have of digestion, to suppose that children living in this manner will be well nourished?

The picture which I have drawn may seem severe, and in many cases these conditions exist to a lesser extent, but in others it is in no wise overdrawn. I remember distinctly a statement made to me by a member of the party which came to Ann Arbor to visit our institution for the purpose of obtaining ideas to be used in the building of the Forsyth Dental Infirmary. This was early in the history of the movement, and as I heard the account of the magnificent scale upon which oral hygiene was to be carried out, and the large number of chairs which they planned to operate, I asked them if they had need of so large an institution. This member of the group then told me of the thousands of poor children in and about Boston that, to their knowledge, needed attention, and in conclusion, he said: "Why, hundreds of children are in such a condition that they cannot eat dry bread, unless it is dipped in milk, or more often beer."

INEFFICIENT MASTICATION AS DETERMINING SELECTION OF IMPROPER FOOD.

It is, then, very evident that the lack of proper function of the mouth strikes at the first basic feature of cell metabolism, viz, that of proper food. The indigestion and poor assimilation which must result from lack of mastication reduces materially the carbohydrates, fats, and amino-acids, which will not be furnished to the cell unless the digestive apparatus is of extremely high efficiency. The cells of the body will not then be able to meet the demand for active metabolism and growth that is so essential with the child, and we have the picture of malnutrition with all of its attending evils, which may be traced back in large measure to the loss of function of the oral cavity.

ORAL AND NASAL DEFECTS (MOUTH-BREATHING) AS INDUCING DEFECTIVE OXYGENATION.

Furthermore, in regard to the second requisite of food metabolism, what effect have the oral and nasal defects upon the supply of oxygen? It goes without saying that the growing child needs plenty of fresh air and oxygen for the aeration and nutrition of his tissues. The cells of the body, upon which there is so great a demand for synthetized food materials, require for their action an abundance of oxygen, and the blood, that common carrier, overburdened with waste products of an excessive metabolism, needs oxygen for its own aeration and purification; so that oxygen is an indispensable necessity for nutrition and metabolism. And yet how many of our children do we see sitting and standing in a stooping position, breathing shallowly and superficially, never taking a full, deep, or normal breath. Such children are using but the upper lobes of their lungs, while a large part of their deeper lung alveoli are never filled, and are not functionating. Consequently, the lung surface in which there is contact of blood and air for the purpose of interchange of gases, instead of developing the full capacity which is so necessary to the child metabolism, is but a fraction of the normal, and greatly deficient in its function.

The practice of shallow breathing is but a habit, and may be established by a variety of conditions, but every student of child nature will testify that one of the greatest of these is mouth-breathing. Here again we are brought back to mouth and nose conditions as a causative factor. The effect of irregularities of the teeth upon the size of the nasal passage and the obstruction of that passage by irregularities, adenoids, etc., are too well known to need elaboration. And all these defects, producing a partial or complete stenosis of the nasal passages, readily establish in the individual the habit of mouth-breathing.

And what of the effects of mouth-breathing? We have all seen its connection with shallow and superficial breathing, and have inferred that this, in turn, results in a deficiency in the oxygen furnished to the cells. And what is the result? We can best answer this by pointing to the children who are mouth-breathers, and present them as evidence. They are a familiar sight in every school—stoop-shouldered, listless, with a drooping expression of the face, dull in mentality, and below the average in scholarship. Not that all these effects, which are so commonly seen in mouth-breathers, should be accredited to the deficiency of oxygen, for there are other factors which enter into the case, but it seems very probable that a certain portion of these effects are the result of a malnutrition arising from a deficient oxygenation of the tissues. Untoward mouth and nose conditions, then, do have an effect upon that second great necessity of metabolism, oxygen, and therefore they have their effect upon all nutrition.

SYSTEMIC, SEPTIC, AND TOXIC DISEASES ARISING FROM DEPRAVED ORAL CONDITIONS.

We have said that, in addition to their effect upon the foods and oxygenation of the cells, the depraved oral conditions may also affect those other indispensable life conditions, namely, proper physical condition, proper waste removal, and proper innervation. We know full well that among the vast army of children with uncared-for and diseased mouths, there is in all of them an incredible amount of infection and fermentation. Much of this infection exists in the cavities of the teeth and about them, whereby all foods that are eaten are contaminated with the infectious material. It is possible that in children, especially, the infections which are passed down the digestive tract are killed by the high hydrochloric acid content of the stomach. Regarding this there is some question, as it is found that in individuals having highly infected mouths, the intestinal infections are also above normal. This fact is being made use of in the National Jewish Hospital for Tuberculosis in Denver, where the unfailing rule has been established to insist that the mouths of the patients be put in perfect condition before beginning specific treatment, and it is claimed that this practice has been of great benefit in the treatment of tuberculosis.

In addition to the superficial growth of bacteria upon the foods and tissues of the mouth, there is also a large amount of deep infection about the roots of these decayed and neglected teeth, assuming the form of virulent and extensive abscesses. That the products of this infection, the bacteria and their toxins, are picked up directly by the circulation, to a greater or lesser degree, is very well established. As Dr. Evans, Chicago's health board commissioner, said, in speaking of these conditions in school children: "The major harm that is being done is in those children who have decayed teeth, these decayed teeth being harborers of bacteria that slowly poison, and, as a result of that slow poisoning, there is, in many instances, enlargement of the neighboring glands, and those glands stand as vicarious sacrifices protecting the remainder of the body from the invading poison. Absorption is taking place from these infected areas, and the influence of that absorption is felt, not only in the neighboring glands, but also in this group of physical conditions —anemia—the relation of which is difficult to understand."

Our attention was very forcibly called to these facts some two years ago by Dr. William Hunter, who wrote a series of articles upon oral sepsis and its grave significance in the whole body. In one of them he says: "The problem is an important one for the dental profession, and its solution is an important one in the interests of public health, especially of our school children, thirty to fifty per cent. of whom suffer from dental and oral sepsis, and its tonsillitic, pharyngeal, glandular, and other defects."

We must, then, recognize that there is a variable amount of septicemia and toxemia arising from those infections and suppurations which are so commonly seen in the mouth, upon the gums, and about the teeth. But this is not confined alone to the mouth, for we find that these neglected children have not only diseased mouths, but also diseased tonsils and adenoid growths. In these, infections may be very rife, and there is also from them a variable absorption, both through the digestive tract and directly to the lymph and blood streams. Hunter sums the matter up very well in the following strong statement: "The chief feature of this particular oral sepsis is that the whole of it is swallowed or absorbed into the lymphatics or blood. Unlike the sepsis of wounds on the outside of the body, none of it is gotten rid of by a free discharge on the surface. The effect of it, therefore, falls, in the first place, on the whole of the alimentary tract from the tonsils downward. These effects include every degree and variety of tonsillitis and pharyngitis, of gastric trouble, from functional dyspepsia to gastritis and gastric ulcer, and every degree and variety of enteritis and colitis and troubles in adjacent parts, *e.g.* appendicitis. The effects fall in the second place on the glands—adenitis; on the blood—septic anemia, puerperal fever, septicemia; on the joints—arthritis; on the kidneys—nephritis; and on the nervous system."

LACK OF PROPER WASTE REMOVAL, FOLLOWING IN THE WAKE OF DENTAL INEFFICIENCY.

If, then, infection and infectious material are being transferred with such frequency and regularity from the mouths and throats of neglected patients, we may well ask, What is the effect of this absorption and metastasis upon nutrition? We can readily see that in those cases in which the intoxication is general, the cells of the body are receiving, in addition to their foods, these toxins and poisonous ptomains, which act upon them after the manner of poisons. There is, then, a direct effect upon the physical condition of the cell, and in addition a clogging of the sewers of the body, viz, the lymphatics, interfering with the waste removal. The cells must then carry on their life process under the handicap of these adverse conditions, and react to them. They must either spend a large part of their energies in fighting this toxin enemy or succumb to its influence. If the vitality is high they may react to the occasion, and the child be nominally and to all appearances in a fair degree of health, while they are receiving and caring for a daily dose of poison. This condition, which Dr. E. C. Kirk aptly called "toxin habit," is an insidious attack upon the nutrition of children, and their elders as well, which is of the greatest importance. We are but just beginning to realize the full meaning of these conditions, and we as dentists and physicians must look more deeply into this question. Dr. Chas. Mayo recently threw a challenge to the dental profession in a discussion of the absorption of septic material from the oral cavity. He said: "The dentist's patients must be warned of the mouth as being by far the greatest portal of entry of germ life into the body, the most infected part of the alimentary canal. The next great step in medical progress in the line of preventive medicine should be made by the dentists. The question is, Will they do it?"

EFFECT OF SEPTIC INTOXICATION UPON THE NERVES.

Briefly I would mention that last factor in cell nutrition, proper innervation, and the influence of the oral conditions upon it. In the statement which we quoted from Dr. Hunter he made allusion to the effect of septic intoxication upon the nerves. Dr. Henry Upson has also done some very valuable work on the reflexes produced by irritation of the fifth nerve, as in dental disorders. From these and other opinions, which there is not time to enumerate, we may infer that both the septic conditions and the pain attendant upon dental and oral diseases is able to affect the nervous control of the body. Many have suggested that there is a direct effect upon the socalled "trophic" nerves, by which nutrition suffers through the innervation of the cell. Although evidence is not yet complete, the indications of present knowledge point quite definitely toward the influence of faulty oral conditions upon the general innervation of the body.

THE CONCURRENCE OF MEDICAL AND DENTAL OPINIONS REGARDING ORAL HYGIENE.

As briefly as possible we have reviewed some of the work and opinions of men outside of the dental profession in our attempt to justify our belief that depraved oral, nasal, and throat conditions do have their effect upon nutrition, and that occurring so frequently as they do in our school children, these conditions are affecting their general health and welfare. In addition to these I would quote but one contribution from our profession, which could not be left out of a consideration of this subject. The experiment which Dr. Ebersole, our worthy secretary, carried out in the city of Cleveland was of the nature of a scientific experiment, and has given to us more accurate information than has been gained in any other way. In this experiment he had the co-operation of medical men, psychologists, educators, and dentists. Every effort was made to eliminate errors and conflicting circumstances, and although these did creep in, and must certainly be allowed for, still the results produced in these twenty-seven children, even granting a liberal allowance for error, show a decided improvement in the general health, mental efficiency, and moral tone, resulting from the proper care and use of the oral cavity. I take great delight in using the "before and after" pictures in my public lectures on oral hygiene, and I say to my audience: "Watch especially the change in the eyes and the expression in these children." And indeed they are remarkable! Many of those young people have been changed from street waifs, irresponsible and even criminal in their appearance, to entirely new individuals, fast becoming self-reliant and self-respecting American citizens. This is evidence which cannot be controverted.

Feeling secure, as we do, in the tenability of our claims and in the certainty of the fact that by reason of neglected oral conditions children by the hundreds and thousands are suffering nutritional disturbances which are preventing them from attaining their full normal growth and development, let us do all that lies within our power to relieve the conditions which are under our control, and continue to spread the gospel of ORAL HYGIENE.

Correspondence.

DOES "SECONDARY ENAMEL" OCCUR?

To the Editor of the Dental Cosmos:

Sir,—The July issue of the Dental Cosmos contains an interesting and very learned paper on "Syphilitic Hypoplasia of the Teeth," by Dr. Bethune Stein, and an equally interesting discussion of this subject. In the course of this discussion Dr. Broomell says: "Had the child recovered, these defects (enamel pits) might have been repaired by a secondary deposit of enamel," etc.

With all due respect for such an authority as Dr. Broomell, I wish to inquire whether the formation of "secondary enamel" is possible, or whether this statement is meant as an indorsement of the now generally abandoned theory of Holtzmann and Boedecker, according to which physiological changes can, from time to time, take place in the enamel owing to the presence of a certain reticulum of organic, vital matter. The authorities with whom I am familiar teach that, while the formation of secondary dentin occurs occasionally, owing to the persistence of the odontoblasts, the formation of secondary enamel is never observed, owing to the disappearance of the ameloblasts after completion of the enamel covering. The mention of secondary enamel, therefore, by such an authority as Dr. Broomell, is somewhat puzzling.

A brief explanation of this matter will, I am sure, interest a large number of your readers, and will be highly appreciated by

Yours respectfully,
David Tabak, *Senior Student,*
N. Y. Coll. Dentistry.

Proceedings of Societies.

EASTERN ASSOCIATION OF GRADUATES OF THE ANGLE SCHOOL OF ORTHODONTIA.

Annual Meeting, held in New York, N. Y., April 26, 1913.

The annual meeting of the Eastern Association of Graduates of the Angle School of Orthodontia was called to order on Saturday morning, April 26, 1913, at 10 o'clock, by the president, Dr. Milo Hellman, New York, in the assembly room of the Academy of Medicine, New York, N. Y.

The first order of business was the reading of a paper by Dr. J. Lowe Young, New York, N. Y., entitled "The Rational Treatment of Infra-occlusion."

[This paper is printed in full at page 869 of the present issue of the Cosmos.]

Discussion.

Dr. A. P. Rogers, Boston, Mass. I think we should congratulate ourselves today, because we are really getting the best of one of the most difficult problems the orthodontist has had to face. You remember a few years ago that a case of infra-occlusion or open bite was very unwelcome; in fact, we undertook the treatment of such a case with reluctance, but after a few years' experience with it we are beginning to solve this problem. I am particularly delighted with the new ideas which Dr. Young presented this morning, and do not feel that there is very much of scientific value that I can add. There are, however, a few suggestions I should like to make, and you may take them for what they are worth.

In the first place, I think the essayist failed to say anything about the method of determining the overbite, which is really a very important factor in the treatment of these cases. The length of the overbite in the incisal region, according to my experience, must be determined before the correction of the infra-occlusion in molars and bicuspids is started. This, of course, must be left largely to the intelligence of the operator, but as a guide he has the length of the cusps of the longest teeth and the type of the individual, so that the overbite may be established correctly by the position of the inclined-plane or bite-plane plates on the anterior teeth.

Dr. Young mentioned the element of habit in the production of these various classes of infra-occlusion, and he leads us to believe that the infra-occlusion of the anterior teeth is entirely due to habit. In my practice I have found one or two cases in which absolutely no habit of any kind could be ascertained. In fact, I can conceive very readily how infra-occlusion of the upper incisors may be brought about by lack of lateral development, where the incisors are caught, so to speak, in their effort to grow. I have one or two cases which show this very clearly, yet, at the same time, the habit theory is correct for most cases. The essayist did not mention how the acquisition of habits has anything to do with the lack of vertical development in the bicuspids and molars. It is difficult sometimes to determine the etiology in these cases, but I believe that in growing children, especially in class I cases, where the orthodontist is at a loss to put his finger on the cause, he will find often that lack of vertical development is caused from biting the tongue on both sides at the same time. There are cases on record which show this to be true. It is perfectly true, of course, that the distal occlusion of the mandible at the time or during the period of vertical development must be a factor, because if the mandible is in distal position the distance between the bony structure of the upper and lower jaw is less, and in that way the vertical development of the bicuspids and molars is mechanically interfered with. As the essayist has pointed out, these cases may be caused by lack of lateral development in the upper jaw. It is of the utmost importance for us to correct this lack of lateral development as early as possible, because in children of three, four, and five years of age, if the canine region can be developed, then the mandible, in my opinion, will take its proper position, and lack of vertical development will be obviated.

The question of the correct development of the face should claim a great deal of our attention at this period of the progress of orthodontia, because a thorough understanding of all these various developments will help us materially in solving these problems early.

While the essayist was reading his paper, I was reminded of a case that shows very clearly that the deciduous molars elongate or assume a higher vertical position during the eruption of the first molars. I also recall a case from my own practice in which the upper molar was for some reason caught or wedged so that the first deciduous upper molar and the first permanent molar erupted and left these teeth far back, probably one-eighth of an inch in the vertical development between the teeth that remained stationary and the two teeth on either side of the arch. With the treatment that Dr. Young advises I believe that many of these cases will be overcome.

In the treatment of these cases we should not be in any hurry to apply inclined plates or bite-planes, but first should be sure that both arches are of proper shape and size. This has been one of the principles upon which I work, and which I have advocated, and if I deviate from this principle in the slightest degree, I find that everything must be readjusted. We must first determine the size and shape of the arch and the correct overbite which we wish to establish, then the rest seems to come naturally.

The period of retention requires serious consideration. After retaining a few cases for a considerable length of time, I have been disappointed, owing to the fact that the overbite seemed to grow more pronounced, and I do not believe that this is the tendency of nature to establish the proper type, because I have been quite well convinced that I had produced the correct overbite; but I think the period of retention should be prolonged in most of these cases. In the cases where we apply lateral force and allow the bicuspids to erupt unassisted, the period of retention can be very much shortened.

One other thought occurred to me, while Dr. Young was speaking, with regard to depressing the lower incisors. We often find, of course, that it is difficult to convince ourselves that that form of treatment should be followed; but when we come to analyze nature's efforts, I think we will decide that it is the best method to employ. In studying the eruption of the incisors, one of the laws of nature—namely, that the bones develop normally when unhampered—must be taken into consideration; and in the eruption of the central incisors nature will develop unhampered, as in any other part of the mouth. The centrals develop to a certain height and stop at that position; then the lateral incisors begin to erupt, and gradually lift themselves to the same plane as the central incisors, and there stop. I do not believe that nature if unhampered will develop these teeth beyond the line of occlusion. We are safe, therefore, in establishing the bite in all cases where there is reason to believe that there is too great elongation of the premaxillary region, and there we must look for difficulty in deciding just what type the case belongs to.

Dr. R. H. W. Strang, Bridgeport. For a number of years we have known that the development of the jaw takes place in three directions, lateral, forward, and downward, yet, while we have most conscientiously established by treatment a normal lateral and forward growth, there has been an almost universal tendency to give but little thought or attention to the production of a normal downward or vertical development. Is it not reasonable to assume that failure in vertical development will appear in just as many cases as failure in growth along other lines? I believe that Dr. Young has touched upon one of the most important subjects we have to deal with.

I have been watching these cases of infra-occlusion for some time. In most of them the origin of this deformity dates back early in the history of the denture, for this failure in development is plainly to be demonstrated in the deciduous arches. Establishing itself at this period in the life-history, it in turn becomes a most powerful agent in the production of further errors of occlusion. This takes place in a decidedly mechanical way. We note that in these cases the lower incisors occlude with the upper at or near the gingival border.

The arc of a circle drawn at the gingivo-lingual line of the upper incisors is much smaller than that of one drawn at their cutting edges, so that the lower incisors, in their attempt to accommodate themselves to this smaller circle, must produce or assume one of the following types of deformity or a combination of two or more of them: Either the lower incisors will take a position lingually to normal, the upper incisors will be forced labially to normal, or the whole lower denture will be forced distally to normal, with the production of a class II case. I thoroughly believe that herein lies the cause of cases in class II, division 2, *i.e.* primarily a failure in vertical development in the deciduous denture, followed by the mechanical driving backward of the lower arch. Whether this change occurs in the joint or in the body of the mandible I do not know, but I am rather inclined to believe that it is a distal displacement within the condyloid fossa.

Dr. Rogers mentioned the fact that he does not believe we should correct this lack of vertical development until toward the latter part of our treatment. I do not agree with him. I believe that it is one of the primary etiological factors in the abnormality, and so should receive attention as soon as possible.

Dr. Rogers. Supposing the upper central incisors and upper first molars are not in their proper physiological position—what then?

Dr. Strang. Even in those cases I am in the habit of putting in the appliance that I will show later, to open the bite at once, and so allow the lower jaw to come forward, while at the same time the upper incisors are moved to their correct position.

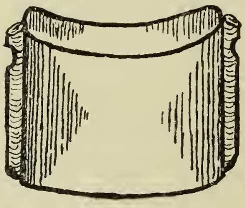
With the bite-plate that I use it is usually possible to do this. I do not say that it can be done in all cases, but where it is feasible it certainly should be done. Again, there are many cases of class I in which the lower incisors have been forced lingually, that do not admit of proper treatment until the bite has been opened. That is the first thing to do; then the lower incisors should be moved forward. Otherwise, in an attempt to move such incisors labially, one would be most liable to throw the mandible into distal occlusion or the upper incisors far forward of normal.

I have tried to treat infra-occlusion with the appliance that Dr. Rogers suggested a few years ago, but—undoubtedly owing to faulty technique on my part—I have not been able to obtain satisfactory results. In thinking it over, it seems to me that that appliance is not as practical as it should be. I do not see why we should not elongate the upper molars as well as the lower ones, nor why we should say that the lack of vertical development lies in the lower arch entirely. It would seem that if the growth of the denture is at fault in this respect, both arches would be involved.

It also appears to me that with this appliance too much force is brought to bear upon the upper incisors during mastication, and while they are supported by a heavy wire running back to the molars, yet this has not been sufficient in my cases to prevent these incisors from being driven into their sockets, rendering the appliance useless. I believe it is necessary, in order to overcome this tendency, to have the force of occlusion transferred to the hard structures in the roof of the mouth.

The bite-plate as ordinarily used has been most unsatisfactory, because it is so unstable. After experimenting a great deal, I have found an attachment that is quite positive, and although the plate can be removed for cleansing, yet, when it is snapped in position, the patient apparently forgets that it is a removable appliance. I know that this statement will give rise to doubt in the minds of many present, but I have used a great number of these appliances, and as we know that our best proof for the practicability of an appliance is its working efficiency, I can truthfully say that I have not as yet found a case in which it has not done its part, though doubtless I shall find such cases as time goes on.

Fig. 1.



The attachment is made on the upper first bicuspids, if these are in position, otherwise on the second deciduous molars. These are banded, using coin or 22-k. gold, .007″ and of proper width to extend to the gum line. On the lingual and labial side of these bands a vertical wire is soldered of 18-gage clasp metal. Close to the gingival end of this wire a notch is cut of sufficient size to receive a 16-gage wire. (See Fig. 1.)

These are placed on the teeth and a plaster impression is taken, after which they are removed and placed in the impression, and the model is obtained. Two clasps are now made of 16-gage clasp metal wire. (See Fig. 2.) The sides of these clasps engage the two notches in the vertical wires on the bands and pass over the occlusal surface in the interproximal space between the clasped tooth and the one mesial to it. (See Fig. 3.) To each one of these is soldered a strong T-bar of 16-gage clasp metal wire for attachment to the vulcanite plate. This takes the form of the well-known bite-plate. (See Figs. 2 and 3.)

Fig. 2.

When finished, this appliance should go to place with a decided "snap." In fact, it is often necessary to release some of the spring in the clasp, owing to the fact that the patient cannot remove it.

Fig. 3.

In these cases I also place an E arch in the upper jaw, making my anchorage on the first molars, while in the lower jaw I use the "new appliance." The triangular intermaxillary elastics, either alone or in combination with the regular elastics, are also worn.

Such a combination of appliances allows the molars and bicuspids to elongate to the line of occlusion, except, of course, the two to which the plate is attached. The result is usually quick and positive. Such a plate, however, should be worn for a long period of time, since the retention of this class of cases must be prolonged for years. In the later part of this period the plate may be worn at night or during the day only. [A case was then shown under treatment, with the plate and appliances in position.]

Dr. A. F. Gough, Brooklyn. I thoroughly agree with Dr. Strang in regard to beginning treatment at once. Formerly I used such a bite-plate as was suggested, I believe, by Dr. Baker of Boston. At any rate, I got the idea in Boston while attending a society meeting some six or seven years ago. Nearly all of the Boston practitioners were using it, and Dr. Reoch showed me some cases in which the bite-plate was attached to the incisors, with a wire running back to the molars. I sent to Boston and had three or four of these appliances made. Afterward I made them myself, but in my hands they were not nearly so successful as the little appliance Dr. Strang has suggested, with which I have seen some really marvelous results obtained. The principle upon which this appliance is based is also of considerable use in other cases. For instance, when the teeth on one side of the arch that were in lingual occlusion have been moved to normal position, and one does not wish to displace them on either side, the principle of this appliance is very valuable.

Dr. Harry E. Kelsey, Baltimore, Md. Dr. Young's case, in which he said no bite-plane had been worn, and yet the result was very good, attracted my attention.

I have used different kinds of bite-planes and had some good results from each, but have never been fully satisfied with any of them in every case.

The effect of the bite-plane is secured, I think, in a few cases by simply altering the mesio-distal relation of the jaw by the use of intermaxillary elastics, thereby causing the bite to be sustained by the lower incisors striking on the lingual tuberosity or shoulders of the upper incisors, thus holding the molars and bicuspids apart, until they grow up to the new occlusal plane; but in many cases that does not bring about the result desired, and some sort of bite-plane must be used.

I do not think it would be profitable to go into a discussion of what supra- and infra-occlusions are, and whether they may occur in one or both jaws, because we do not know quite enough about it as yet.

Furthermore, I do not think that we have any definite ideas regarding the diagnosis of this particular form of malocclusion, as we have regarding other forms which are diagnosed by the mesio-distal relation of the jaws to each other, because, in that case, we have definite inclined-plane cusps that must have a definite relation to each other if normal. If anyone is able to discover such a definite relationship for supra- and infra-occlusion, we shall be very much indebted to him.

I wish to thank the essayist for the valuable technique shown, which has proved so effective in all cases he has exhibited, and I think the opinions which he hazards in regard to infra-occlusion are as worthy of consideration as any offered by anyone else.

Dr. H. C. Ferris, New York. About a year ago I described the use of a bite-block, which seemed to be considered as a joke. I want to ask what takes place when these teeth fail to erupt and when they are brought out of their sockets by mechanical devices; what happens in the bottom of these sockets? We can all surmise what takes place. We must appreciate the fact that bone does not grow during that rapid removal of a tooth from its socket. The tooth will return very readily unless we hold it. When the patients were young enough, I have had a great deal of success by using the principle of mastication which I advanced before this society a year or two ago. I endeavor to induce the patients to use the blocks, although it requires a good deal of pressure on the parents and guardians to make them carry out directions, but I have a number of children using these blocks without any appliance in the mouth, and I am getting results. We cannot get away from the fact that bone grows under functional stress, and these bite-blocks stimulate normal function. I hope to be able later on to show some of the results obtained.

Dr. C. A. Hawley, Washington. This problem has confronted us for years. I have tried a great many appliances, but have never found any one ideal. We have had successes and failures and there is no form of retention that does not involve some difficulties. I agree entirely with Dr. Ferris on the question of underdevelopment in these cases. Whenever we see a case of infra-occlusion, we may conclude that there is something wrong with the development of the child. The internal structure of the face is not developed properly, and the primary cause is probably lack of use of the teeth. After many years of work, I am very much impressed with the fact that a great deal of our early treatment has produced some bad results, in that many of the appliances have had a tendency to break up the habits of mastication already formed, thus aggravating and extending the primary cause of the defect. An ideal appliance should cause absolutely no irritation, and no interference with mastication. Such an appliance is rarely found. Dr. Ferris' statement, that for the final retention we must look to the re-establishment of the perfect use of the teeth that have been lost in the first place, seems very pertinent. I am of the opinion that if we could thoroughly establish again the function and the use of the teeth, some of the maldevelopments would disappear without other treatment. The question, after all, when we have used the bite-plane or the bite-plate, is the establishment of the proper use and function of the teeth. The position in which the teeth will finally settle will depend on the type of the individual and the habits of mastication, and this adjustment will inevitably take place in spite of us.

In regard to the establishment of the exact length of the bite-plane, I see a little difficulty. While we may, no doubt, theoretically figure out the length of the bite by the cusps, yet that would presuppose exact harmony of the size of the teeth in the upper and lower jaw, which does not always obtain. That lack of harmony is naturally taken up in the overbite, and it is the anatomical shape and the size of the teeth which must finally establish the bite-plane. I do not know whether I make that point clear, but I will try and illustrate it. [Dr. Hawley then illustrated his views by means of blackboard drawings.] There is a certain occlusion, a certain length of the bite that will be established after retention in spite of any appliance.

Dr. Young (closing the discussion). I have been very much pleased with the discussion of this paper. It proves to my satisfaction that it is not advisable to write long papers, because nobody will discuss them. We have had a lot of discussion, and I think we have learned something this morning. I do not think it necessary to answer Dr. Rogers' question with regard to the depth of the overbite, as Dr. Hawley has just answered that to my way of thinking, viz, that the length of overbite is determined by the shape of the lingual surfaces of the upper incisors. In this connection, in order to save time, I may say that the case which Dr. Kelsey referred to (Fig. 13) in which I obtained a good result without the use of a bite-plane, I believe was due to the fact that the lingual surfaces of the upper incisors were of such shape that they acted as a bite-plane when the case reached that stage of treatment that permitted the correction of the mesio-distal relation and the lower incisors to strike on the upper ones.

Dr. Rogers spoke of the lack of vertical development in the anterior region being due possibly to lack of lateral widening. I have thought that in two or three cases, but I have found in each case that I was wrong; but by keeping an eye on these children I found that the irregularity was due to habit. I believe that all cases are due to some habit which can eventually be detected, and not to lack of lateral development.

Dr. Baker asked Dr. Rogers as to whether the second deciduous molar was in the arch. Whenever I see a second deciduous molar decidedly below the line of occlusion, I insist on an X ray. I am always suspicious, when seeing a deciduous tooth in infra-occlusion, that there is no permanent tooth to replace it. I am glad to say that the X ray shows permanent teeth present in as many of these cases as it shows them to be missing.

I wish to thank Dr. Strang for his discussion and for the description of his appliance. I can see great possibilities in that appliance, and am satisfied that, in very young patients, it will work, and will be very much easier to use than it is to build up these teeth as I have done.

I agree with Dr. Hawley that, no matter how accurately we may figure out where to place the bite-plane, nor how accurately we shape our upper and lower dental arches, after we remove the appliance there will be a final adjustment, and these teeth will settle down, until they come to their proper position as determined by their anatomical shape.

The next order of business was the description of clinics to be given in the afternoon. Several of the members described clinics to be given, among them Dr. A. M. Desnoes, Brooklyn, whose clinic, entitled "Suggestions in the Technique of Retention," was published in full in the June 1913 issue of the Dental Cosmos.

The society then adjourned until the afternoon session.

Afternoon Session.

The meeting was called to order at 2 P. M. by the president, Dr. Hellman.

The first item on the program for the afternoon session was the reading of a paper by Dr. Milo Hellman, New York, N. Y., entitled "The Significance of Normal Occlusion."

[This paper is printed in full at page 887 of the present issue of the Cosmos.]

Discussion.

Dr. R. B. Stanley, New York, N. Y. Dr. Hellman has covered so much ground in his paper that it is not possible to discuss every phase of the subject in the time at our disposal.

Orthodontia has passed the empirical stage, and is well on its way toward a scientific basis. Occlusion is the great principle which vitalizes it, and its true significance is only beginning to dawn upon us. Too great attention has been centered, I believe, upon the occlusal aspect of the teeth, without taking into consideration the factors which bring it about and maintain it.

Dr. Hellman shows a masterly grasp of the subject, and has correlated in his essay the researches of scientists in allied subjects in a manner calculated to lead us to a better understanding. His interpretation of Dr. Angle's dictum—"the line with which in form and position, according to type, the teeth must be in harmony if in normal occlusion"—is broad and comprehensive, and invites further study in the direction indicated.

"In proportion as we are able to grasp and interpret the ideas implied by the term normal occlusion, we will conceive how far-reaching are its effects." These words of our essayist suggest the question, What is it that is implied by normal occlusion? I take it that normal occlusion is the evidence that all changes, from beginning to end, in the development of the structures concerned in it, have taken place without interruption or deviation from the prescribed plan. Normal occlusion is not, therefore, a cause, but a result of these changes, consummated for the purpose of fulfilling a requirement of the physical economy.

The general scheme of embryonic development is carried on according to certain established laws, and is probably, as the essayist says, an epitome of the entire process of evolution. The first cleavage of the cell is a simple process, comparatively, yet without it no further change takes place; each step, therefore, is a preparation for the subsequent one. With this thought in mind, we can study the development of the oral cavity and its contained organs.

I do not intend to repeat in detail the history of embryonic development. In a general way, the maxillary, mandibular, and fronto-nasal processes, and the tissues that are to form the tongue, are differentiated at about the same time.

Yet, before the processes that are to form the jaws unite, the tongue assumes a commanding position, and acts as a mold or core, around which the jaws take form.

The significance of this fact should not be lost sight of, for the influence of this muscular tissue, both before and after birth, in molding and maintaining the dental arches, is more potent, I believe, than any other. When it is remembered that the soft tissues are developed first, and the bone last, it is not difficult to grasp the truth of this statement.

In early infancy the normal function of the tongue is of material assistance in molding and enlarging the jaws, thereby preparing for the normal eruption of the first teeth. During this process of growth, the crowns of the deciduous teeth have kept pace in their development with the jaws, and when it is necessary for them to fulfil their mission in life, they descend and take their rightful places in the scheme of occlusion. When their position is established, they in turn take part, through their functional activity, in the further growth of the jaws, until they are lost. There is no essential difference between the development of the first and second dentures; both are governed by the same laws. In both instances, occlusion plays no part until the final act.

The illustrations thrown upon the screen, showing the relation of the direction of the roots of the teeth to the structures above them, are of special interest to us.

The significance of the position of the roots is far-reaching, for only when the normal development of the superstructures or supporting structures has taken place, is this root relation possible. In other words, root position, or inclination, is dependent upon the development of the supporting structures. Any corrective measures which involve the bodily movement of the roots of the teeth must take into consideration all the factors concerned in jaw-growth.

Of more than passing interest to us are the observations of Professor Patten with regard to the effect of "lowland" and "highland" climates upon the shape of the jaws, the skull, and also the stature.

As to whether the character of the teeth influences the shape of the skull, or *vice versa,* the observations of Prof. Raymond C. Osburn, also of Prof. Henry Fairfield Osborn, when combined with those of Professor Patten, show a fundamental agreement as to an actual correlation between the shape and size of the teeth, the arches, and the skull.

Personally, I believe that occlusion occurs too late to determine materially the character of the skull. I interpret the observed correlations as evidence of the existence of definite laws which harmonize the proportions of all parts of the anatomy, for the preservation and perpetuation of the whole. Normal occlusion is but one phase of the whole scheme; to understand its true significance, we must explore still farther the mysteries of life and living.

Dr. W. M. Dailey, New York, N. Y. I think this is one of the most valuable contributions I have ever heard presented before any society. All the men of the "old school," as it is stigmatized by the Angle orthodontists, were considering irregular teeth and not malocclusion, like the Angle school. The new thought of bone-development or development of the human being according to type, and of irregular teeth being a manifestation of the lack of or non-development of bone, as described by the essayist, goes far beyond anything that had been considered heretofore, inasmuch as the men who are practicing orthodontia are really now becoming bone-stimulators, bone-developers. Another factor, namely, the condition of the parents at the time of conception, has been little considered, and must be studied in the future.

Dr. Hellman (closing the discussion). I wish to thank the two gentlemen who have discussed my paper. It is, however, difficult for me to interpret the meaning of the general silence. Does it indicate approval or disapproval? I would have preferred to hear a discussion one way or the other.

The only statement I wish to correct is Dr. Stanley's remark with regard to the cephalic manifestation after occlusion is established. I would ask Dr. Stanley to repeat his words.

Dr. STANLEY. I said that when occlusion is completed, it is too late to be of any influence in establishing the cephalic index.

Dr. HELLMAN. I do not think so, and I would call Dr. Stanley's attention to the fact I mentioned in my paper, namely, that the pressure exerted in infancy during the act of nursing is probably as effective as that which is exercised in later life, when the teeth are in position and perform the function of mastication.

I wish to thank the members and guests for their kind attention to my paper, the length of which must have been very trying for them.

The next item on the program was the reading of a paper by Dr. A. L. JOHNSON, Springfield, Mass., entitled "An Introductory Study of Habit."

[This paper was published in full in the June 1913 issue of the DENTAL COSMOS.]

The next order of business was the election of officers for the ensuing year, which resulted as follows:

President—Dr. R. H. W. Strang, Bridgeport, Conn.

Vice-president—Dr. A. L. Johnson, Springfield, Mass.

Secretary—Dr. E. S. Butler, New York.

Treasurer—Dr. F. R. Stathers, Philadelphia.

The meeting then adjourned.

CONNECTICUT STATE DENTAL ASSOCIATION.

Forty-ninth Annual Convention, held at Waterbury, Conn., April 15 and 16, 1913.

(Continued from page 836.)

TUESDAY—*Evening Session.*

THE meeting was called to order Tuesday evening at 8.30 o'clock by the president, Dr. Abbott.

The first item on the program for the evening session was the reading of a paper by Dr. F. T. VAN WOERT, Brooklyn, N. Y., entitled "The Future of Porcelain in Dental Art."

[This paper is printed in full at page 920 of the present issue of the COSMOS.]

Discussion.

Dr. E. S. GAYLORD, New Haven. The few words I shall have to say in the discussion of this paper I shall direct more particularly to the men who are not acquainted with Dr. Van Woert. Those of you who are acquainted with him know perfectly well his standing, and that he is considerably overworked, as he conducts a very large practice, so that it is very difficult to induce him to leave his office and present a paper. I wish to say to those who know him from his writings only, that he is one of the most painstaking, most precise operators in our profession in any field that he takes up, and he has come to us bringing the best work of his life, which has embraced more than thirty years of labor in the field of dentistry. He has worked out the technique of porcelain to a degree of precision which makes this material much more valuable than it has ever before been in the hands of the dentist. He has reduced shrinkage by his method of mixing the body with the medium, as he has explained to us, and forcing that into a mold, thereby imparting to the mass a degree of solidity which reduces the shrinkage to one-tenth. Consequently he brings to us something that is invaluable, and he offers it to us for free use. I regret, however, exceedingly that he did not elaborate more fully on his methods of perfecting this work.

Even those men who have condemned porcelain and taken up other materials must acknowledge that our shortcomings in porcelain work are to be attributed to poor technique rather than to the material itself. The early days of porcelain date back more than thirty years. I have still the old Downey furnace that was brought out for this work, and I still adhere to it. Porcelain certainly is one of the most valuable materials we have for filling cavities in teeth, from the esthetic standpoint as much as from the standpoint of durability, when used in cavities in which it is safe to use. I wish to emphasize this statement "in which it is safe to use." All occlusal surfaces are regarded as unsafe, but as a rule in approximal, labial and buccal surfaces, nothing is superior to porcelain, particularly in the buccal surfaces of molars.

While the profession has drifted away from porcelain, and there has been little demand for it hitherto, this demand is increasing, showing that dentists are coming back to its use. Dr. Jenkins in a recent conversation on this subject, said that he proposed to reopen his post-graduate school in New Haven next fall for the teaching of porcelain work, which he conducted a number of years ago. I was telling this to Dr. Van Woert this afternoon, and he replied that he would be glad to sacrifice his time and give lectures at Dr. Jenkins' proposed school. I say this to show that porcelain is being revived. Other filling materials have failed to such an extent that the value of porcelain is being reconsidered and properly estimated.

Dr. C. W. Strang, Bridgeport. I wish to say at the outset that it seems to me the limit of incongruity for one who has had but little practical experience in the manipulation of porcelain to discuss a paper prepared by an artist in that department. I admire the system presented by Dr. Van Woert, and recognize him as a man of high ideals, who has made a close study of this subject.

The man who is satisfied with present attainments never gets very far; but the man who wisely and judiciously follows high ideals is the one who succeeds. High ideals are the guardian angels of life; they are guiding stars to us poor mortals, and are not like the rainbow in the distance toward which the child runs with open hand to grasp, only to find it always the same distance away, the hill-top bringing him no nearer to it than did the valley. A high ideal is one of the great realities in life.

I have to admit that the best I have to offer to my *clientèle* is the old Richmond crown. From experience I know that, when this crown is well made, it is reliable and permanent. I have, however, experienced sore disappointments; after spending days in selecting porcelain facings that would be in harmony with the natural teeth, when the tooth had been backed and soldered I have found that its translucence was gone, and both patient and dentist were disappointed. Sometimes, when the patient has expressed dissatisfaction with the work, I have said, "I have done the best I can, and if you can find anybody who will guarantee to do any better than I have done, I will pay the bill." You see we put a little of the risk on the patients, because if they fail to get satisfaction anywhere else, they have to pay the bill themselves, and I want to confess that I have never been called upon to pay the expense of a second operation under these conditions.

Some years ago, before a gathering of dentists, I made the statement that I had not yet set one Logan crown, and they all congratulated me. That statement holds good today. I have never, in my practice, been over-enthusiastic in running after new things. I remember how many years ago, the practice of pulp capping was sweeping the country. Dr. Atkinson, as some of you remember, was fostering that work; and everything, regardless of pathological conditions, was treated in this way—"Cap it, kiss your patient good-by, and all will be well." Some of you know very well the ultimate results of that method, and I venture to say that very few dentists today have much confidence in pulp capping. This method probably is advisable in case of not quite fully developed teeth, for the purpose of saving the pulp as long as possible; but I think most of us get rid of an exposed pulp by the shortest possible route. The same is more or less true of cataphoresis. I remember when the cataphoresis fever spread over the profession, we found enthusiasts at almost every convention; but we do not now hear very much of that method of obtunding sensitive dentin.

I have nothing new to offer in regard to porcelain work. I was very much surprised to learn that it is practically impossible to obtain an accurate porcelain inlay from a direct impression of the cavity. I am now assured by a number of practitioners who have been using the direct method for a number of years that they have abandoned it.

Dr. J. W. CANADAY, Jr., Albany, N. Y. When I was asked to give a clinic before your society I had no idea that I would be called upon to discuss the paper of so eminent a practitioner as Dr. Van Woert, and I feel it an honor and a privilege to do so. Dr. Van Woert is an artist of great ability in his line, as his lantern slides and specimens have shown.

His description of the Buell method, especially that portion following the preparation of the root, was perhaps not as clear to the audience as he intended it to be, and it would be well for those interested in this method to read the description when this paper is published.

In contradistinction to the Buell crown, the essayist described his own method of carving a crown from an ingot obtained by high pressure in a steel mold, using a fixed proportion of porcelain body of the same quality as is used by the manufacturers, and a menstruum of tragacanth jelly. By comparison of the two methods described we find that a crown made by the Buell method shrinks one-sixth of its size and requires two or three bakings, while one made by the Van Woert method shows a shrinkage of only one-tenth, and requires but one baking, also conforms more nearly to the essayist's qualifications of the perfect porcelain crown, which is—(1) One that possesses the maximum strength, (2) one that can be made to occlude with the opposing teeth normally, (3) one that will harmonize with its neighbors in shape, color, and contour, (4) one that will perfectly fit the end of the root to which it is attached, and (5) one that shrinks the minimum amount.

Such a crown can only be constructed by an expert with very high artistic ability; but how many men of ordinary ability can do this without special appliances? A man of ordinary ability, however, can, by using care, select a stock crown with an iridio-platinum detached post, adapt it approximately to the root, make it conform in color, contour, occlusion, shape, etc., and make it fit absolutely with a casting of gold which will not show at all, and thus produce a very serviceable and esthetic result. Unless we shall all be more familiar with porcelain, and consequently more skilful in its manipulation in the "raw" state, more esthetic and serviceable results will be obtained with this method by the dental profession at large than by the all-porcelain hand-carved crown.

Dr. VAN WOERT (closing the discussion). I regret exceedingly the condition under which I addressed you last evening. It was utterly impossible for me to read the manuscript which I had prepared, because of defective light, and the result is that I have evidently not made myself clear. I wanted to emphasize particularly the many advantages of the hand-carved porcelain crown, and prove at the same time, if possible, that it was not so complicated or difficult a matter to produce such a crown as is generally supposed.

The gentlemen who have been kind enough to discuss this paper are crediting me with an undue amount of skill and artistic ability, as either of the methods presented for this purpose are within the province of all of you.

The Buell method is very much simpler in technique, but has the disadvantage of a large percentage of shrinkage and the necessity of two or more fusings before completion. Just as beautiful results can be obtained by it, however, as by this later method. On the other hand, the method just described offers the decided advantage of a minimum and exact amount of shrinkage, which renders easier reproduction possible and brings it down nearer to an exact science. I hardly think, however, that facings could be made with the appliances shown as easily and accurately as they can with the Buell method.

The meeting then adjourned until the Wednesday morning session.

WEDNESDAY—*Morning Session.*

The meeting was called to order on Wednesday morning, April 16th, at 10 o'clock, by the president, Dr. E. J. Abbott.

The first item on the program for the morning session was the reading of a paper by Dr. GEORGE E. HUNT, Indianapolis, Ind., entitled "Mouth and Health."

The society then adjourned until the next annual meeting.

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

PUBLISHED BY

THE S. S. WHITE DENTAL MFG. CO., PHILADELPHIA, PA.

SUBSCRIPTION PRICE, including postage, $1.00 a year to all parts of the United States, Hawaiian Islands, the Philippines, Guam, Porto Rico, Cuba, and Mexico. Canada, $1.40. To other foreign countries, $1.75 a year.

PHILADELPHIA, SEPTEMBER 1913.

EDITORIAL DEPARTMENT.

A QUESTION OF ETHICS.

IN the stress of circumstances incident to a recent attempt in one of our oldest commonwealths to pass an act of legislature regulating the practice of dentistry, one of the results of the involved political conflict, apart from the failure to secure passage of the bill, was to defeat the reappointment of one or two members of the existing board of dental examiners, each distinguished for a long term of efficient service under the existing dental law which it had been sought to improve. The removal of the officers in question was compassed by their opponents upon the specified grounds that they and others of the board were "not progressive." This vague indictment, with its suggestion or implication of inefficiency, furnished the state executive with a, to him, sufficient excuse for keeping favor with their opponents by removing the officers in question.

All of which is a commonplace example of ordinary political methods, and of the manifest injustice of petty politics in dealing with professional problems. The conflict in the case grew out of an attempt to pass a bill which, while many of its provisions were most admirable, yet contained certain features which were highly objectionable, and which in their purpose were bad enough to more than offset the manifest advantages which the proposed act otherwise contemplated. Unfortunately, such measures are the source of much heated debate, for the reason that opposition to their obviously iniquitous provisions is too often made to appear as opposition to the entire act, its good features included; and so it was with the case in question, with the result of the indictment of "non-progressiveness" preferred against the more conservative members of the board of examiners, and the removal of two who had achieved records of long, equitable, and efficient service.

Two phases of the issue are important: First, the damage to the state, in the work of its board of dental examiners; and second, the damage to the personal and professional reputation of the deposed members of the board.

It may occasionally be true that a poet is born and not made, but with dental teachers, dental examiners, and ordinary experts in general it is usually a long, careful, and often tedious making, especially when the product amounts to anything important in the way of efficiency. Moreover, in the case of examiners and teachers, the making is not accomplished by a specialized course of college training, but in the hard school of experience—from which fact it follows that within reasonable limits their efficiency increases as their experience enlarges; hence it is a damage to the state of no small consequence to remove an experienced and efficient examiner for political reasons on the outward pretext that he is "not progressive"—whatever that phrase may mean. As a matter of fact it is true that the new and inexperienced appointee must, if faithful to his trust, be markedly progressive in order to develop the same efficiency as his predecessor, and in that view of the case may for a time exhibit greater progressiveness; but it is probably not in that sense that the phrase "non-progressive" was used in criticism of the predecessor, if in any sense at all except as an expression of a desire to get rid of him.

Considered in its literal sense, "progressive" means having the tendency to go forward; it carries with it no sort of implication as to the goal toward which the progressivist is tending, and in that particular, like many other terms, is purely relative and therefore has no absolute application or meaning unless coupled with some other qualifying term. As applied to the case under consideration the charge of being non-progressive is about as lucid and precise a definition of technical efficiency as members of the dental examining board as to say of them that they were "corkers," "bricks," "mutts," or "bull-moosers," according to the opinions and taste of those who express themselves in terms of that character. It is, however, the very vagueness and indefiniteness of the indictment of non-progressiveness in this instance that gives to it its malignant character, for the reason that its want of precision permits full play for the imagination in the effort to decide just what was meant by the charge. A public official removed because he is said to be non-progressive is presumably deficient or unsatisfactory as a public servant; therefore it must be that to be non-progressive is to be at least negatively guilty of some sort of misdemeanor as related to the public service. To make public announcement of such official removal and for the cause stated is to not only do an injustice but to work a definite damage to the professional reputation of the party involved.

We have spent much time in tinkering with what we dignify by the term "professional ethics," and have concentrated much thought upon the construction of a code, especially those portions of it that relate to the material interests of professional men. We are impelled in this connection to call attention to a very ancient code of ethics handed down to the present generation through the records known as the Hebrew scriptures; one article of the said code being, "Thou shalt not bear false witness against thy neighbor." We are well aware that certain provisions of the code of dental professional ethics have reference to certain aspects of this same ethical standard, but we know of no other specification that is quite as clear, direct, and to the point in question as that to which we refer in the Mosaic code. Therefore with some slight sense of diffidence we are impelled to suggest to those who are seeking for higher ethical standards in the dental profession, Why not adopt that one article as a whole and without alteration or amendment into our dental code?

Correction.—In the series of diagrams of the angles of various mandibles accompanying the paper by Dr. M. H. Cryer, as printed in our July issue, the diagrams Nos. 12 and 13 should be transposed, likewise Nos. 14 and 15. The correspondence of the diagrams and the illustrations of jaws and skulls is as follows: Diagram 9, Figs. 1, 16; 10, Figs. 2, 17; 11, Figs. 3, 19; 12, Figs. 5, 22; 13, Figs. 4, 19,A; 14, Figs. 6, 19,B; 15, Figs. 6, 19,A. Exact re-measurement of various angles involves the following corrections in the text: Page 675, 2d col., 10th line from foot, *for* "135°" *read* 139°; p. 676, 3d line, *for* "133°" *read* 135°; 8th line, *for* "107°" *read* 108°; p. 683, 2d col., 6th line, *for* "125°" *read* 124°; p. 684, 1st col., 12th line from foot, *for* "135°" *read* 136°.

Review of Current Dental Literature.

[*Oesterreichische Zeitschrift fuer Stomatologie*, Vienna, May 1913.]

TEMPORARY DISPOSITION TO CARIES. By Dr. L. Fleischmann.

The temporary disposition to dental caries which is so frequently observed in patients after a period of comparative immunity, is, according to the writer's observations, caused by disturbances in the calcium content of the organic portion of the enamel—which in turn are due to disturbances or changes in the internal secretions. This contention, in the author's mind, is fully borne out by the tendency to rapid dental caries during pregnancy, chlorosis, and in cretinism, which conditions involve a marked change in calcium metabolism. The important relationship of the structure of the enamel and the disposition to dental caries has been emphasized also by Baumgartner and Von Ebner, who by the aid of carefully prepared microscopic slides of enamel have proved fairly convincingly that metabolism does take place in enamel even after the eruption of the tooth. The facts that enamel is softer in youth than in adult age, therefore much more susceptible to caries, that it changes its color and loses its luster in later years, seem to indicate, in Fleischmann's opinion, that the organic substance in the enamel undergoes progressive calcification, and that the less uniformly the organic substance has been calcified, the more readily the enamel is invaded by micro-organisms. The trend of Fleischmann's argument, which has quite a few notable supporters among European scientists, justifies the hope that it may be possible to favorably influence the calcium metabolism in enamel by therapeutic measures, thereby establishing effective prophylaxis. The effort to exert such a favorable influence upon the calcium content in enamel is in direct line with Röse's studies on deficiency of mineral salts and degeneracy (see Cosmos for January 1909, page 135), and the suggestions contained in the writer's paper; although they are diametrically opposed to the views generally accepted on this side of the ocean, surely deserve earnest thought.

[*Journal of the American Medical Association*, Chicago, June 7, 1913.]

THE POSSIBLE RELATIONSHIP OF ORGANIC DISEASES OF THE NERVOUS SYSTEM TO RIGGS' DISEASE. By Dr. J. Collins, New York.

The occurrence of purulent diseases of the alveolar processes is so common and so widespread that it has come to be regarded by many patients, and even practitioners, unfortunately, as disagreeable and esthetically offensive, but not dangerous and capable of causing serious disease. The writer's experience convinces him that Riggs' disease may be the source from which serious organic diseases of the nervous system flow. Though he can offer no other proof of the truth of this statement than the occurrence of such disease in persons afflicted with alveolar pyorrhea, and the absence of other etiology and the amelioration or disappearance of the disorder after the pyorrhea has been treated locally and constitutionally by means of autogenous vaccine, he feels constrained, nevertheless, to present a few of these observations for consideration. From a large number of cases in which he believes pyorrhea alveolaris played the chief rôle in the causation of nervous trouble, he has selected three specially instructive cases, in which the peripheral motor neurons bore the brunt of the disease. From a careful study of these and many similar cases, he is of the opinion that the neuro-muscular system is most vulnerable—after the joints—to the streptococcus viridis. That a very considerable number of the cases of chronic arthritis are of bacterial origin, there can be little doubt. In a recent article, Dr. T. W. Hastings quotes the histories of six cases of arthritis deformans of from two to fifteen years' duration which reacted to strains of streptococcus viridis. From four of these cases the same organism was isolated from a tooth socket after extraction of the tooth. Improvement resulted from injections of vaccines.

The writer concludes with an earnest plea for a full appreciation of the seriousness of pyorrhea alveolaris, and the early institution of measures that will prevent a systemic infection which may become far-reaching and extremely serious.

FORMALIN ECZEMA OF THE FINGERS. By Dr. H. Hoelzer, Danzig.

[*Deutsche Zahnaerztliche Wochenschrift*, Berlin, March 8, 1913.]

OCCUPATIONAL DERMATOSIS IN DENTISTS, CAUSED BY THE USE OF TRICRESOL-FORMALIN. By Professor Wolters, Rostock.

After having observed several cases of eczema of the fingers in himself and some colleagues, the writer comes to the conclusion that these cases are due to the habit of removing cotton twists saturated in formalin from smooth broaches with the fingers. In all these cases the trouble started in the finger of the left hand which was used for this purpose. Healing is very slow, since medicaments, acids, alcohol, etc., break up the granulation tissue formed, and produce renewed irritation. The formation of this formalin eczema is facilitated by the continual washing of the hands in warm or tepid water, whereby the pores of the skin are opened. After trying in vain the remedies recommended by several physicians, the writer effected a complete cure after four months of great discomfort, in the following manner: The affected fingers are nursed as much as possible, and protected during work and at night by a rubber cover, to prevent additional irritation and to produce hyperemia. In the morning the fingers are bathed in hot water of a temperature of from 35° to 40° C., and coated with pure vaselin. No formalin should be used for some time. Medicaments are useless, the healing process being much more expeditious without them. At night a little cotton may be wound around the fingers.

Several replies received by the writer from various *confrères* seem to confirm the prevalence and seriousness of this "formalin eczema," although one contributor suggests that the habit of mixing amalgam alloys in the hand may be responsible for a mercurial eczema.

A specially valuable contribution to this important subject is furnished in the article by Wolters, who, being a dermatologist, has observed that whenever new remedies for external use, especially for disinfection, are brought upon the market, numerous cases of dermatosis occur, as was the case following the adoption of phenol, sublimate, lysol, lysoform, iodoform, iodoformogen, formalin, etc. Dermatosis once produced by tricresol-formalin can easily become chronic, since any other irritating drug, as well as the continued mechanical and chemical cleansing of the dentist's hands and finger-nails, adds to the susceptibility of the skin. Small breaks and erosions are thus caused, which, when again brought in contact with the irritating drug, are cauterized and become inflamed. The epidermis undergoes horny alteration; infiltrations, chaps, pustules, and blisters are formed, and the resulting pain is often so intense as to disguise the very disagreeable itching present in milder cases. The soft tissues surrounding and underlying the finger-nails are affected, the skin is reddened, swollen, and very sensitive, and the process gradually involves the end phalanges, sometimes extending in patches over the palmar surfaces of the fingers, or even the whole hand. The same process may be transmitted to the nose, lips, and face by accidental transmission of the drug by the fingers. The nails undergo brown discoloration, which persists even after cure; Galewsky even reports their swelling up and splitting. The surface of the nail shows irregular elevations and depressions, proving that the inflammatory process has attacked the nail matrix and affected the growth of the nail. The soft tissue at the edges in some cases undergoes sausage-shaped deformity.

In regard to treatment, Wolters demands that tricresol-formalin should be entirely eliminated from dental practice, as being too dangerous and unnecessary. In opposition to Hoelzer, he opposes the use of rubber covers, as the fingers perspire under these and predispose them thereby to eczema. For the same reason he rejects warm water and vaselin treatment. For disinfection of eczematous hands, only warm water, a brush, soap, and alcohol should be employed. Practice is best suspended for a while in order to avoid renewed irritation. The best form of treatment consists in Roentgen treatment, to be repeated from three to four times at intervals of from eight to ten days. In the meantime wet dressings of 2 per cent. alsol, aluminum acetate, and salicylic acid, 1:1000, are used to produce granulation, powder or tumenol zinc for drying up the pustules and blisters, and zinc-bismuth salve for softening and removing the horny skin formation. When the condition is improved so that only redness, slight infiltration, and scales remain, coal-tar in the form of solutio lithantracic acetonica, as indicated by Sack, or liquor carbonis detergens, as indicated by Wright, is applied, this application to be followed by a neutral salve to restore the softness and smoothness of the skin. If the nails have suffered considerably, the X-ray treatment is especially beneficial for the return to normal growth of the fingernails.

The careless habit of dentists of allowing the fingers to come in contact with drugs is signally discountenanced by the above investigations. That many cases of eczema are due to the careless manipulation of formalin we are induced to believe after observing the same phenomena in three *confrères* who were in the laudable but evidently impractical habit of keeping their instruments in a formalin solution for the sake of sterilization.

[*La Province Dentaire*, Lyons, November 15, 1912.]

CASE OF ANESTHESIA BY AUTO-SUGGESTION IN AN HYSTERIC PATIENT.

By Dr. V. L. Bourselet, Paris.

Bourselet relates the case of a young woman of twenty-five years, in whom he injected a 1 per cent. solution of cocain for the purpose of extracting the upper right first molar. Before the extraction could be executed, the patient exclaimed that the operator was using ether, and that she was about to fall asleep. Her eyes became fixed, and she began to cry and to gesticulate violently for about five minutes. Upon recovering, she asked as to her whereabouts and as to what had happened. Upon her second visit, the tooth was extracted without an anesthetic. Referring to her experience on the occasion of her first visit, the patient confessed having had sexual affections. The writer, not willing to attribute this case to the topic action of the cocain, cites two similar cases which have been reported by Guérard of Paris and Ernst of Lunéville. He refutes the idea of emotional syncope, since the syndrome of symptoms, viz, pallor of the face, profuse perspiration, lividity of the skin, etc., were not present in his case. Syncope due to the cocain cannot be assumed, as the space of time which elapsed between the syncope and the injection was too short to permit of diffusion of the alkaloid through the circulatory system and intoxication of the nervous system. Moreover, the syncope came on immediately upon the patient's fallacious conception that ether was being used, in consequence of which she imagined falling asleep. Her confession of moral remorse, her nervous hyperexcitability, and the fact that she believed herself to be asleep immediately upon thinking that ether was being administered to her, induce the writer to conclude that this was a case of narcosis due to auto-suggestion in an hysterical patient.

The importance of the presence of a third person in all cases of anesthesia, no matter whether general or local, is signally demonstrated by this report.

[*Lancet*, London, April 19, 1913.]

THE MORBID ANATOMY OF PERIODONTAL DISEASE. By J. F. Colyer.

Colyer gives an interesting and well-illustrated description of an excellent, probably unique series of specimens illustrating the morbid anatomy of periodontal disease, as contained in the odontological collection in the museum of the Royal College of Surgeons of England. The specimens include examples of the disease in man as well as in the lower animals, the value of the collection being enhanced by the fact that all stages of the disease are illustrated. In discussing the more instructive specimens in the collection, Colyer makes a point worthy of special notice, viz, the difference in the spreading of the disease in the maxilla as compared with that in the mandible, which is especially marked in the region of the molars. This limitation of area of bone destruction in the mandible is to be accounted for by the different nature of the osseous tissues in these two bones. In the maxilla the bone is of a much more cancellous character than in the mandible. This difference in the spread of the disease in bones of different density is especially well marked in lower animals. Clinical experience shows that the disease varies in its rapidity, and that in some individuals there is a definite reaction of the periosteum of the bone to the injury from the toxins. This is shown by a general thickening of the alveolar bone, and in a few cases by the formation of nodulated masses simulating exostoses. The teeth also exhibit definite changes, the hard tissue showing absorption and the periodontal membrane thickening, both indications of a chronic inflammatory process. The molars frequently show large masses of adventitious tissue in the cleft between the roots, indicating extensive loss of osseous tissue at these points.

An examination of teeth removed in certain cases of periodontal disease indicates that, with the formation of a pocket around the tooth, pathological changes commence around the apex of the tooth. The roots of the teeth, especially at the apical portion, show signs of absorption, although in one such case of persistent gingivitis, as far as could be ascertained, neither the pockets nor the bone destruction were very extensive. This condition the writer explains as follows: From the septic focus around the neck of the tooth, absorption of toxins or organisms takes place through the periodontal membrane, probably by lymphatics. The material absorbed is held up, as it were, in the tissues around the apex. In other words, there is probably a natural defense at this part of the tooth, to prevent the organisms and toxins from passing into the general circulation. With the arrest of the toxins, etc., the tissues around the apex naturally react to injury; that is to say, the phenomena of inflammation appear. The formation of these septic foci around the apices of the teeth has, in the writer's opinion, not been recognized, but it is clear that it is an important factor to be reckoned with in considering treatment.

In the second part of his paper, Colyer describes pyorrhea alveolaris as seen in animals. It is of frequent occurrence in horses, cats, and dogs, and in wild animals that have been kept in captivity. The study of the disease in these animals is most instructive, and throws considerable light on its etiology and pathology.

The conclusions to be drawn from the examination of these specimens in man and animals are: (1) That the bone lesion is a progressive rarefying osteitis commencing at the margin of the alveolar process. (2) That the disease is purely local in origin and has its immediate cause in the formation of stagnation areas around the teeth. (3) That the varying density of the bone influences the rate of destruction.

[*American Journal of Clinical Medicine*, Chicago, February 1913.]

RELATIONS EXISTING BETWEEN TEETH AND EYES. By Dr. W. E. Bruner.

[*Ash's Wiener Vierteljahrs-Fachblatt*, Vienna, May 1913.]

METASTATIC OPHTHALMIA FOLLOWING TOOTH EXTRACTION. By Dr. Dimmer.

The relationship between the eyes and teeth is the subject of an interesting article by Dr. Bruner, which appeared originally in the *Annals of Ophthalmology* for October 1912. The association of certain eye conditions with changes in the teeth is not a new discovery, and its recognition long ago is suggested in the term "eye-tooth." The writer concerns himself more particularly with the production of ocular disturbances or diseases from abnormal conditions of the teeth, and these he divides into two classes, functional and organic.

The functional disturbances may be produced by abscesses or disease about the roots of the teeth or by an impacted tooth, and such reflex effects are found more frequently when the teeth of the upper jaw are at fault. The effect upon the eye on the affected side may consist in disturbances of the pupil or the motility of the iris, in restriction of the range or complete paralysis of accommodation, spasm of the orbicularis, disturbance of the muscle balance, asthenopia or amblyopia—with absence of ophthalmoscopic findings—all of which are entirely relieved upon removal of the cause of irritation.

The author cites Coopman's interesting case of blepharospasm from physiologic eruption of a tooth, occurring in a healthy child of three who made no complaint about the teeth. After five days of marked blepharospasm, examination disclosed a slight swelling back of the second deciduous molar. Incision over the permanent molar banished the spasm.

The writer himself has seen cases of strabismus, asthenopia, and other symptoms which occurred either during the eruption of the teeth and disappeared when the tooth was through the gums, or which occurred while children had their teeth regulated and disappeared when the appliances and all pressure had been removed.

Blindness following the extraction of a tooth has been reported. Organic or structural changes in or about the eye, resulting from the teeth, have been observed in many varied forms, and inflammation of almost every structure of the eye, depending upon, or at least attributable to, dental trouble, has been reported. The author mentions a case of abscess of the orbit which stood in relation to an abscess about the root of a tooth. Ulcers of the cornea of various types have been attributed to the teeth by various writers. The possibility that an intractable keratitis may be due to reflex irritation should also not be lost sight of.

Pyorrhea alveolaris has not infrequently been found to be a cause of ocular disturbance. An important point in reference to this and to other septic conditions about the mouth is that, when such is found in a patient upon whom an operation upon the eyeball is contemplated, it is most important to correct this septic condition before proceeding to any operation. Knapp reports a case of blindness from periosteitis originating from caries of the teeth extending to the floor of the orbit, where it caused some thickening and involved the optic nerve within the canal.

A remarkable fact upon which the author lays particular stress is that not infrequently the patient is wholly unconscious of anything being wrong with his teeth, and he will state that the latter are examined regularly by supposedly competent dentists. The author has grown suspicious of a mouth showing numerous gold crowns and fillings, and places great weight upon an X-ray examination, which he insists upon when he does not feel certain of the work previously done. He has succeeded in several instances in finding abscesses at the roots of teeth, or of improperly filled roots, where nothing wrong was suspected by the patient, with the result of securing relief of the ocular symptoms by treatment of the pathologic dental condition.

The possibility of ocular disturbance due to dental disease is corroborated by a case reported by Dimmer in the *Wiener Med. Wochenschrift.* A lower right molar, which had been considerably destroyed by caries, was removed in three portions in a patient of eleven years. Though no swelling or suppuration had been present in the mouth, vomiting and fever occurred two days after the operation. On the fifth day the right eye became hazy, and the pupil underwent a yellow-gray discoloration. Fever blisters of the lips and catarrhal angina supervened, and the right eye exhibited hypopyon, though the extraction wound showed no inflammatory symptoms whatever. Treatment consisted in atropin and the application of hot, wet poultices, by which the eye was gradually reduced in size. Two months after the extraction, the right eye was somewhat smaller, bloodshot, the cornea normal, the anterior chamber shallow, the iris slightly discolored, the pupil contracted with a narrow, hard synechia postero-inferiorly; the lens was transparent. In the fundus a gray reflection was noted, which in the lower half of the bulbus assumed an intensely white shade. Dimmer states that diseases of the eye of dental origin are usually due to metastasis of purulent processes from a diseased tooth to the orbit by way of thrombo-phlebitis. The inflammation of the orbit thus caused may involve the eye, which may be lost entirely by panophthalmitis. In the case cited, no inflammatory disease was present in the tissues between the orbit and the alveolar wound; the symptoms noted must therefore be explained as metastatic endophthalmitis. It is noteworthy that ocular disease following tooth extractions is very rare.

PERISCOPE.

Drying Out Root-canals.—Old hypodermic needles will be found useful to screw on the end of the chip-blower for drying out root-canals, as the heat can be applied nearer to the apex of the root-canal. Generally, part of the point should be broken off before using. —*Dental Digest.*

Removing Dental Cement.—Dental cement should never be removed from a post or crown with a bur. It is far more practical to immerse the surface to be cleaned of cement in very strong ammonia. Over night all trace of cement will have disappeared.—*Bulletin du Syndicat des Chirurgiens Dentistes de France,* per *Revue Trimestrielle Belge de Stomatologie.*

A Method of Refitting Artificial Dentures.—Modeling compound is warmed, spread over the plate, and inserted in the mouth; the patient is ordered to close to get proper occlusion. The compound is hardened by using cold water, removed, the edges are trimmed to suit, the case is invested in a flask, which is warmed to soften the compound. The flask is then separated, the compound removed, and the old rubber roughened by using large burs or carborundum points. The plate is then packed, vulcanized, and finished.—L. E. DAY, *Dental Summary.*

Removing Broken Crown Posts.—With an S. S. White trephine No. 253, the operator should trephine around the post into the end of the root to a sufficient depth. The shoulder of an ordinary screw mandrel is then reduced on the lathe to the diameter of the shank, the mandrel is shortened to one-half inch, and the sides are flattened, so that it can be grasped with the pliers. The small steel mandrel thus provided will, when forced over the post, cut a thread. The mandrel is then screwed down firmly and grasped with a post-puller, thus removing the broken post.—C. C. STONE, *Dental Summary.*

Pouring Liquids.—To pour a liquid into a narrow-mouthed bottle when a funnel is not at hand, a match-stem or wooden toothpick is moistened and laid across the top, holding it there with the forefinger. When poured, the liquid will run along the bit of wood into the bottle. A fountain pen may be filled in this manner. Chemists have a little trick for pouring liquids into a paper filter. Filter paper is not strong and is apt to break unless used with care. To avoid accidents, the chemist holds a glass rod touching the side of the filter and the lip of the vessel from which the liquid is poured. In this way the liquid is conveyed to the filter in a gentle stream and without impact.—*Dental Brief.*

Burnishing Gold Inlays.—Whatever may be the cause or causes, cast inlays do not always fit. They sometimes fit well except at certain points. The readiness with which cast gold flows under stress, owing to a disturbance of its molecular arrangement in the process of casting, greatly facilitates burnishing, and this seems to be resorted to in many instances as a means of improving the fit. That good is accomplished in this way is unquestionably true, but that harm may be—indeed, often is done—is also quite true.

When resorted to after the setting of the inlay and the hardening of the cement, as is seemingly so often done, if the burnishing accomplishes anything at all beyond the smoothing of the exposed surface of the gold, it does harm instead of good. The cement is crushed at the margins, and imprisoned though it may be for a time, its dissolution and washing out by the secretions and the darkening of the margins are the results which are sure to follow. An inlay should be burnished, and burnished well, but always either before cementation or before the setting of the cement.—J. H. CROSSLAND, *Dental Brief.*

Transmission of Disease and Sterilization of Dental Instruments.—The monthly bulletin of the St. Louis Health Department refers to a lack of aseptic precautions in certain dental offices, and of the possible spread of tuberculosis occasioned thereby. The bulletin continues: "Many dentists are deplorably lax in the manner in which they use their instruments, and often observe no care at all in the possible transmission of disease conditions. When we consider that almost every disease transmissible from one person to another is most readily transmitted through the medium of the air-passages, it can be seen easily how important the cleanliness of the dental instrument is. It is not enough that dental instruments should be wiped, for wiping does not remove all infection. Such instruments should be immersed in boiling water after the work on each patient is completed. Dental cleanliness cannot well be forced by the health department, but public aid is necessary." The bulletin asks that all dental patients insist that only carefully sterilized instruments be used on their teeth and gums, and that cases where such precautions are not taken be reported.—*Oral Health.*

Bismuth Intoxication in the Mouth.—Bismuth produces a characteristic pigmentation of the mouth which one should look out for in any case where large doses of bismuth have been used either for X-ray purposes or in the cure of fistulæ by Beck's method. Symptoms develop about three weeks after its administration. They may be ushered in by a livid discoloration of the skin, which is soon followed by the appearance of small, bluish ulcers on the gums, especially about the third molars. These gingival areas of pigmentation soon become larger and extend to the under surface of the tongue and the adjacent mucous membrane, which become intensely stained with a dark blue color, which shines through the overlying normal mucous membrane. These areas may assume a very large size; their contours are very irregular. In advanced cases, patches of diphtheritic membrane may be found on these pigmented plaques, and gangrene has also been reported in some patients. The constitutional symptoms then become very severe, and include headache, vomiting, diarrhea, and other symptoms of colitis. Fever is always present in the later stages of the disease, and albuminuria is also common. Not infrequently these patients die from the progressive weakness and constantly increasing gastro-intestinal symptoms.—M. MANGES, *N. Y. Med. Journal.*

Opening Submaxillary Abscesses Through the Mouth.—H. Morestin advises this mode of intervention in cases where the disfigurement resulting from the scar of a skin incision in the treatment of acute suppuration of the submaxillary lymphatics is a matter of serious concern to the patient, as in the female sex. He reports three cases in which incision through the mouth proved entirely satisfactory, healing taking place promptly and without any complication. In each case, at the time of operation, the suppurative process had already caused infiltration of the subcutaneous tissues and adhesion and redness of the skin. Under general anesthesia, and with the mouth held wide open and the tongue pulled to the opposite side, the author incises the floor of the mouth at the point of deep induration, if this is palpable, or, if not, at any point between the first bicuspid and the angle of the jaw. The first jet of pus is taken up by gauze previously placed at the back of the mouth; this is quickly replaced by more gauze, the cavity roughly cleared out, and the incision then enlarged, so that the pocket can be carefully cleansed and disinfected with ether or tincture of iodin. A rather tight gauze packing is then inserted. This is removed in two or three days and replaced by shallower drains. In six or seven days healing is already so far advanced that no more gauze can be introduced.—*Presse Médicale* per *N. Y. Med. Journal.*

Nitrous Oxid and Oxygen Analgesia in Various Types of Patients.—Patients who are to be placed in the analgesic condition may come under one of the four following classifications, viz, the alcoholic, the nervous and easily excited, the susceptible and the non-susceptible.

The alcoholic patient is the one that we have more or less trouble with, no matter what the anesthetic may be. So long as we keep the alcoholic patient in the first or analgesic stage, he will prove to be just as good a patient as the non-alcoholic, but if an apparatus be used whereby the gases and air cannot be controlled accurately, this type of patient will get over the borderline into the stage of excitement, and the operation will result in failure. Therefore the gas and air must be accurately mixed.

The nervous and excitable individual is the most difficult type of patient to deal with. When a patient of this type presents herself for this work, a little more time should be allowed for using a great deal of suggestion and winning her confidence. Suggestion plays a very important part with the nervous and easily excited patient; quickly inducing the analgesic stage in such a one tends to make her more nervous. The patient is allowed to hold the inhaler with her left hand; the air-valve is opened one-half, and the gas is shut off so that she will breathe nothing but air for several minutes. This will enable the operator to gain her confidence. After nothing but air is breathed for several minutes, the nitrous oxid controlling valve is slowly opened.

The susceptible individual is, of course, the easiest type of patient in whom to produce the stage of analgesia. Anemic individuals are, as a rule, very susceptible, and are easily controlled. The air-valve, in these cases, is opened to three-fourths, excepting in hypersusceptible cases, in which it is fully opened.

The non-susceptible patient is one whom the gases do not affect so readily. Such patients require a higher percentage of nitrous oxid to produce analgesia. This is accomplished by closing the air-valve to three-fourths—one-fourth being open. It takes a little longer to produce the stage of analgesia in such cases. As a rule, it takes at least five minutes for good results. When the air-valve is closed to this extent, the percentage of air is reduced, thereby lessening the percentage of oxygen and allowing the nitrous oxid to be given somewhat purer to the patient. The nitrous oxid then produces a deeper stage, and analgesia is induced without increasing the flow of nitrous oxid. —A. E. Smith, *Oral Hygiene.*

Manipulation of Cements.—The non-hydraulic and the hydraulic varieties of oxyphosphate zinc require different treatment in manipulation. The one is indicated where dryness can be maintained until the cement has set; the other where moisture can be brought into contact very soon after stiffening begins. The principal difference is found in the liquids, the non-hydraulic liquid containing less water and, in most cases, a larger proportion of sodium. The sodium causes slow setting, some pores, less strength, but greater adhesion. The lack of water causes slow setting and expansion during setting. The hydraulic liquid contains more water, is not so heavy, and has less of the phosphates in the solution. This class of cements requires more water for crystallization than is contained in the liquid, therefore must be subjected to water during setting. These cements require gradual mixing and thorough spatulation. The powder should be added in from six to eight portions, spatulating each portion well; the first portion added having the most thorough mixing of all. It should be spatulated until every particle of powder has been taken up by the liquid, and the mass becomes smooth and free from perceptible granules. Thorough spatulation and sufficient time at this point permits the formation of zinc phosphate, which acts as a cementing medium, holding together the zinc oxid granules which are not acted upon by the phosphoric acid. The remaining portion should be added a little faster, only allowing time to incorporate each portion to a smooth consistence. When the consistence of heavy cream is reached, and the mixture drops from the spatula reluctantly, enough powder has been added for crown and inlay setting.

If a filling is desired, a small portion of this thin mix is placed to one side of the slab for lining the cavity, and powder is added rather rapidly until a putty-like consistence is reached. The cavity is lined with the thin mix and the filling made with the stiff mix, shaping it to the desired form and contour.

The hydraulic and non-hydraulic cements require the same technique of manipulation up to a certain stage. When the hydraulic cement has well begun to set, and the excess around the edges shows stiffening, moisture should be brought into contact with it in order to secure the best results, while the non-hydraulic must be kept dry until it has become quite hard.

Copper oxyphosphate, when properly manipulated, makes a very strong and enduring filling. In its use the same technique applies as in the zinc oxyphosphate, up to the stage where the mass begins to show a medium degree of stiffness, and works heavily under the spatula. This stage is indicated when the mix drops lazily from the spatula held above the slab, and flattens or spreads slowly after dropping on the slab. When this stage is reached, no more powder should be added, but spatulation should continue till the mass shows a considerable degree of stiffness, not too great, however, to prevent insertion into the cavity. When mixed in this manner it sets rapidly, and fillings made in form of one-tenth inch cubes have stood up under more than 250 pounds of pressure.—C. M. McCauley, *Items of Interest.*

HINTS, QUERIES, AND COMMENTS.

PRESSURE ANESTHESIA IN MULTI-ROOTED TEETH.

OPERATIONS are many times delayed owing to the necessity of waiting for pulp devitalization, because difficulty is experienced in the employment of pressure anesthesia in multi-rooted teeth. The cause of this difficulty lies in the fact that the cocain solution is forced into the pulp tissue of the larger canal instead of into that of the smaller—that is, it follows the line of least resistance—making the removal of the pulp from the small canals very painful.

To avoid this, an exposure of the pulp is made, a small pellet of cotton previously saturated with the anesthetic solution is placed over the exposed pulp, and pressure is produced. I prefer wax, base-plate wax in summer, bite-wax in winter, to vulcanite rubber, especially in cavities involving the approximal surface. Generally, by one application the pulp in the chamber and in the largest canal will be anesthetized. If the initial exposure is small, one application may be required to allow painless excavation for a larger opening. The pulp is removed from the large canal, a wisp of cotton inserted, a ball of wax slightly larger in diameter than the mouth of the canal is rolled, and packed firmly into it. The first procedure is then repeated in order to anesthetize the pulp tissue in the smaller canals, the pulp is removed, and then a barbed broach is pressed through the wax in the large canal, and given a half-turn to engage the cotton. On removal of the wax stopping, the canals are ready to be dried and filled.

W. N. MILLER, D.D.S.
David City, Nebr.

OBITUARY.

DR. S. B. PREVOST.

DIED, July 26, 1913, in Madison, Iowa, Dr. S. B. PREVOST, in his sixty-ninth year.

Dr. Prevost was born in Champlain, N. Y. He went to Kansas City in 1865, after the close of the civil war, in which he served. He began the practice of dentistry in that city. His professional practice continued there for forty years, and he became known as one of the leading dentists, and later as the "dean" of the dental profession of Kansas City. Dr. Prevost had been honored by his professional brethren with the presidency of the Missouri State Dental Association. He was a member of Farragut Post, G. A. R., and of the Elks organization.

Dr. Prevost is survived by a married daughter and a son, Harry L. Prevost of San Francisco.

DR. JAMES W. HINE.

DIED, in Albany, N. Y., on June 4, 1913, Dr. JAMES W. HINE, in his fifty-sixth year.

The sudden death of Dr. James W. Hine at his residence, 103 Lancaster st., Albany, N. Y., was the occasion for deep regret among his best friends. The deceased, although ill with heart trouble, was not considered to be in a serious condition until the day before his death.

Dr. Hine was very popular in local professional circles. He had practiced dentistry in Albany for thirty-two years of his fifty-five years of life, and was very prominent in the state dental fraternities, his happy talents as well as his sympathetic nature winning him much attention.

He was a well-known Mason, being a member of the Temple Commandery. He was a vestryman of St. Paul's Episcopal Church, and affiliated with the Atkinsonian, a local dental society.

Dr. Hine is survived by his wife, with whom all his friends and associates sympathize in her great loss.

DR. R. B. MILLER.

DIED, July 15, 1913, in Dorchester, Mass., Dr. RUSSELL B. MILLER, in the sixty-fourth year of his age.

Dr. Miller was born in Herman, Penobscot county, Me., July 30, 1849, and received his education at the public schools and academies of that state. He was engaged in business and taught in the public schools at Hermon, and was also at different times town clerk, tax collector, constable, and deputy sheriff.

In 1882 he enrolled as a student at the Boston Dental College, and after being graduated went to Rockland, Me., and remained there in the practice of dentistry until 1895. He was for two years member of the Rockland common council and for three years member of its board of aldermen, of which he was president. He also served on the school board of the city.

Removing to Boston in 1895, he entered into partnership with Dr. F. J. McFarlane on Warren st., remaining with him until 1899, when he established himself at Roxbury, where he had since had his office.

In Maine he had been president of the Maine Dental Society and for several years a member of the Maine State Board of Dental Examiners. He was an ex-president of the Dorchester Dental Society and active in the Massachusetts, Northeastern, and Roxbury Dental Societies. He was also a member of St. John's Lodge of Masons.

DENTAL COLLEGE COMMENCEMENTS.

UNIVERSITY OF MICHIGAN, COLLEGE OF DENTAL SURGERY.

THE sixty-ninth annual commencement exercises of the University of Michigan, College of Dental Surgery, were held in Ann Arbor, Mich., on June 26, 1913.

The commencement address was delivered by Prof. Geo. E. Vincent, LL.D., president of the university.

The degree of Doctor of Dental Surgery was conferred on the following graduates:

Bert M. Adams
Henry M. Ballard
Richard L. Benedict
Harold S. Bennett
Harry L. Black
Mahlon H. Bristol
William E. Brown
Charles W. Burkheiser
Lewis F. Burlingame
Arthur S. Chichester
Earl L. Church
Frank A. Clear
Willard C. Creath
John D. Eichelbarger
Andrew A. Eriscon
Charles W. Fargo
Frank Feuerstein
Clifford C. Forrester
Shelley A. Foy
Howard W. Geiger
Edward M. Griffin
Alfred T. Grossman
Cortez R. Hall
John W. Hall
James F. Hannon
Firn R. Harding
Arthur W. Hogan
James H. Howell
Lawrence C. Jackson
Augustus H. Jensen
Paul A. Johnson
Howard L. Jones
Seward L. Kingsbury
Edward J. Kosanke
Claude S. Larned
Alfred J. Lautmann
William C. Leggett
Ira A. Lehman
Cornelius Locke
James J. McCarthy
Harry W. Mack
Henry H. McUmber
George B. F. Monk
Edward J. Mudge
Harry E. Myron
Conrad H. Nelson
Eugene LeR. O'Conner
Richard C. O'Donnell
Miguel A. Pastrana
Charles W. Peasley
William F. Quinn
Harry S. Read
Berton D. Roe
George C. Robinson
Warren E. Sargent
Louis V. Savage
Gladys R. Schiller
Alfred J. Schroeder
Raymond F. Sitter
Fred W. Smith
William B. Smith
John W. Snyder
James F. Spencer
Frederick C. Tesch
William T. Verhoeks
Orvie N. Wilton
Ralph E. Woleslagel
Homer P. Yoder

SOCIETY NOTES AND ANNOUNCEMENTS.

NATIONAL DENTAL ASSOCIATION.

Notice from Committee on Scientific Research.

COMPETENT research workers are wanted for the National Dental Association. State qualifications, experience, languages read, and preference for pathological, biological, pharmacological, metallurgical, or anatomical work is preferred. Address WESTON A. PRICE, D.D.S., Chairman of the Committee of the National Dental Association for Scientific Foundation Fund, 10406 Euclid ave., Cleveland, Ohio.

INTERNATIONAL DENTAL CONGRESS, 1914.

THE Sixth International Dental Congress will be held in London from August 3 to 8, 1914, at the invitation of the British Dental Association.

His Majesty King George V has graciously consented to be the patron of the congress, which will take place at the University of London and at the Imperial College of Science and Technology, South Kensington.

The president of the congress will be Mr. J. Howard Mummery, and the joint general secretaries are Mr. Norman G. Bennett and Mr. H. R. F. Brooks. Mr. H. Baldwin is honorary treasurer.

A Committee of Organization, under the presidency of Mr. W. B. Paterson (president of the International Dental Federation), with Mr. F. J. Pearce as honorary secretary, has been busily engaged for some time in making the preliminary arrangements.

Previous congresses have taken place in Paris, 1889; Chicago, 1893; Paris, 1900; St. Louis, 1904; and on the last occasion at Berlin, in the Reichstag, in 1909, when the German Emperor took a personal interest in the meeting, delegates attended from twenty different countries, and the governments of many of them were officially represented.

Invitations are being issued to dental organizations throughout the world, and it is hoped thus to secure the co-operation of leading specialists and representative authorities in all branches of dental surgery.

The rules of the International Dental Congress provide that all ethical practitioners of dentistry possessing the qualification of the country in which they receive their professional education, or of the country in which they practice, are eligible for membership.

The subscription for members of the congress will be 30s. ($7.50; 38 fr.; 31 mks.), and for members of their families accompanying them 15s. (19 fr.; 15½ mks.; $3.75).

The offices of the congress are 19 Hanover Square, London, W., to which address all communications should be sent.

THE PANAMA PACIFIC DENTAL CONGRESS.

As one of the attractions of the Panama Pacific International Exposition, a dental congress, international in character, to be known as the Panama Pacific Dental Congress, is to be held in San Francisco, California, beginning on the last Monday in August 1915, and continuing for ten days.

A committee of Organization has been perfected, including representatives from the Pacific Coast states—California, Oregon, Washington, Utah, Idaho, Colorado, and Arizona.

This committee is now actively engaged in perfecting the work of organization, including the establishment of executive committees in every state of the United States and in every foreign country where dental organizations are known to exist, which will be empowered to promote the business of the congress by bringing it to the attention of their national, state, and local societies, and securing memberships and contributions to the program.

The American Society of Orthodontists and the National Dental Association, of the United States of America, have already made arrangements to meet in San Francisco in 1915 as a part of the congress, and invitations will be extended to other dental societies to take similar action.

Manufacturers of dental goods have signified their intention to maintain during the congress the greatest exhibition of dental supplies ever held. Ample space for this purpose has already been promised by the Exposition authorities, and we are assured of their hearty co-operation in all things pertaining to the success of the congress.

The membership fee has been fixed at ten dollars, and the finances of the congress are being cared for by a corporation, formed within the Committee of Organization, and known as the "Pacific Dental Congress Commission of 1915."

Ample funds for promotion of the congress are assured, and in due time committees on Local Arrangements, Transportation, Exhibits, Clinics, Program, etc., will be appointed, and everything possible will be done to insure the success of the congress and make it in attendance and scientific and professional interest the greatest dental congress ever held.

The whole world is coming to San Francisco in 1915 to participate in and enjoy the Panama Pacific International Exposition, which will commemorate the completion of the world's engineering masterpiece, the Panama Canal.

Never in the history of the profession has there been so auspicious a time for holding a great dental congress, and the Panama Pacific International Exposition Company and the Committee of Organization of the Panama Pacific Dental Congress unite in a cordial invitation to the members of the dental profession to come to San Francisco in 1915 to attend the congress and view the wonders of the Exposition and the Pacific Coast of the United States of America.

Frank L. Platt, *Ch'man,*
Committee of Organization.

NORTHERN INDIANA DENTAL SOCIETY.

The twenty-fifth annual meeting of the Northern Indiana Dental Society will be held at the great Steel City of Gary, September 23, 24, and 25, 1913.

W. Leroy Myers, *Sec'y,*
Rensselaer, Ind.

NORTHEASTERN DENTAL ASSOCIATION.

The nineteenth annual meeting of the Northeastern Dental Association will be held in Footguard Armory Hall, Hartford, Conn., October 14, 15, and 16, 1913. Every effort is being put forth to insure a most attractive meeting. All ethical members of the profession are invited to attend, and those eligible are requested to join the association and help sustain the meetings.

Frederic T. Murlless, Jr., *President,*
Edgar O. Kinsman, *Sec'y,*
Cambridge, Mass.

VERMONT STATE DENTAL SOCIETY.

The thirty-seventh annual meeting of the Vermont State Dental Society was held in Burlington, Vt., May 21, 22, and 23, 1913. There was a good attendance and the meeting was a very successful one. The meeting next year will be held at Rutland, Vt.

The officers elected for the ensuing year are as follows: Dana E. Dearing, South Royalton, president; Thomas Mound, Rutland, first vice-president; W. H. McGoff, second vice-president; P. M. Williams, Rutland, secretary; W. H. Munsell, Wells River, treasurer. Executive Committee—H. M. Smith, Lyndonville, G. E. Partridge, Burlington, and W. R. Pond, Rutland.

P. M. Williams, *Sec'y.*

NEW JERSEY STATE DENTAL SOCIETY.

At the annual meeting of the New Jersey State Dental Society, held at Asbury Park, July 16 to 18, 1913, the following officers were elected: Wm. H. Gelston, Camden, president; Walter F. Barry, Orange, vice-president; Chas. F. Jones, Elizabeth, treasurer; John C. Forsyth, Trenton, secretary. Executive Committee—Walter F. Barry, Henry Fowler, Harrison; James I. Woolverton, Trenton; Joseph Kussy, Newark; Edwin W. Harlan, Jersey City. Membership Committee—A. S. Burton, Asbury Park; Franklin Rightmire, Paterson; J. F. Crandall, Atlantic City; A. L. Westcott, Atlantic City; M. B. Van Dorn, Red Bank.

John C. Forsyth, *Sec'y,*
430 E. State st., Trenton, N. J.

ARMY DENTAL SURGEONS.

MEMORANDA OF CHANGES.

For the week ending July 12th:

J. H. Snapp, ACT.D.S., left San Juan, P. R., June 28th, for his station, Camp E. S. Otis, Panama.

First Lieut. G. E. Stallman left Fort Sam Houston, Texas, July 2d, on leave of absence for three months.

C. E. Sherwood, ACT.D.S., and F. C. Cady, ACT.D.S., *en route* to San Francisco and Manila.

First Lieut. C. E. Lauderdale left Sheridan July 5th, and arrived at Fort Leavenworth July 6th.

C. G. Baker, ACT.D.S., relieved from duty at Fort Oglethorpe, Ga., and will proceed to Fort Adams, R. I., for duty.

For the week ending July 19th:

First Lieut. R. H. Mills left Fort Riley, July 7th, on leave of absence for two months and fifteen days.

First Lieut. R. H. Rhoades ordered to Hachita, N. M., for temporary duty by para. 6, S. O. 94, Headquarters, Southern Dep't, July 8th, and on completion of this duty ordered to Apache for not to exceed twenty days.

First Lieut. G. I. Gunckel, July 15th, left post Columbus Barracks, on ten days' leave.

First Lieut. J. L. K. Laflamme, July 15th, to DuPont for temporary duty.

For the week ending July 25th:

First Lieut. G. H. Casaday reported for duty at Letterman General Hospital, San Francisco, Cal., July 14th.

First Lieut. Robert T. Oliver granted leave of absence for two months on surgeon's certificate of disability. Upon the expiration of this leave Lieut. Oliver will return to the Letterman General Hospital for further examination and observation.

For the week ending August 1st—(No changes.)

UNITED STATES PATENTS

PERTAINING OR APPLICABLE TO DENTISTRY

ISSUED DURING JULY 1913.

July 1.

No. 1,066,360, to ALBERT C. ALEXANDER. Method of repairing dental plates.

July 8.

No. 1,066,691, to FRANCIS M. WILLIS. Amalgam mixer.

No. 1,066,966, to HENRY A. WETTSTINE. Dental instrument.

No. 1,067,015, to WILLIAM W. FOWLER. Dental broach.

July 15.

No. 1,067,571, to JAMES H. ABBOTT. Dental tool guard.

No. 1,067,572, to JAMES H. ABBOTT. Mouth-prop.

No. 1,067,696, to FRANK W. WALLACE. Dental tool.

July 22.

No. 1,067,993, to THEODORE G. LEWIS. Soldering-block holder.

July 29.

DENTAL COSMOS.

VOL. LV. | OCTOBER 1913. | No. 10.

ORIGINAL COMMUNICATIONS.

THE STRUCTURE OF ENAMEL.

By H. P. PICKERILL, M.D., Ch.B., M.D.S., L.D.S.Eng., Dunedin, N. Z.,

PROFESSOR OF DENTISTRY AND DIRECTOR OF THE DENTAL SCHOOL IN THE UNIVERSITY OF OTAGO; FORMERLY LECTURER ON DENTAL HISTOLOGY AND PATHOLOGY IN THE UNIVERSITY OF BIRMINGHAM, ENG.

FOREWORD.

THE original notes forming the basis of this communication were, I find, written in 1908, but pressure of other work has prevented my offering them for publication before now. It is not my intention in this presentation to traverse at all in detail the mass of work already done on the structure of enamel by Tomes, Williams, Black, Walkhoff, Von Ebner, and others; that is sufficiently well known, and needs even no bibliographical references. My immediate object is to endeavor to present a more accurate conception of the structure of enamel as a whole, by drawing attention to the value of additional methods of examination. Some of these methods I have already described in the Cartwright Essay (1911) of the Royal College of Surgeons,* and I only propose to refer quite briefly here to some of the findings there related, in order that the present picture may be less imperfect than it otherwise might be.

THE ENAMEL SURFACE.

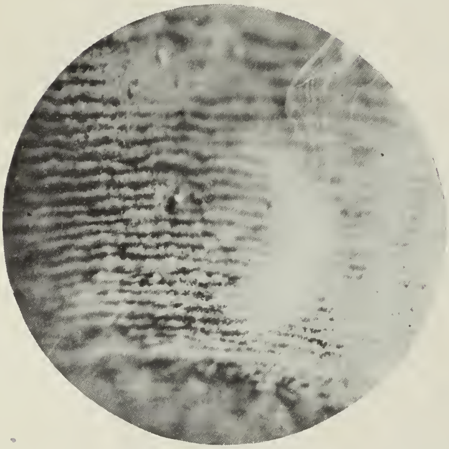
In the publication referred to above I have dealt at some considerable length with the histological and physical natures of the surface of enamel. It is obvious that from a clinical point of view our knowledge of this surface. both microscopical and macroscopical, should be as accurate as possible. It is in this surface that nature has invested the whole of the passive resistance of the tooth to disease. Once this rubicon is passed, the fate of the tooth, in the vast majority of cases, is sealed. I have shown (*ibid.*) that in all human permanent teeth the enamel surface is not normally smooth, but corrugated or "imbricated." This may be demonstrated by the following methods:

(1) By rubbing the surface with fine graphite and examining by reflected light. The depressions retain the graph-

* See "The Prevention of Dental Caries and Oral Sepsis," by the author. London, 1912.

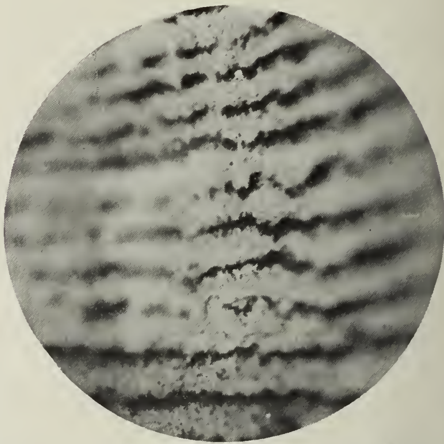
ite, the elevations remain white. (The reverse may be obtained by very light rubbing.) By this method exceedingly fine black bands can be seen running round the surface of all teeth. The character of these bands differs in susceptible and immune teeth, being deeper, wider, and more numerous in the former than the latter. In all teeth they are also most marked and farther apart just below the "point of contact" region. (Figs. 1 and 2.)

Fig. 1.



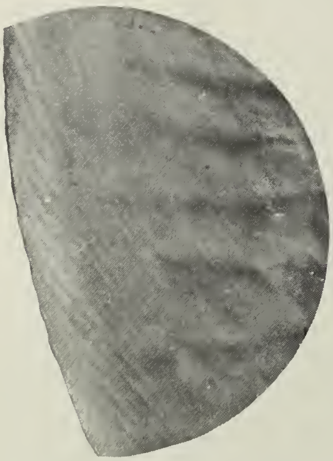
Surface of enamel treated by the author's graphite method, showing the imbrications in the cervical region.

Fig. 2.



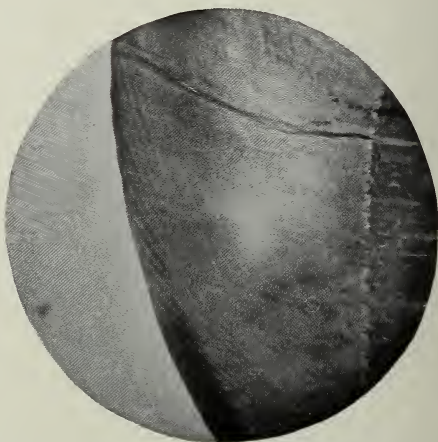
Surface of enamel treated by the graphite method, showing the imbrications. From a point half-way up the crown of a tooth.

Fig. 3.



Vertical section of the enamel surface viewed by reflected light. The surface imbrications are seen in outline, and also their relationship to the incremental striæ in the enamel is quite clear.

Fig. 4.



Vertical radial section of enamel. Shows the incremental lines as "brown" striations—being viewed by transmitted light. Shows also the surface imbrications in outline and the convexities of the enamel at the amelo-dentinal junction.

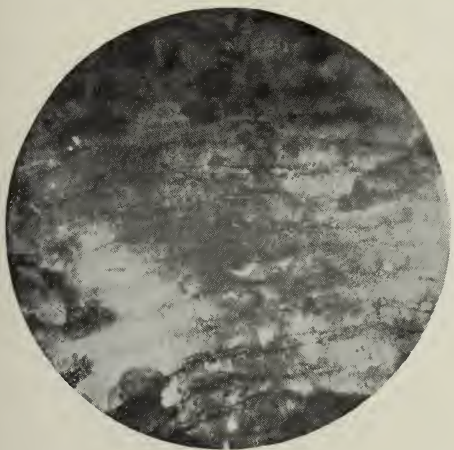
(2) By means of an apparatus which I term an odontograph, graphic representations of the surface of the enamel may be obtained. These odontograms clearly show the surface to be imbricated and that the imbrications are modified in different types of teeth.

(3) By examining sections of enamel by reflected light the imbrications at the surface can be clearly seen, and also their connection with the so-called "brown striæ" of Retzius—which are not really brown at all. It is seen that each imbrication represents the surface termination of a stria or stratum of the enamel. (Fig. 3.)

(4) By accurate substage lighting in thin sections the imbricated outline may be seen by transmitted light. (Fig. 4.)

(5) There is also another method which I have not previously described by which the presence of these superficial imbrications may be demonstrated. I refer to the microscopical examination of the under surface of the surface pellicle (which for the present I should prefer not to call Nasmyth's membrane —but this is a side issue to which I propose to return on some future occasion). The surface of the tooth to be examined is first fixed with formalin and stained with a 5 per cent. solution of silver nitrate exposed to the light and neutralized with a sodium chlorid solution. The pellicle is then removed with nitric acid in the usual way, washed, and mounted. The appearance shown is seen in Fig. 5. The dark striations of the pellicle correspond to the furrows between each imbrication, and take the stain more deeply because the pellicle is there a little thicker.

FIG. 5.



Surface pellicle stained with silver nitrate and removed from a tooth with nitric acid. Distinctly shows the impressions of the imbrications.

FIG. 6.

Vertical section of a hypoplastic tooth, showing that the obvious cessations of growth in the enamel are accompanied by exaggerated imbrications. This simply means that the ameloblasts ceased functioning for a longer period than normal, and that an abnormal number atrophied (or became necrotic) at each period.*

(6) Where enamel has been obviously arrested in its development at several periods owing to constitutional disturbances, the resulting effect is that of exaggerated imbrication. The normal process of forming imbrications is merely prolonged and magnified. (Fig. 6.) As regards the physical nature of the enamel surface, I have shown that teeth are divisible into *malacotic* (soft) and *sclerotic* (hard) types. That is to say

* See page 75 of the author's "Prevention of Dental Caries."

that the enamel of these types of teeth differs as regards its permeability, its solubility, its density, and its hardness—and further, that these differences are measurable.

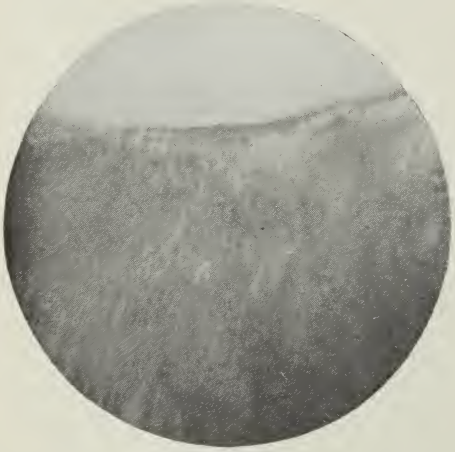
The permeability of the enamel surface to silver nitrate was found to vary very considerably, the depth of penetration being uniformly very much deeper in malacotic than in sclerotic teeth.

The solubility of the surface in different acids showed similar variations, dependent presumably upon the differences in permeability rather than upon differences in chemical composition.

The density of malacotic and sclerotic enamel was found to vary appreciably if suitable means were taken to estimate it. Again, presumably, the differences in density are brought about by differences in the permeability of the surface layers of the enamel.

The hardness of the enamel surface was also found to vary in the same manner, namely, to be appreciably less in malacotic than in sclerotic teeth when tested by the sclerometer method. (Chemical composition and resistance to crushing stress have of necessity no direct relationship to the "hardness" of a tissue, and in this respect the researches of Black and Miller did not meet the point at issue.)

Fig. 7.



Section of enamel showing cessation apparently of the prisms near the surface; their place seems to be taken by a faint horizontal striation.

Nevertheless, in spite of all the above differences, I have been unable to distinguish any difference under the microscope in the minute structure of the enamel of the different types of teeth—with the single exception, perhaps, that very occasionally in malacotic enamel the prisms appear to cease before reaching the surface, their place being taken by a comparatively clear, transparent structure having a very faint striation in a direction at right angles to that of the prisms. (Fig. 7.)

This pointedly illustrates the fact that all that is to be learned about an organ is not to be acquired by the microscope alone; that tissues with apparently identical structures may have quite different properties. I believe that the physical differences between sclerotic and malacotic teeth are, in part if not wholly, acquired after eruption; and further, that it may be possible to bring about such an acquisition; but for the detailed evidence which has led me to this conclusion I must refer to the original publication.

BROWN STRIÆ OF RETZIUS.

I think I have shown conclusively (*ibid.*) that these as such do not exist, but that their appearance by *transmitted* light is due to an increased *optical* density of the prisms. (Fig. 4.) The striæ appear an intense white by reflected light (see Fig. 3); this may be imitated exactly by painting overlapping films of Chinese white on a glass slide, and examining it under the microscope, when the overlaps appear brown by transmitted, but white by reflected light. (Figs. 8 and 9.) These striæ should, I think, be termed "lines of growth," or "incremental lines," as being more expressive of their mode of origin.

Leon Williams concluded that these striæ were due to true pigmentation, and Hopewell-Smith* indorses this by stat-

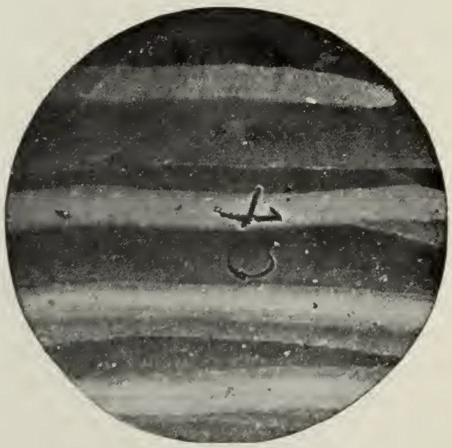
* "Histology and Patho-histology of the Teeth."

ing that their brown appearance is due "finally and correctly to pigmentation." It is however inconceivable that a deeply pigmented substance should (i) be pure white by reflected light, (ii) be perfectly translucent. Furthermore, when enamel is pigmented, as it occasionally is pathologically, the pigment is evident however it may be viewed, but is *less* intense by transmitted than by reflected light, whereas the opposite is the case with the striæ of Retzius. The same applies too, when enamel is artificially pigmented by various stains. A pigment, however, is not necessary to produce the brown appearance of enamel—a weak acid alone is sufficient, for, as is well known, in the earliest stage of caries in enamel, a *white* opacity appears *brown* under the microscope, and the whiter it is the browner it appears.

Fig. 8.

Overlapping films of Chinese white viewed by transmitted light. The overlaps, +, appear a dark brown.

Fig. 9.



Same as the preceding, but viewed by reflected light. The "brown" bands have become white.

THE COURSE OF THE PRISMS.

The description given by Tomes* of the course of the prisms in enamel is brief, perhaps, yet so good that I propose to quote it in full. I doubt very much, however, whether many histologists or dentists have ever realized the truth of this description, largely because text-books are content to show, as a rule, sections of enamel cut in a vertical radial plane only, and these latter are all that a student during his course of dental histology usually sees. Hence in visualizing the structure of enamel one is apt to conceive of it as a mass of tightly packed prisms running inward roughly at right angles to the surface and pursuing a very slightly flexuous course near the dentin. Nearly all the published illustrations of the structure of enamel are misleading to the student, and give him only an erroneous idea of what that structure really is. Tomes says:

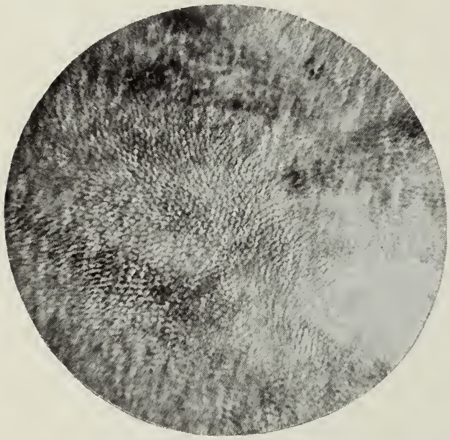
> In human enamel, on the whole the prisms are parallel and run from the surface of the dentin continuously to that of the enamel. Their paths are not, however, either perfectly straight or perfectly parallel, for alternate layers appear to be inclined in opposite directions, while they are also wavy, forming several curves in their length. The curvature of the enamel prisms is most marked upon the masticating surface, while on the sides the layers, alternating in the direction of their inclination as just described, are in planes transverse to the long

* "Manual of Dental Anatomy," p. 19.

axis of the crown, and correspond to the fine striæ on the surface of the enamel, which appear to be caused by their outcrop. The curvatures take place in more than one plane; in other words, the course of the individual prism is more or less a spiral.

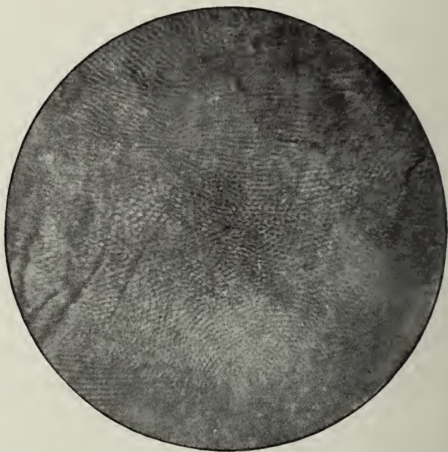
There are two clauses in this description to which one may take exception. "On the whole the prisms are parallel" hardly agrees with the later statement that the enamel prisms, in places, are "in planes transverse to the long axis of the crown." It would be more correct, perhaps, to say that the prisms run in groups, the component prisms of each group being roughly parallel to each other. Also we have seen that the surface striations (which Tomes, in common probably with most dentists, regarded as only occasionally present) are related causally to the outcrop of the incremental lines of growth. Moreover, this arrangement of the prisms referred to is present in teeth in which the surface striæ are absent; for instance, in human deciduous teeth and in dogs' teeth.

Fig. 10.



Transverse section of enamel prisms from near the amelo-dentinal junction. Slightly etched with weak formic acid. Note the "winding" appearance of the prisms; also compare the size of these prisms with those in Fig. 11. (Leitz No. 7 obj., No. 1 eyepiece. Length of camera bellows 21 cm.)

Fig. 11.

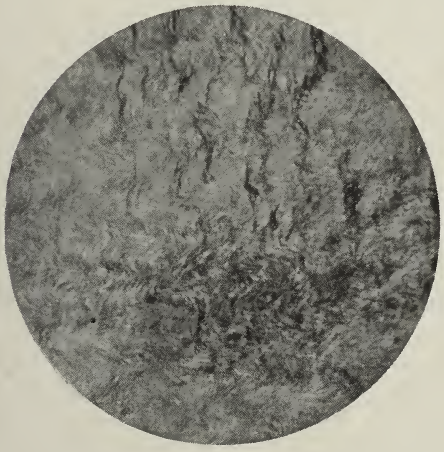


Section of enamel cut parallel to a vertical surface (central incisor). The prisms are grouped into longitudinally and transversely cut bundles. Note as to the latter that the focus is quite different for adjacent groups of prisms.

The true direction taken by the prisms in their course from the dentin to the surface can be learned only from attempts to cut sections at right angles to their course. I say attempts, for two reasons—first, it is difficult to cut sections of enamel in this direction because of its great tendency to break up into small fragments before it is thin enough for the microscope; and secondly, because it is difficult to estimate the direction in which to cut sections which will show enamel prisms cut at right angles to their course, and again, it is difficult to maintain that direction during cutting. It might be thought that cutting sections parallel with the vertical surface of a tooth would show the prisms cut at right angles. That, however, is by no means the case; with the utmost care, sections may be cut in this direction and yet show practically no transverse sections of prisms, or only isolated groups. Of course flat sections cannot be absolutely parallel with a somewhat curved surface except at one point; but here one might reasonably expect to find the enamel cut transversely so as to show a field of hexagonal prisms. Yet that is not so; the prisms even here are for the most part cut somewhat obliquely.

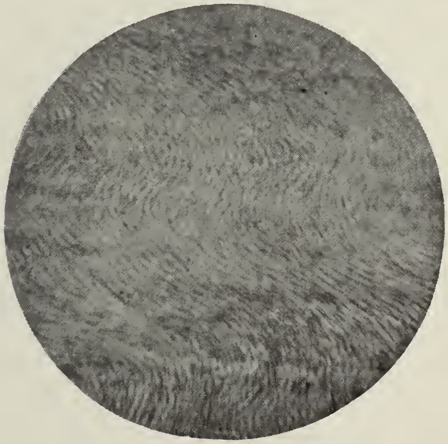
The first thing to be realized is that the course of every prism from its start at the amelo-dentinal junction is a very spiral one—it is in fact a corkscrew course; and the next, that the enamel is arranged in horizontal layers in which the prisms pursue opposite spiral courses. In the upper of two courses, for instance, the prisms upon fine focusing may be seen to be winding upward from left to right, while in the next layer they are winding upward from right to left, and so on. (See Fig. 10.)

Fig. 12.



Low power view (No. 3 obj.) of "transversely" cut enamel, to show the wavy appearance of the prism groups.

Fig. 13.



Vertical parallel section of enamel, showing the corners of the prisms about halfway between the dentin and the enamel. (No. 7 obj., No. 1 eyepiece.)

This spiral winding of alternate layers about each other gives rise, a little farther out from the dentin, to curious effects. Lines of prisms may be seen cut transversely, and between these, rows of prisms cut longitudinally, and both of these groupings run horizontally in rings or layers around the tooth or at right angles to its long axis. (Fig. 11.)

Farther out still, about half way through the thickness of the enamel, and when the prisms are cut more obliquely, the appearance again changes, and at first sight and under low powers the structure seems to be one of prisms cut longitudinally pursuing a very wavy course parallel to the surface of the section. (Fig. 12.) It is only by critical examination with higher powers that this inference is seen to be erroneous. On the top of the waves the prisms are seen to be cut transversely, and the whole appearance is, I think, explained by the lessened flexuosity of the prisms seen through the thickness of the section. (Fig. 13.)

Even at the enamel surface the prisms are not parallel, but run in groups in a variety of directions, always of a spiral nature, as is evidenced by watching the section whilst fine-focusing backward and forward, by the difficulty or impossibility of obtaining a field of transversely cut prisms, and by the fact that only a small portion of the field can be focused at once. (Fig. 14.)

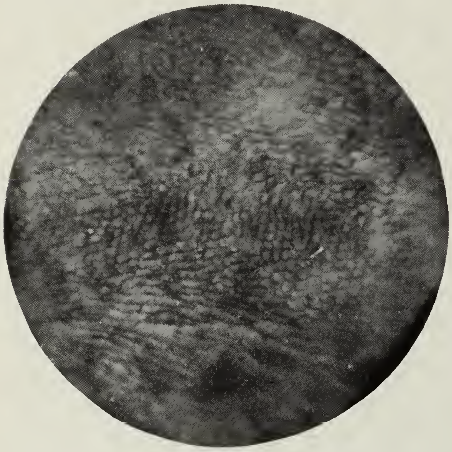
The angle which the prisms make with the surface even in vertical radial sections is very rarely a right angle. The prisms strike the surface (at least the vertical surfaces) at more or less acute angles; even when, as appears in the cervical portion of enamel, the general course of the prisms is nearly rectangular to the surface, as they approach the surface they are frequently bent sharply toward the occlusal surface, and thus make an acute-angled outcrop.

A study of surface parallel sections of enamel rapidly convinces one that we are dealing with a highly translucent and highly refractive tissue, and the different appearances, therefore, that it may present with different lighting and focusing are considerable. One further realizes that the distinctness with which the outlines of transversely or obliquely cut prisms are visible depends almost entirely upon the angle at which they are cut. When they are cut absolutely transversely or very obliquely it is very difficult to distinguish individual prisms, *i.e.* the light passes without inequalities in refraction through prisms and cement substance. When, however, prisms are cut at a certain intermediate angle the cement substance shows up quite darkly. This I believe is due to the angle coinciding with or being greater than the optical critical angle for enamel prisms as compared with cement substance, and hence the light is totally reflected.

It is a little difficult at first to reconcile the appearances seen in vertical parallel and vertical radial sections. In the latter frequently the prisms can *apparently* be traced from the dentin to the surface, yet an absolutely continuous section from the same tooth at right angles to the former shows that the prisms are in some places running almost at right angles to each other. The only explanation would seem to lie in the optical conditions just referred to, namely, that in vertical radial sections what appear to be continuous prisms are not really so, but are merely coincident oblique sections of many prisms, whose terminations do not show because the angle of section is less than the critical angle for enamel.

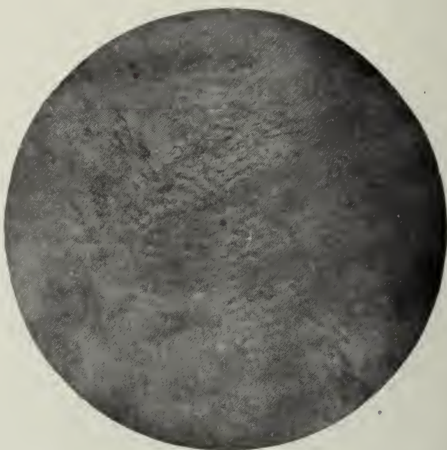
This is borne out by the fact that in vertical parallel sections under the low power, and frequently under the high power, while the enamel prisms appear to be cut longitudinally and to be running in parallel curves, yet by slightly etching the surface with weak acid it at once becomes obvious that what appeared to be prisms cut lengthwise are really rows of hexagons, *i.e.* prisms cut

Fig. 14.



Enamel prisms from just below the surface, cut as transversely as possible. Stained with silver nitrate. Shows the very different directions of contiguous groups of prisms.

Fig. 15.



A small area of enamel cut quite transversely to the prisms, viewed under the 1/12-in. oil immersion objective, to show the very regular hexagonal shape of the prisms. From near the amelo-dentinal junction. (Only a very small area could be accurately focused at one time.)

transversely. This method of etching, as an additional and comparative one, is undoubtedly of value and might perhaps be employed more frequently.

Of course in many cases the flexuosity of the prisms can be distinguished in vertical radial sections, but this feature is not the prominent one, as it is in sections cut parallel to the surface.

In these sections (*e.g.* vertical radial) by fine-focusing up and down, the prisms of two layers can alternately be brought into focus. The prisms in these two layers are seen to cross in direction at angles varying from 30° to 60° something like two types of the letter—X and X, the thick stroke being taken to indicate the prism in focus at the time.

THE NON-EXISTENCE OF "SUPPLEMENTAL" PRISMS IN ENAMEL.

It is generally affirmed, in order to account for the difference in area at the surface of the enamel from what it was originally at the amelo-dentinal junction, that supplemental prisms "are present in the outer portions which do not penetrate far inward."* In this view Hopewell-Smith † concurs. The latter author states:

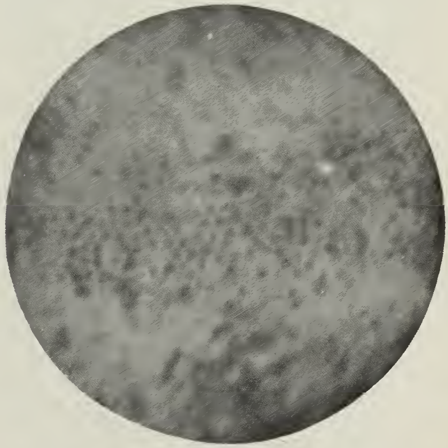
> As the rods run outward, and approach the free surface, it is obvious that many narrow spaces must be left between them as they radiate centrifugally from the dentin, the total area of which is considerably smaller than that of the cortex of the enamel. These clefts are filled with numerous short supplemental prisms, which are histologically identical with the other columns, but are of varying length. These rods are best observed over the cusps of teeth.

No photomicrographs are given, however, which show such prisms, neither have I personally been satisfied that such prisms exist; in fact, on *a priori* grounds alone it would seem exceedingly probable that such prisms do not exist.

Prisms are certainly very flexuous in their course, and thus in a thin section a prism coming up from a lower plane may appear to originate *de novo.* In order to avoid this source of error, thicker sections should be used which have been well cleared in xylol and mounted in xylol-Canada balsam; then, with the finger on the fine adjustment and the substage diaphragm closed to the minimum, prisms can be traced into higher and lower planes.

The hypothesis of supplemental prisms necessarily presupposes either the proliferation of or a considerable addition to the original ameloblasts, and I have never seen, either under the microscope or in any photomicrograph or drawing, an enamel cell undergoing mitosis.

FIG. 16.



The enamel surface treated by the graphite method. Shows the center of the enamel prisms retaining the graphite. (Reflected light.) This is not an uncommon condition in present-day teeth, and is to be regarded as a sign of slightly incomplete development.

Neither do I think it can be held, in view of Leon Williams' demonstration of the secretory function of the stratum intermedium, that these cells are capable of forming fresh ameloblasts; certainly no ocular evidence seems forthcoming of their mutation. Tomes* seems skeptical on the point, for the most he says is

* Tomes, "Dental Anatomy," p. 20.

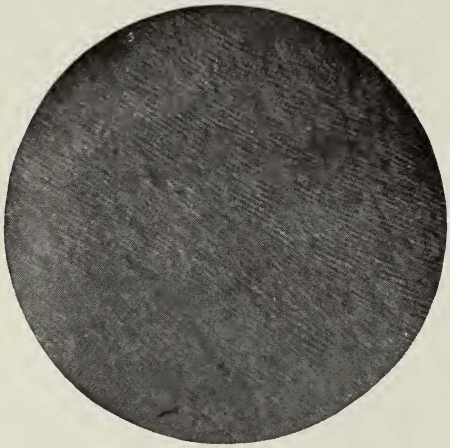
† "Histology and Patho-histology of the Teeth," p. 34.

* "Dental Anatomy," p. 172.

that it has become customary to attribute the function of recruiting the enamel cells to the cell of the stratum intermedium.

Measurements of the prisms and of the enamel as a whole are quite opposed to the presence of "supplemental" prisms, and quite relieve us from the necessity of supposing their presence to account for the difference in area at the amelo-dentinal junction and at the surface.

FIG. 17.

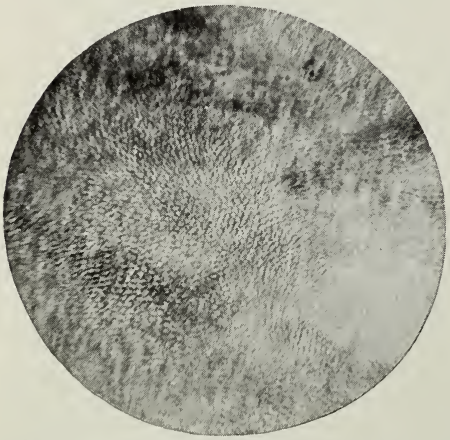


Section of enamel cut in the direction of the long axis of the prisms from near the amelo-dentinal junction, to show their size as compared with prisms near the surface (*cf.* Fig. 18). Leitz obj. No. 7, eyepiece No. 1. Camera length 21 cm.

FIG. 18.

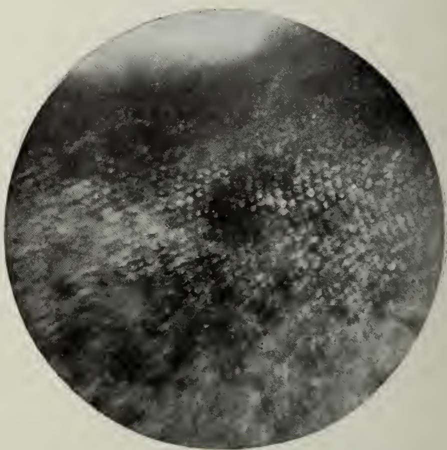
Section of enamel showing prisms cut longitudinally, near the surface. The prisms here are obviously wider than those in Fig. 17. These two illustrations are of exactly the same magnification.

FIG. 19.



Transverse section of enamel prisms near their origin. Compare their size with those seen in the next illustration.

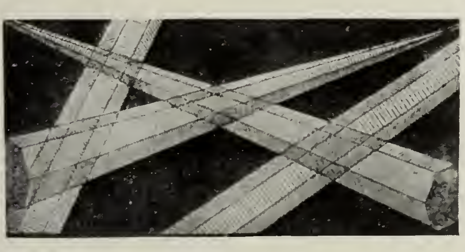
FIG. 20.



Transverse section of prisms at their termination at the surface of enamel, obtained by grinding the enamel from "underneath" and leaving the surface intact. Stained silver nitrate. Compare the size of these prisms with those shown in Fig. 19. Both are of exactly the same magnification.

I have measured a large number of prisms across their diameter, both at the amelo-dentinal junction and at the enamel surface, in different teeth, both native and European, and in all there is a marked increase in the diameter of prisms at the surface. Especially is this the case with regard to prisms over the cusps of molars and premolars. (Compare Figs. 17 and 18, also 19 and 20.) The average measurements of the diameter of prisms at the buccal curve of teeth are—(1) At the amelo-dentinal junction, 0.0031 mm.; (2) at the enamel surface, 0.0057 mm. This gives a proportion of 1 to 1.83. The measurement of the buccal surfaces of the same teeth, measured from the commencement of the enamel to the summit of the buccal cusp, compared with the length of the subjacent amelo-dentinal curve, gives an average proportion of 1 : 1.76.

FIG. 21.



Separated prisms from the outer layer of a pinna shell.

Proportion of prisms	=	1:1.83
" " surfaces	=	1:1.76
Difference	=	0.07

These proportions do not coincide with mathematical exactness, but they do so sufficiently to demonstrate the exact anatomical relationship existing between the two. Moreover the discrepancy between them may be due to experimental error, as also to the fact that the cusps and incisal edges of some of the teeth may possibly have been worn down a little, though I think not. Immediately over the cusps the prisms increase in diameter more than elsewhere, average measurements being—

At the amelo-dentinal junction, 0.0025 mm.
" " enamel surface .... 0.0065 "

[Kölliker gives the diameter of enamel prisms as varying from 0.0064 to 0.0051 mm.; Tomes and Hopewell-Smith as 0.005 mm.]

From the above it will be seen that there is obviously "no room" for the existence of supplemental prisms either in actual fact or hypothetically. There is supporting evidence by analogy that such is the case, and that enamel prisms taper somewhat from the periphery centripetally in that the hexagonal prisms of the shell of the pinna have a similar longitudinal configuration, only more markedly so. (See Fig. 21.)

SCHREGER'S LINES.

Czermak and Hopewell-Smith* affirm that these lines are dark by transmitted light, and light by reflected light. Tomes,† quoting Von Ebner, says they are seen only by reflected light, being quite invisible by transmitted light. These statements are somewhat conflicting, and at first I could find no means of reconciling them. On further investigation, however, the solution of the discrepancies seems to lie in the fact that sections of different thicknesses give very different appearances. In very thin sections the lines are invisible by transmitted light alone (*i.e.* care must be taken to avoid all sources of reflection from the surface of the section), and the lines appear dark by reflected light.

Hopewell-Smith says: "All sections by no means exhibit them"—*i.e.* Schreger's lines. It would probably be more correct to add, "when viewed by transmitted light"—for I have not yet seen a section (vertical) of enamel which did not show them very distinctly by reflected light. They may always be

* "Histology and Patho-histology of the Teeth," p. 36.

† "Dental Anatomy," p. 29.

seen by the naked eye on any cut and polished vertical surface of enamel.

The appearance of these lines is, in fact, entirely dependent upon the manner of lighting the section. They stand out broadest and most marked, like undulations with one side illuminated and one in the shadow, by combined reflected and transmitted light, especially if the latter be made oblique and small in quantity. (See Figs. 22–28.)

by giving three separate explanations of the phenomenon one of them would contain the truth—which is doubtless the case, but which, nevertheless, it must be admitted, is somewhat confusing.

There are two other possible explanations which might be added to the above list.

(1) The lines might be an effect produced by the polarization of light by the enamel prisms, seeing that enamel

Fig. 22.

Schreger's lines as seen ordinarily in a vertical radial section by reflected light.

Fig. 23.

Optical effect produced by passing a beam of light through the long axis of a sheet of glass, and resembling Schreger's lines in enamel.

CAUSATION OF SCHREGER'S LINES.

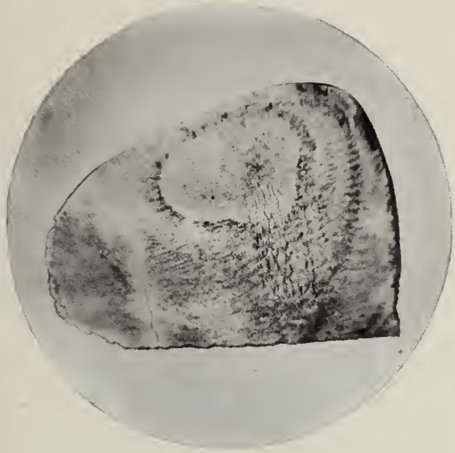
Tomes, apparently quoting Von Ebner, states* that these lines are dependent upon the different directions of contiguous groups of prisms, and are visible only in longitudinal sections. Hopewell-Smith says of them that they may be seen in ground perpendicular sections—"entire band-shaped layers of prisms alternately decussating in such a manner as to form lines . . . . High powers reveal the fact that the prisms are histologically normal, and it is only low magnifications which make apparent their occasional lengthwise groupings." He also refers to Schreger's lines as "cloud-like masses through dense pigmentation." The latter author seems to have proceeded on the assumption that

* *Loc. cit.*

in this respect resembles somewhat a polarizing prism. If a section of enamel be placed on a revolving stage and illuminated by oblique reflected light, the lines of Schreger have two points in the circle where they appear at a maximum and two points at which they appear at a minimum, and these maxima and minima points are at right angles to each other.

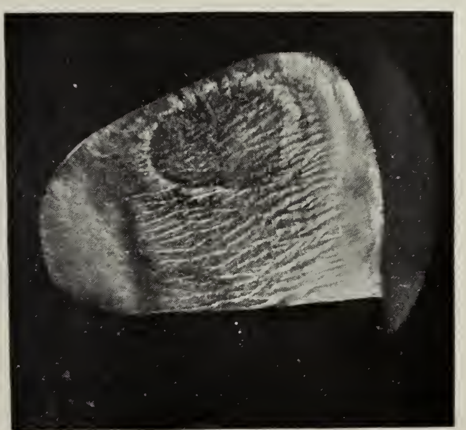
(2) They might be due to a simple optical effect such as may be produced with any piece of thick, clear glass by directing a beam of light obliquely through its long axis and examining the grouping of reflections at the other end. The close resemblance of such an appearance to Schreger's lines is seen in Fig. 23.

FIG. 24.



A "vertical parallel" section of enamel *from the center* of the labial surface of an incisor. (Transmitted light.) Shows (1) Schreger's lines cut transversely, running across the section. (2) Incremental lines (Retzius) running concentrically, much spread out and separated owing to the direction of the section. (3) "Interprismatic spaces" running vertically up the center of the section. (Compare with these the artifact crack toward the lower left corner.)

FIG. 25.

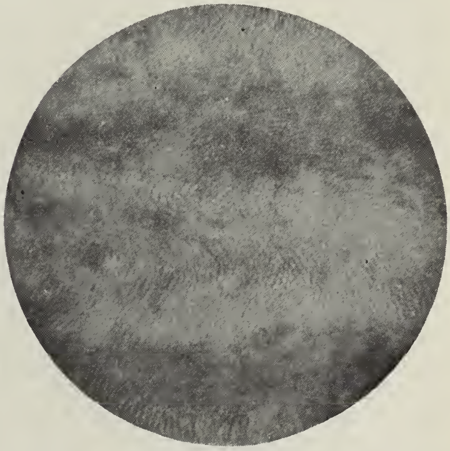


The same as the preceding but viewed by reflected light, with a very slight amount of transmitted light. The transversely cut Schreger's lines stand out very boldly. Note that dark and light areas are now transposed. The "interprismatic spaces" can be made out as glistening white markings.

I do not, however, think that either of the above suggestions gives the cause of the appearance of the Schreger's lines in enamel. They are capable of a much simpler explanation.

The usual appearance of Schreger's lines in vertical radial sections is, I take it, well known, but I am not aware that attention has been drawn to their appearance in transverse section, which really gives the key to their causation. It is obvious that a vertical section of enamel cut parallel to the surface should show these lines as horizontal bands one above another, whilst a section cut in the direction of their long axes should not show them at all, which is precisely the case. Figs. 24 and 25 show Schreger's lines cut transversely; they are more visible in these sections by both transmitted and reflected light than they are in sections cut radially. Examination with higher powers shows that these lines are caused by differences in optical density of contiguous groups

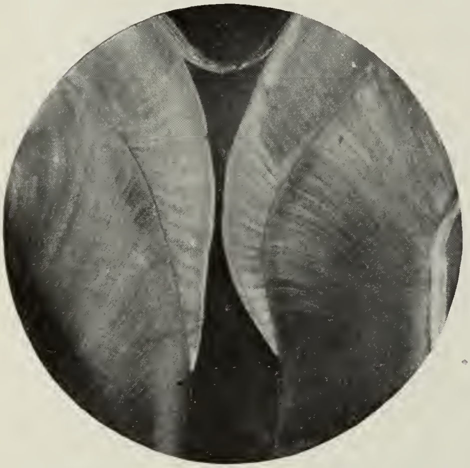
FIG. 26.



Schreger's lines cut transversely in a vertical parallel section of enamel viewed under high power; transmitted light. The dark bands are due to the diminished amount of light coming through prisms which are running more or less transversely to the direction of the light. It is impossible to get these and the transversely cut prisms in focus at the same time.

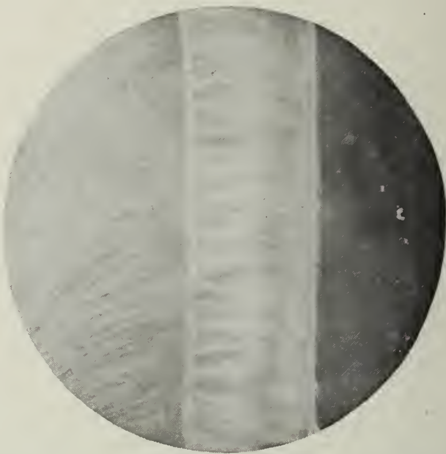
of prisms running in directions sometimes apparently at right angles to each other. (See Fig. 26.) The prisms cut longitudinally are denser than those cut transversely, hence by reflected light the former appear white and the latter dark owing to their allowing the light to pass through them; by transmitted light, of course, the exact opposite obtains, and these very facts show that the appearance of the lines cannot be due, as Hopewell-Smith suggests, to "dense pigmentation"—for if so they should appear brown by reflected light.

Fig. 27.



Lines of Schreger in the enamel of a permanent and a deciduous tooth (human). The section also shows that the bulbous termination of the enamel at the cervix of the deciduous tooth is due not to any increased thickness of that tissue, but to a bulging-out of the dentin.

Fig. 28.



Lines of Schreger in the enamel of a dog's tooth. No imbrication lines are ever present on the surface.

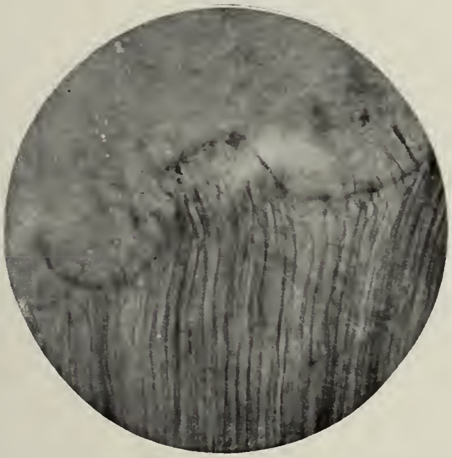
Now, enamel in vertical radial sections—and this I do not think has been noted before—has the peculiar property of picking up and transmitting light which falls upon it horizontally in the direction of the prisms. If all substage light and all light between the cover-slip and objective be cut off, the section will still be illuminated. Under such conditions, if a beam of light be sent along the long axis of the prisms, Schreger's lines will show up very distinctly. That is to say, light is readily transmitted along the prisms, but is absorbed by groups of prisms running more or less at right angles to its direction. This disposes of the polarizing suggestion. This fact, also, further disperses the pigmentation hypothesis. For it might possibly be suggested that although the tissue was very white to look at, it might contain pigment in its substance; but by this method the "interior" of the tissue is illuminated, and no color is visible (and this applies equally to Retzius' striæ). We therefore conclude that the lines of Schreger (like the striæ of Retzius) are due to effects produced by the different optical densities of contiguous groups of prisms.

Figs. 27 and 28 illustrate the presence of Schreger's lines in human deciduous teeth and dogs' teeth, and also dispose of Tomes' suggestion that the fine striæ on the surface are due to the outcrop of transversely arranged prisms. We have seen that these latter cause Schreger's lines, but although these are present in the two kinds of teeth here referred to, no "surface striæ" or imbrications are present. On the other hand, Schreger's lines may be seen on highly polished surfaces of such teeth as alternating light and dark bands wavy in outline.*

THE AMELO-DENTINAL JUNCTION.

This is a region of peculiar interest from three points of view: First, as to its microscopical anatomy; secondly, as to the possiblity of elements of sensation or nourishment crossing the dividing line; and thirdly, as to the nature of the union between the two tissues.

FIG. 29.



The amelo-dentinal junction, showing a "tongue" of dentin inclosed between two convexities of enamel. The tubules in the enamel (?) are seen to be at a different angle from or obviously not connected with the dentinal tubules.

Microscopical anatomy. The line of union between the enamel and dentin may be marked by a straight or curved dark line; it is usually broken up by the presence of numerous small convexities of the enamel looking toward the dentin. These convexities inclose between them a more or less tongue-shaped wedge of dentin. (See Fig. 29.) The dentin in the region shows as a rule the conjoining of originally separate tubules and also the anastomosis of adjoining tubules. Some of the tubules are said to cross the dividing line and to penetrate the dentin. Personally I prefer to say that they may appear to do so. Certainly some tubules terminate more or less abruptly at the junction line, and more or less opposite them in the enamel is a similar dark tube-like appearance; but it is exceedingly difficult to say that the two are actually connected, because of the impossibility of really tracing them across the line.

FIG. 30.

Diagrams illustrating the cause of fallacious appearances at the amelo-dentinal junction. I. A convexity of enamel embedded in the dentin. II. The order of the layers on looking down A–B. III. A tongue of dentin penetrating the enamel. IV. The order of the layers on looking down through the line A′–B′.

There is, however, another condition which I imagine has been mistaken for the former. It is that owing to the small convexities on the inner enamel surface a very thin film of dentin may overlie the enamel at this point, and because of its transparency the enamel prisms are seen, as well as a few dentinal tubules—this is illustrated by the

* See illustration p. 55 of the author's "Prevention of Dental Caries" (1st Eng. edition).

accompanying diagram. Careful focusing, however, will show that the prisms and the amelo-dentinal junction are in reality on a different plane and usually below the dentinal tubules. The dentinal tubules are also said to connect with the *enamel spindles.* The latter, as is well known, in vertical radial sections appear as small dark spindle-shaped bodies jutting out from the dentin into the enamel, and are seen more numerously under the cusps of teeth. (Figs. 31 and 36.) A similar objection occurs here. It is extremely difficult to trace actual continuity, and against it is the fact that the spindles nearly always run at an abrupt angle from those dentinal tubules with which they might possibly be connected. I think, however, that it is extremely doubtful whether they should be called "spindles" at all, and I believe the usual conception of their shape and what they actually are to be incorrect, for the following reasons:

(1) Supposing them to be small cylindrical spaces, filled or unfilled with protoplasm, on cutting a section of enamel tangentially to the surface of the dentin they should appear as a series of small circles or round black dots. But it is just this appearance which one never gets. Instead there appear a number of dark sinuously curved lines, fringed at their margins, running in the direction of the long axis of the tooth. (See Figs. 12, 24, and 31.)

Now, these sinuous lines and the spindle appearance are never present together, but it may be seen that where the direction of a section suddenly changes to a different plane (in relation to the amelo-dentinal junction) the one condition gives place to the other. (See Fig. 31.) Also it will be readily understood that if these sinuous lines (which may be regarded as being horizontal if the tooth were lying flat on a table) were cut by a vertical section in either direction they would appear as small dark columns. The accompanying diagram illustrates this. (Fig. 32.)

Under higher powers it is seen that

Fig. 31.

Section of enamel cut tangentially to the surface of the dentin. "Enamel spindles" are seen in the upper portion giving place to the dark sinuous fringed lines of the "interprismatic spaces" lower down, and the relationship of the two is clearly shown in the highest of the latter.

Fig. 32.

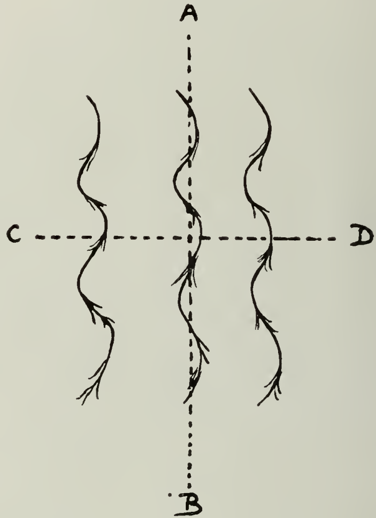

Diagram of interprismatic spaces cut in a plane at right angles to their long axes, showing that sections in either of the other two planes A–B or C–D would cut them more or less transversely, and thus show them as short tube-like structures.

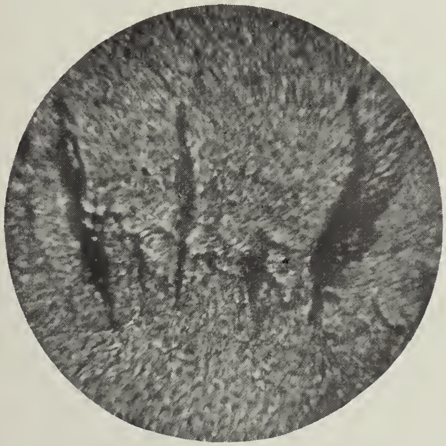
these dark sinuosities run parallel to the flexuosities of the enamel prisms; they wind up from a lower plane, and where the fringes can be accurately focused they seem to be related to a darkening of the interprismatic substance and of the outer portions of the prisms themselves. (Fig. 33.) This darkening appears a deep brown by transmitted light,

Fig. 33.



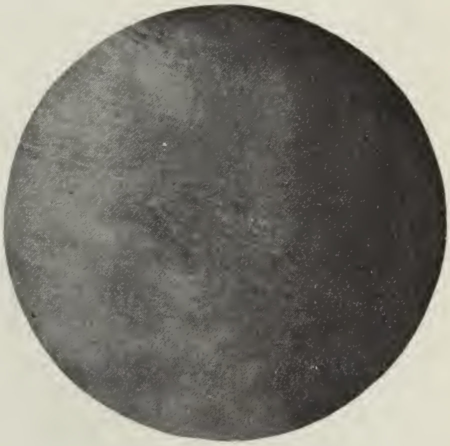
The amelo-dentinal junction, showing the interprismatic "spaces" cut horizontally, and their fringe-like processes. This section illustrates the fallacious appearance caused by the dentin overlapping the enamel, as indicated in the diagram Fig. 30. The real relationship of these structures to the dentin could only be adequately demonstrated by a kinematograph picture taken while focusing down through the thickness of a section.

but glistening white by reflected light. (See Fig. 25.) It is therefore not due to pigmentation.

(2) It may be inferred that, if the above is the correct explanation, a vertical radial section would not always cut across the curves, but sometimes along their crests. This is undoubtedly so. And then we should expect to see a broader fringed appearance somewhat similar to the appearance on transverse section. This is precisely what does appear, but such appearances are usually styled "groups of deeply pigmented prisms,"* or faultily formed prisms, and must be familiar to most histologists. (Fig. 34.)

(3) Not infrequently if a *vertical radial* section be thick enough, and also sufficiently transparent, the connection between two contiguous spindles may be traced by fine focusing through the depth of the section.

Fig. 34.



Vertical radial section of enamel showing one of the curvatures of the interprismatic "spaces" cut tangentially. The black mass to the right is dentin, the section having been submitted to a temperature of 600° F. for thirty seconds. This turned the dentin a deep yellow color, but no discernible effect was produced in the enamel. Interprismatic "spaces" may be seen of *exactly* the same character in sections not so treated.

As to the nature of sinuosities and "spindles," I think they might well be regarded as being similar in origin and significance to the interglobular spaces in dentin—significant, that is, of imperfectly acquired function. It is well known that pathological causes leading to a hypoplasia of enamel are also manifested at corresponding situa-

* Hopewell-Smith on p. 46 of his book shows an excellent photomicrograph of such a group of prisms, but twice refers to them as "stained" in an "unstained" preparation.

tions on the dentin as interglobular spaces. Now, the interglobular spaces and the "enamel spindles" are both undoubtedly physiological, and chronologically they would correspond—both would be developing at the same time.

Further, dentin is formed by the fusion of calcoglobular masses, enamel by the fusion of prisms; deficient function of their formative organs should have similar results—non-fusion of the calcoglobulin and non-fusion of the prisms. And this, in fact, is the hypothesis I suggest for the formation of sinuosities and spindles (which are identical)—that *they are "interprismatic spaces," combined with the poor formation of cement substance and of the outer portions of the prisms,* due to the enamel organ at that time not having acquired a perfect function.

It is with regret that I add to the numerous hypotheses which have previously been advanced to explain the formation of enamel spindles, and I do so only because the above appears to me to be the only one which both explains all the observed phenomena and harmonizes with our other knowledge of tooth development. As to the contents of these interprismatic "spaces," I am not at present prepared to say anything. When considering the question of the post-eruptive hardening of enamel, the point obviously arose as to whether this came about from within or without—namely, whether or not calcium salts could be passed in solution from the dentin to the enamel and there deposited. My experiments recorded in the publication previously referred to were against any such thing occurring.* (Figs. 35 and 36.) Recently Dr. Theo. von Beust† has attempted to show that a communication does occur between the dentin and enamel. He used alcoholic carbol-fuchsin by capillary attraction, and states that the enamel in the inner portions was stained—more especially along certain "fissures," which correspond, I think, to my interprismatic spaces. I am unable to confirm Dr. von Beust's findings. Certainly in teeth

Fig. 35.

Section of a tooth previously immersed in silver nitrate. The stain has penetrated the enamel to a considerable depth, but no stain has passed from the dentin (itself deeply stained) to the enamel.

Fig. 36.

Similar to the foregoing. Nowhere has the stain passed the amelo-dentinal junction. "Enamel spindles" may be seen, but these do not appear to have taken the stain at all.

† Dental Cosmos, June 1912.

treated in such a manner the enamel is stained *very occasionally,* but it is com-

Fig. 37.

Section of tooth stained with alcoholic carbol-fuchsin by capillary attraction. The dentin is deeply stained up to the amelo-dentinal junction, but nowhere has the stain crossed into the enamel.

Fig. 38.

Section of a tooth stained with carbol-fuchsin by capillary attraction. The staining of the dentin is most intense just beneath the enamel, yet no stain has anywhere penetrated the enamel.

paratively rarely and very erratically that it occurs. In my specimens the stain seems a weak diffusion or absorption throughout a small area of enamel (which might be less highly calcified than the remainder). The majority of my specimens show the dentin deeply stained right up to the enamel, but the latter perfectly white and not stained in the least degree. (Figs. 37, 38, and 39.) But I think it by no means follows that because a highly volatile and deeply penetrating stain like alcoholic carbol-fuchsin may pass occasionally across the amelo-dentinal junction, that

Fig. 39.

Similar to the two preceding illustrations. In this case the enamel is stained in a diffuse manner in two situations. This was the only one out of eleven teeth so treated that showed staining of the enamel.

serum or lymph would do the same. Figs. 35 and 36 are interesting in this respect, in that they show how deeply silver nitrate has penetrated malacotic teeth from the outer surface of the enamel, but that nowhere has the stain coming up the dentinal tubules crossed into the enamel. These are from sections which have been exposed to the light for many months, so that it cannot be said that the darkening of a small quantity of stain has not yet occurred.

The improbability of there being anything but the very feeblest continuity between the dentin and the enamel is further supported by the *nature of the* *union between the two tissues.* Enamel is epiblastic, dentin mesoblastic in origin. Both commence to form at their line of junction, one goes upward and outward, the other downward and inward. The amount of admixture of the two tissues is limited to the small

Fig. 40.

Horizontal ridges on the inner surface of the enamel cap, the latter having been removed by heat.

"tongues" of dentin seen in Fig. 29. These probably correspond to the papillæ of the cutis vera, and not improbably serve as a form of mechanical retention for the enamel cap. The actual substance uniting the two tissues must be a feeble glue-like substance, such as collagen, for it is rapidly destroyed by heat. By heating a tooth to 150°C. for two minutes the enamel will leave the dentin quite cleanly. (Fig. 40.) This, of course, may be partly due to the unequal expansion of the enamel and the dentin, but nevertheless the uniting substance gives way and allows easy separation to occur. On the under surface of enamel so removed may occasionally be seen fine horizontal ridges. (Fig. 40.)

SUMMARY.

(1) That in any study of enamel it is to be remembered that it is a highly refractile tissue, and has the power of picking up and transmitting light from even very weak illumination of the margin of sections.

(2) That no pigmentation exists in normal human enamel.

(3) That the course of the prisms is exceedingly flexuous.

(4) That no supplemental prisms exist in normal human enamel.

(5) That Retzius' striæ are, in fact, incremental lines of growth.

(6) That Schreger's lines are produced by differences in the optical density of groups of prisms passing in different directions.

(7) That "enamel spindles" are really transverse sections of continuous interprismatic "spaces," and are expressive of deficient function.

(8) That there is not sufficient evidence to show that normal secretions or bodily juices may pass from the dentin to the enamel.

(9) That the union of the enamel cap with the dentin is largely mechanical.

THE DEVELOPMENT OF THE ANATOMICAL ARTICULATOR.

By ELLISON HILLYER, D.D.S., Sc.D., Brooklyn, N. Y.

(Read before the Dental Society of the State of New York, at its annual meeting, at Albany, May 8, 1913.)

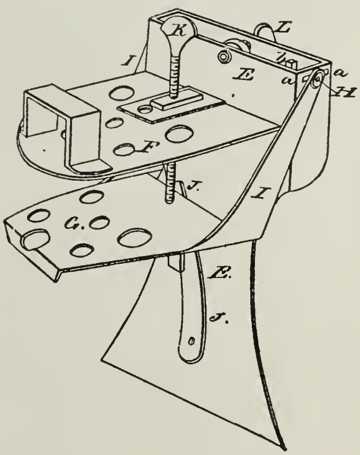
AUTHORITIES upon icthyology tell us that certain fish in seeking a coveted fresh-water pool will travel many miles up a salt-water stream, never deviating or erring in their instinctive certainty of final success. There are many deep and sparkling pools of wisdom lying far "up stream" in the pathway of dental investigation, which must be carefully and unceasingly sought in our efforts to obtain definite and tangible conclusions.

These definite conclusions have been laboriously and painstakingly sought by many men for the past half-century; the exertions of these pioneers to date are but beginning to bear fruit in the results of our dental operations. When we consider the progress of our profession for this half-century period—particularly the last two decades—we are stirred with admiration at many of the results thus far achieved. Progress has been steadily advancing toward the betterment of every procedure. Many of the men who have been the greatest factors in this advancement are among that vast "majority"—who, let us hope, are still watching over our professional welfare and by their inspiration are inciting to greater efforts those who are today carrying on the good work.

Among the many problems which have confronted the profession, one of the most difficult has been that of the anatomical arrangement of teeth. This has been due to the fact that the early conceptions of the mandibular movements were either exceedingly limited, or, if those movements were comparatively well understood, but little effort to reproduce them was exerted.

It seems like the irony of fate that at the time when the least was done to correctly reproduce natural relations of the teeth there was a greater percentage of edentulous cases than at this time, when so much is being done to bring about a solution. The conservation of tooth structure, the preservation of roots, restoration by means of casting methods, the treatment of pyorrhea, and noble efforts in the field of oral prophylaxis, are tending to gradually eliminate the edentulous condition. While, however, gradually diminishing, yet that condition will be, like the poor, always with us, and must receive the best possible consideration.

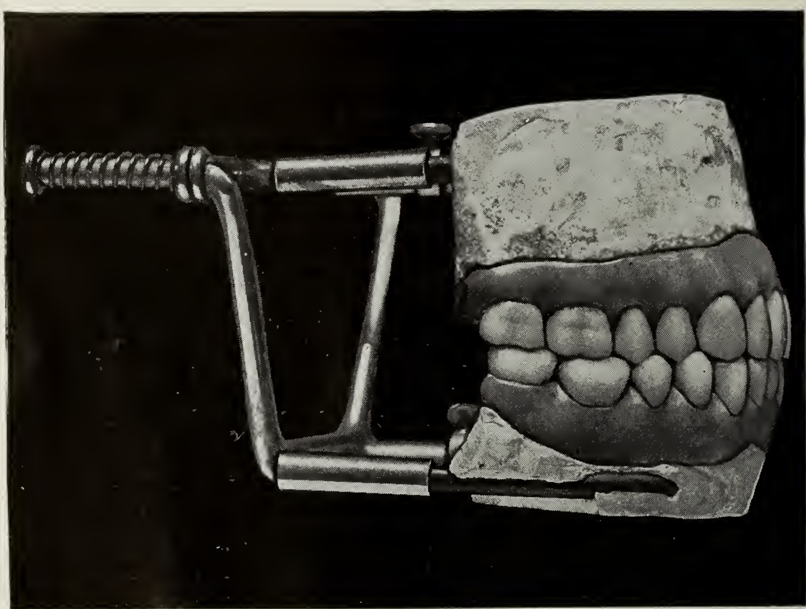
Fig. 1.



THE EARLIEST ARTICULATORS—THOSE OF EVANS AND BONWILL.

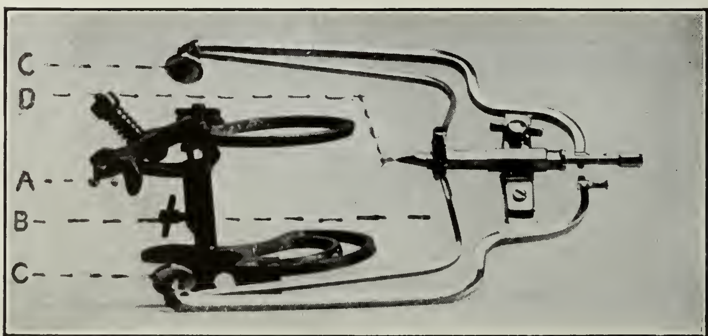
Dr. Bonwill deservedly bears the reputation of being the pioneer in this field, and his articulator is still in use by some practitioners. His work is antedated by that of Dr. D. T. Evans (Fig. 1), who in 1840 was granted a patent upon an articulator which, while showing many evidences of attempts to record the mandibular movements, evidently met with little appreciation, as only the Patent-office records give proof of its having existed. Dr. Bonwill's investigations in the early fifties covered a wide area, and led him to conclusions which were based upon the four-inch equilateral triangle. This measurement from the temporo-mandibular articulations to the symphysis was proved to exist in a large number of skulls examined, with such slight variation that it was made the basis for the construc-

Fig. 2.



Bonwill articulator. (From collection in Univ. Pa. Dental Dep't.)

Fig. 3.



tion of an articulator admitting of the placement of the models in the relation of the four-inch position (Fig. 2). The great fault in this articulator, however, lay in the fact that but two of the many movements of the mandible could be reproduced, viz, the lateral and the protrusive. Neither had Dr. Bonwill any certain means of transfer of the wax articulation from the mouth to the articulator.

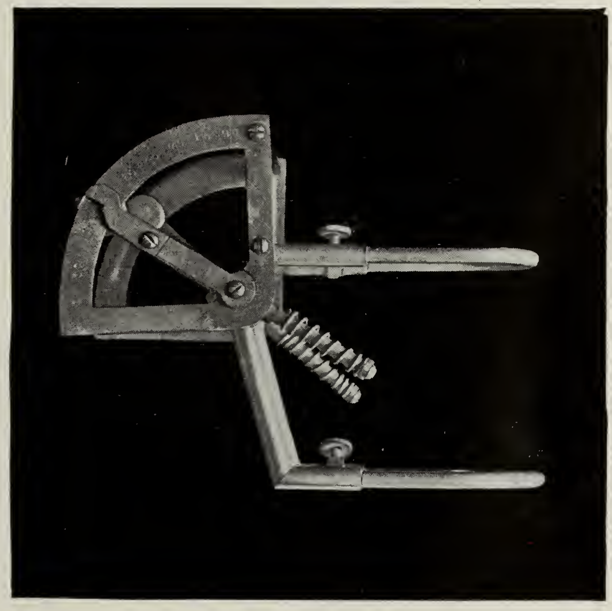
HAYES' ARTICULATOR AND ARTICULATING CALIPER.

This need was evidently impressed upon Dr. R. S. Hayes, who devised an articulator (Fig. 3) and a transfer apparatus which he termed an "articulating caliper." This resembles somewhat the "Snow face-bow" with which we are all familiar, in that it permitted the measurement of a given case, but it afforded no fixed transfer as does the Snow apparatus. Dr. Hayes also made an improvement in the manner of recording the condyle movement by providing a downward incline, which was the same upon both sides—a condition which in nature seldom, if ever, exists.

WALKER'S "FACIAL CLINOMETER."

It is most interesting to follow the trend of development as evidenced in the investigations of Dr. W. E. Walker in the early nineties. The fault in Dr. Hayes' articulator was eliminated by providing attachments to record the path of the condyle independently upon each side (Fig. 4). Dr. Walker's "facial clinometer," with which he computed the measurements and angles of rotation, was not of such a nature as to appeal to the average practitioner.

Fig. 4.



Walker's articulator.

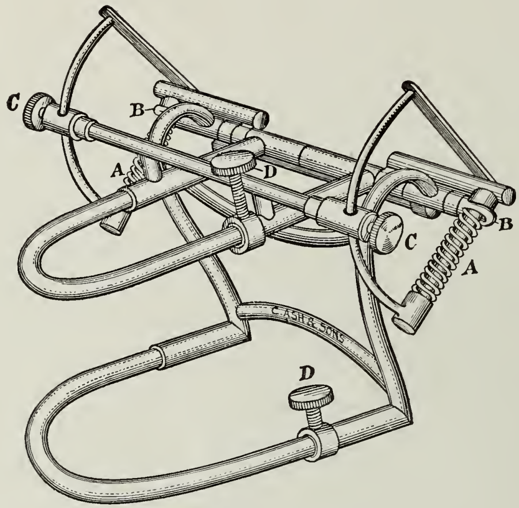
CHRISTENSEN'S ARTICULATOR.

Dr. Carl Christensen of Copenhagen followed this line of investigation, and by means of soft wax placed between the prepared bite waxes at the posterior region recorded the protrusive movement of the mandible. Like Dr. Walker's articulator, that of Dr. Christensen (Fig. 5) admitted of independent record of the condyle movement, but had no means of accurate transfer from the mouth to the articulator.

like its predecessors, however, it lacked means of mechanical transfer of the waxes.

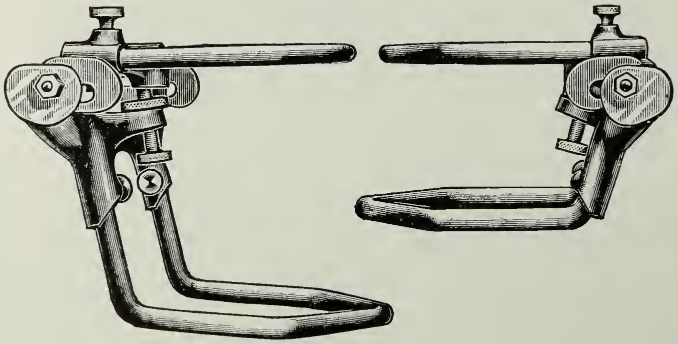
Upon this point of transfer really rested the crux of the greater part of the difficulty.

Fig. 5.



Christensen's articulator.

Fig. 6.



Gritman's articulator.

THE KERR ARTICULATOR.

The Kerr articulator contained a further development in that it provided for the record on each side of independent movement, by a condyle path permitting of a fixation at a desired angle;

GRITMAN'S ARTICULATOR.

This was thoroughly impressed upon the minds of Dr. Geo. B. Snow and Dr. A. D. Gritman, who collaborated at the University of Buffalo, Dr. Gritman producing an articulator which provided, by lateral extensions upon the condyle portion of the frame, for the attachment of the "face-bow" devised by Dr. Snow.

Fig. 7.

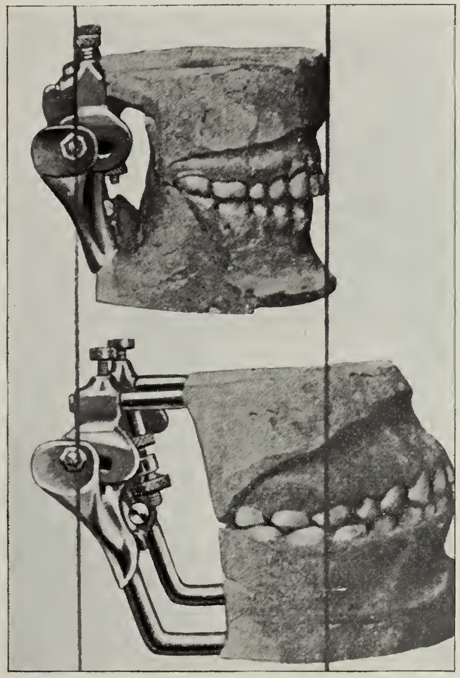


Fig. 8.

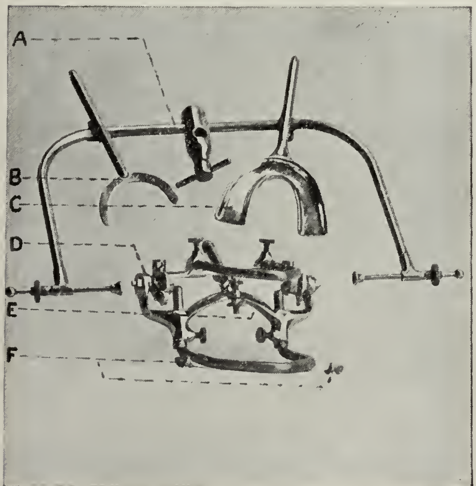

Dr. Gritman's articulator (Fig. 6) had many advantages not possessed by previous ones. The lower adjustable bow, constructed with an upright arm attachment, made it possible to adapt large or small models with equal ease. (Fig. 7.) The condyle paths were almost horizontal, having a very slight oblique slope, the same on both sides—fixed and immovable. This was corrected, in the subsequent articulator presented by Dr. Snow (Fig. 8), by paths movable and adjustable to a given position recorded by means of the "bite gages" (Fig. 9).

Fig. 9.

SNOW'S "FACE-BOW" AND "BITE-GAGES."

It is not my purpose in this paper to enter into the details of the preliminary steps of the preparation of bite waxes, nor of the arrangement of teeth made possible by the use of the anatomical articulator. It is wise, however, to note the essential points of difference, which have developed regarding the transfer of the bite waxes from the mouth to the articulator. Except for the somewhat indefinite methods used by those already referred to prior to Drs. Snow and Gritman, little had been done in this direction. Dr. Snow, in giving to the profession the "face-bow," bestowed an inestimable benefit, and I sincerely hope that we may be able to show to Dr. Snow, while he is yet active, how much we appreciate what he has done. The special virtue in the face-bow lies in its certainty of position due to the fixation of the various parts (Fig. 10). When the bite waxes have been fully developed as to adaptation of trial bases, fulness of contour, lip lines, etc., and the upper and lower waxes united, the fork is placed in the waxes with the bar portion extending in a line parallel with the base of the facial angle (Fig. 11). The face-bow is then adjusted to the bar by means of the clamp, and the adjustable condyle rods placed in apposition with the previously marked temporo-mandibular articulations. The graded marks upon the condyle rods make it possible to adjust

FIG. 10.

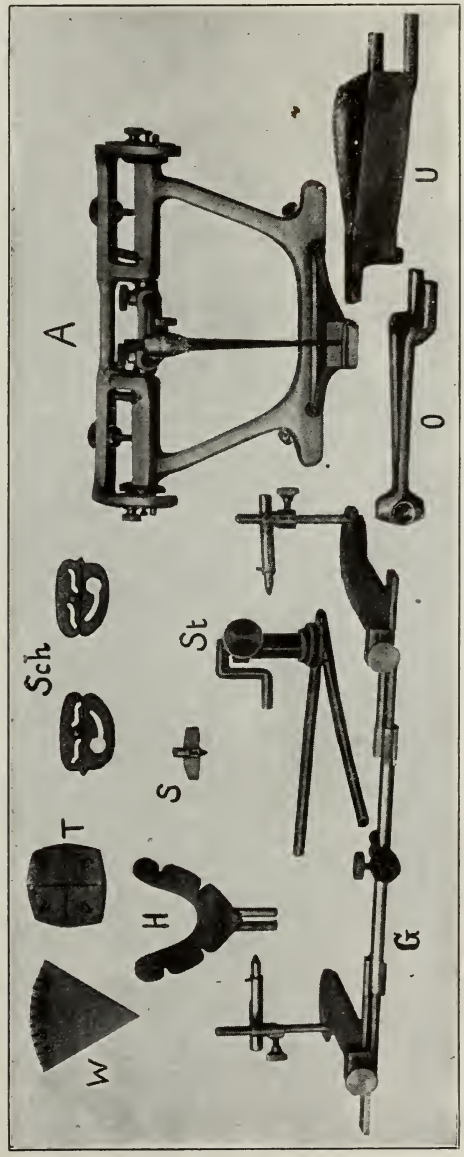
FIG. 11.

the bow equidistant upon each side, thus recording and fixing the condition thought out many years previously by Dr. Bonwill. With the clasp screw set the condyle rods may be loosened and the waxes withdrawn from the mouth. The rods are then placed as far as possible within the bow and set. In this position they fit snugly upon the projections intended for them. The models are then adjusted to position by means of the bite waxes. Care should be used to adjust them upon the articulator in such a position that the fork shall be parallel with the bench upon which rests the lower bow of the articulator. The models being secured by the plaster, the waxes, upper and lower, should be separated, reintroduced into the mouth, and, with the bite gages inserted at the posterior surface of the lower wax surface, the patient should protrude the mandible, allowing the projection on the upper surface of the bite gage to mark the position of the protrusion. The waxes are then replaced upon the articulator, and the set-screws securing the condyle paths released, as also the extension bar at the back. When the models have been approximated by the waxes with the bite gages in position, the inclination of movement on each side is recorded and set by means of the set-screws on each side. The extension spring bar is again hooked into position, the bite gages are removed, and the operator is ready to proceed with the certainty that the individual positions of the case have been correctly recorded upon the articulator, and that, if all subsequent operations be carefully carried forward, results will be relatively certain.

GYSI'S WORK ON THE PROBLEM OF ARTICULATION.

With the exception of Dr. Christensen, all the investigators I have mentioned have carried on their work in this country. There have been many others, however, on the other side of the Atlantic who have used their best endeavors to perfect apparatus to accomplish the desired end. Among these are Dr. Bennett of London, Dr. Breuer of Vienna, and Dr. Gysi of Zurich. The investigations of Dr. Gysi, published in the DENTAL COSMOS in its issues for

Fig. 12.



A, Articulator. *O*, *U*, Extra bows. *G*, Condyle path register. *H*, Horse-shoe plate. *Sch*, Extra pair of condyle path guides. *W*, Angle measure for condyle path slant. *T*, Type plate for molar groove. *St*, Holder for register *G* (to be used when plastering models to articulator).

January, February, March, and April, 1910, created a profound impression. The articulator which he devised (Figs. 12 and 13) seemed exceedingly complicated upon its first introduction, but, like many another apparatus, when understood lost much of its apparent intricacy. The improvement claimed for

Fig. 13.

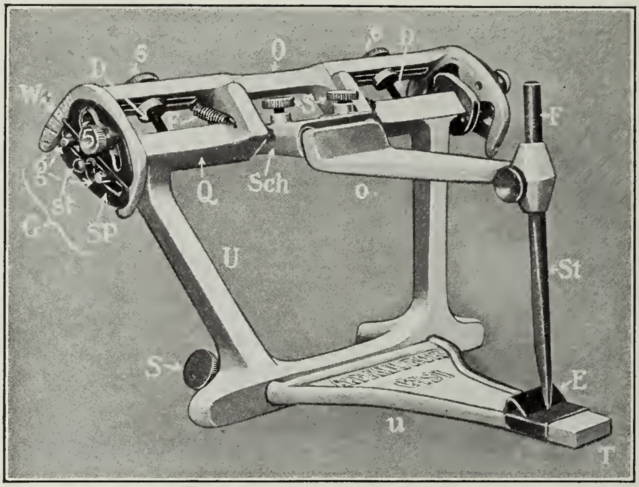


Fig. 14.

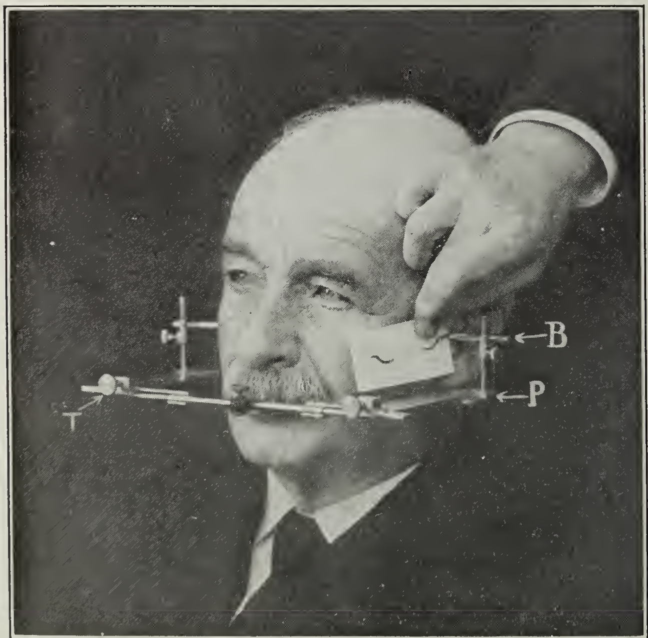
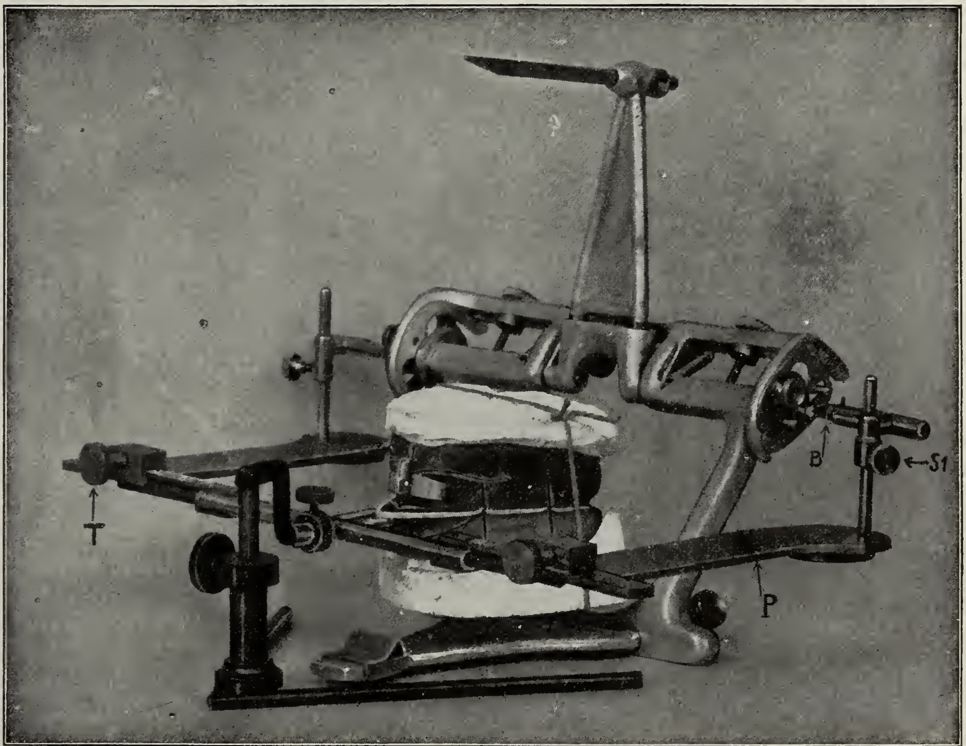


Shows method of determining slant and form of condyle path.

this articulator was its ability to record and transmit in the movement of the mandibular portion of the articulator the precise movement of the condyle upon each side. This was made possible by having selective condyle path plates, attachable to the articulator according to the requirements of the case. The condyle path register differs from the Snow face-bow in that the records of the movements of the mandible are made upon cards placed upon the face in the condyle region. The metallic mouthpiece, termed a horseshoe plate, for attachment to the bite waxes, has several sharp projections upon the under surface for securing it in the lower bite wax. The condyle path register consists of a transverse bar with right-angle arms, right and left, each carrying a graphite point contained in a tube operated by spring tension. The bow is attachable at the middle to the horseshoe plate. The positions of the condyles having been predetermined and marked by crayon, the graphite points on the transfer bow are adjusted to these points. A card is then interposed between the face and the graphite point, with the lower edge of the card parallel to the arm of the transfer bow. The mandible is then moved in all directions by the patient, right and left and up and down, with resultant marks upon the card. The records of both sides are taken upon the same card (Fig. 14). The records of many cases show what great variance exists in the paths of the condyles. No two cases are exactly alike and no two sides of any case are the same. The records obtained, the card is then carefully removed. The graphite

Fig. 15.



Shows models ready to be attached to articulator.

points are then securely fixed in position, the condyle path register with the waxes *in situ* is removed and prepared, by attachment to the holder (Fig. 15), for attachment by plaster to the articulator. The card record is used for obtaining the angle measure of the condyle movement. This is secured by the selection of a condyle path plate (Fig. 16), containing slots one of which will accurately include the line marked. Marks are made in the middle and at each end of the plate, and a line drawn through these will indicate the main line of direction of the condyle path passing through the end marks. By the use of the angle measure (Fig. 17) the degree is obtained. The condyle path plate is

Fig. 16.

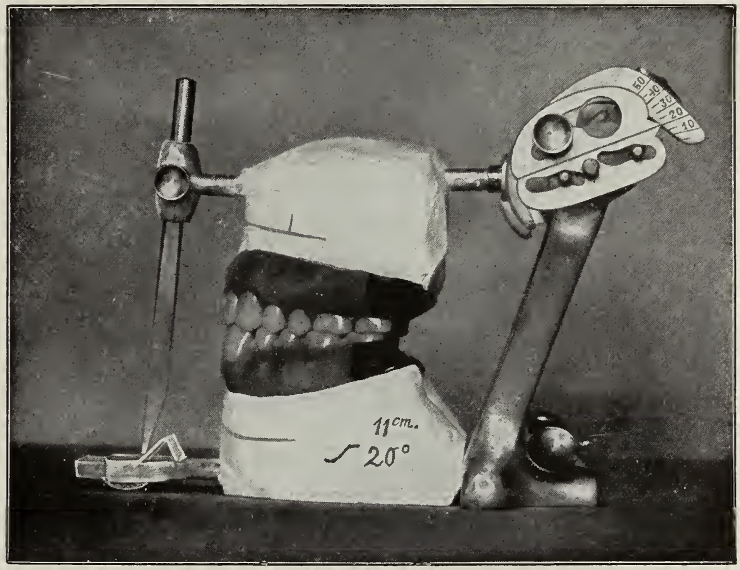
then adjusted to the articulator and set to the degree indicated upon the record —right and left side (Fig. 18).

Fig. 18.



Side view of articulator, with incisor guide.

Another unique feature of this articulator is the incisor bite guide. Provision for this is made by the placing upon the upper wax bite a small register (Fig. 19), consisting of a brass plate bent at an angle on each end for insertion into the wax. Upon the face of the plate is a tube containing a pin operated by a spring. With the horse-shoe plate in position, a film of dark wax the thickness of a sheet of paper is spread upon its upper surface. The patient then moves the mandible from right to left and protruding, for a few minutes, until a definite triangular outline is formed (Fig. 20). Marks are then made upon the upper wax at the

Fig. 19.

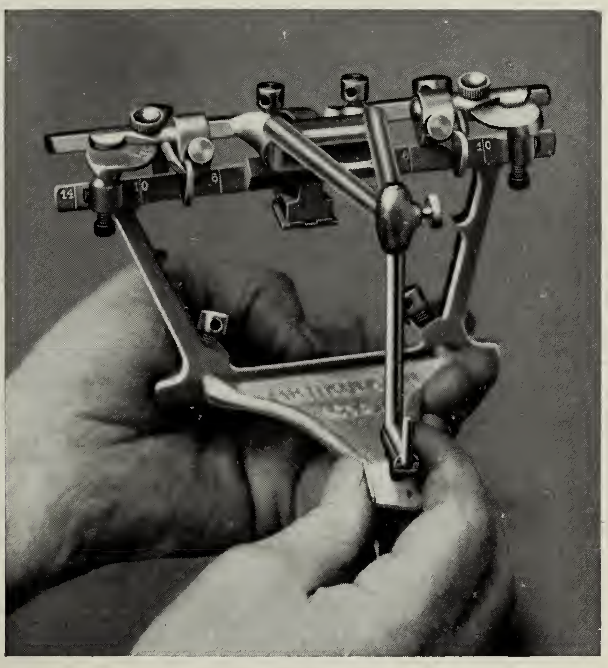
points of depression in the sides of the horseshoe plate to indicate the relative position of the upper and lower waxes. The wax bite plates are fastened to the casts and attached to the articulator by means of the condyle path register. The register is attached to the horseshoe plate and fastened to the holder, which permits of raising or lowering of the graphite points to approximate the point of the temporo-mandibular articulation. When the casts have been secured to the articulator, the register is removed, and with the horseshoe plate in position the two supporting pins are set to mark the limitations set by the marks made by the incisor guide (Fig. 21). These form, according to Dr. Gysi, the true rotation points in the mandible. The incisor guide pin, placed anteriorly to the casts, gives full support to the teeth in setting up (Fig. 13, St.).

FIG. 22.



GYSI'S "ADAPTABLE" ARTICULATOR.

Hardly had the profession been introduced to the Gysi articulator when two others, destined to supplant it, were offered. The Gysi "adaptable" articulator (Fig. 22) differs from the former articulator in that the selective condyle path plates are dispensed with, and both adaptable lateral and downward path plates are attached to the frame to be set according to the degree indicated by the instruments of transfer. The same procedure is followed as previously in obtaining the condyle path records, but in addition there is provided a lateral condyle path register (Fig. 23). This register consists of an adjustable bow carrying at each end a ground-glass plate. The condyle path register has a double-end graphite carrier, one end horizontal, as in the previous method, and the other end vertical for record upon the under surface of the glass plates, held at the region of the articulation. The degree of angle measurement on the card is registered by the adaptable downward path plate; the degree marked on the glass plate is registered on the adaptable lateral path.

GYSI'S "SIMPLEX" ARTICULATOR.

The latest articulator offered by Dr. Gysi is the "Simplex" (Fig. 24). This is a modification of the "adaptable" articulator, and to many of the profession seems to be a step backward. This is explained by Dr. Gysi, collaborating with Dr. Clapp, in the *Dental Digest.* On page 8 of the January 1913 issue Dr. Gysi says, "The Gysi 'Simplex' articulator will not satisfy the requirements of dentists who desire to meet in the best possible manner the requirements of each case." If it were Dr. Gysi's object to interest those who have never used an anatomical articulator and induce them by its adoption to pass on to something better, then its mission will not be fruitless. It offers many advantages which the early articulators lacked. It possesses many of the excellent features of the "adaptable" articulator, viz, the curved glenoid fossa, the condyle post, and the incisor guide. The articulation, however, is fixed at an angle of 33° forward and downward inclination, and 16° lateral inclination, and, contrary to all the later deductions, is made the same on both sides. This angle of 33° is explained by Dr. Gysi by saying that a large percentage of examined cases indicates a close approximation to this degree. The transfer of the bite waxes may be made by either the Gysi condyle path register or the Snow face-bow. In the latter case, small projections are placed upon the condyle posts (Fig. 25), to receive the depressions on the adjustable rods. The use of the transfer instruments, however, is not de-

Fig. 25.

manded in this method. Projections on the upper portions of the mandibular part of the articulator, on a plane with either a notch on the incisor guide pin or an adjustable incisor guide placed in the position of the notch, mark the occlusal plane.

THE WEISS ARTICULATOR.

In the productions of Dr. Gysi the ultimatum in apparatus seems to have been reached. To say, however, that the last word regarding the solution of articulating problems had been said would be most unwise, for there are those who are still delving into the unsolved, the results of whose labors are still to be recorded. About two years ago, Dr. Weiss of Havana presented before several societies in Europe an articulator whose construction and basic principles radically differ from any other in existence. The maxillary portion is fixed upon a standard and fastened securely to the bench. All movements are produced by the mandibular portion—thus mechanically reproducing, as far as possible, natural conditions. Those who have seen its operation and the results obtained by it have been most enthusiastic about its possibilities. Unfortunately there is no specimen of the articulator in this country, as far as I am aware, nor any illustration which I am able to present to you.

Fig. 26.

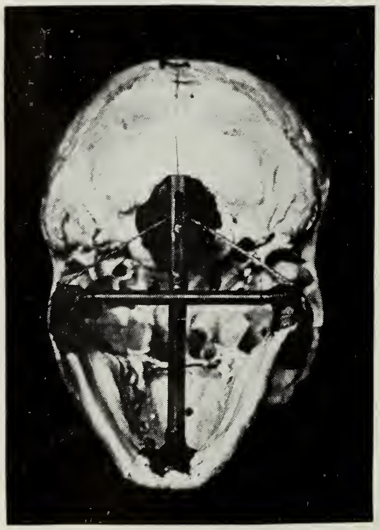

Fig. 27.

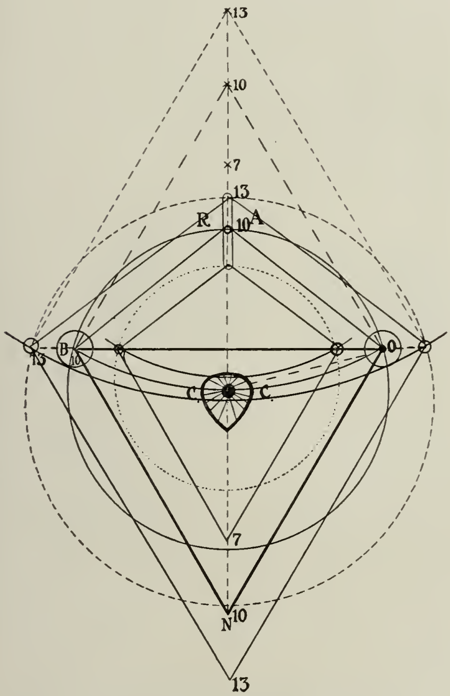
SCHWEITZER'S PROJECTED ARTICULATOR.

For many years one of my valued associates at the New York College of Dentistry, Dr. H. Schweitzer, has been investigating this subject of articulation, and has devised an articulator which also differs radically from all others, in that the rotation point of the mandible is placed at the position of the vertebral axis. This conclusion was reached after the examination of many hundred articulated skulls, and, as can be seen by these specimens (Figs. 26 and 27), applies to animal as well as human skulls. The movements of the mandible, as all investigators have found, have been so difficult to control that if it were possible to obtain an instrument which would furnish a fixed rotation point, much would be gained. Dr. Schweitzer has endeavored to geometrically prove his contention by constructing a double "Bonwill triangle" (Fig. 28), showing calculations upon three sizes of arches, 7, 10, and 13 cm. respectively. These triangles are constructed with a common base. Using the apex of the occipital triangle as a radiating point, he in-

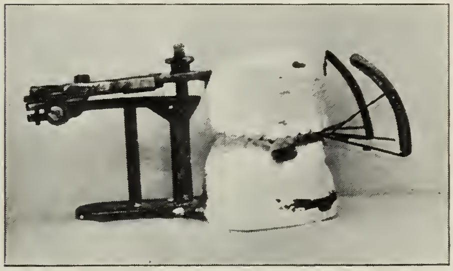
FIG. 28.



The rotation axis of the mandible.

scribed an arc through the condyle points. Bisecting this arc by a line bisecting the two triangles, the points of intersection furnished the centers of circles which when projected *were found in every case to pass through the center of the foramen magnum*—the position of the vertebral axis. Basing his deductions upon these facts, he constructed an articulator (Fig. 29), having a fixed point in the region of the vertebral axis, adjustable by face-bow to the requirements of a given case. The bite relations are registered by an incisor path guide and a molar path guide. While this articulator is still in a somewhat unfinished stage, the projected articulator will certainly offer some unique features to apply to the practical restoration of teeth in their true anatomical relation.

FIG. 29.



CONCLUSION.

My object in this *résumé* has been twofold: First, to show how much labor has already been expended upon a most important part of our work; and second, to stimulate, if possible, the interest of the practitioner who is still holding to the use of the plain-hinge articulator.

The work in this direction which is to-day required of the undergraduate in all the colleges of the land will, we trust, in a few years begin to bear fruit. So many operations are dependent upon proper articulation that the edentulous case bears but its proportionate share in the consideration of the subject. The efficiency of our bridge work and our partial dentures depends largely upon the provision we have made for proper resistance of stress, and this can be best provided for by the use of an articulator which, during the procedures of construction of the denture, will show the various conditions which the restoration must meet. If this paper shall have aroused interest in even a few of my hearers, then the effort will not have been in vain.

A MOLDED PORCELAIN-CEMENT INLAY.

By J. EDWARD LINE, D.D.S., Rochester, N. Y.

CEMENT of the so-called porcelain variety is packed into the cavity in plastic condition by means of suitably formed pluggers and spatulas, and shaped, as with a trowel, to restore the contour of the tooth. This means very careful preparation, viz, the forming of the cavity, the adjustment of the rubber dam and drying of the cavity, the incorporation of the correct quantity of powder in the correct quantity of liquid, the thorough spatulation of the mass, and the introduction and contouring of this mass before the initial setting. Further conditions of success are the following: First, an eye to form and color on the part of the operator; second, manipulative ability that measures up to the requirements of the eye in question and makes plasticity effective within the time limit imposed by the nature of the cement. Operations that compare favorably with the fused porcelain inlay are not uncommon with operators who have made a specialty of this phase of dentistry; they have demonstrated conclusively the possibilities of porcelain cement in competent hands.

In order to attain the same, a similar, or better result, in a more leisurely manner, while at the same time eliminating some of the features involved in the method described, we have to substitute an only slightly different treatment of the material and a few mechanical appliances, viz—a brass flask (Figs. 1 and 2), in two parts and separable, with guide pins in one half and holes to correspond in the other, the approximate surfaces coned out to accommodate the pattern and investment, and each half topped by a lug or trunnion (A) that fits loosely into a hole (B) in the end of the jaw of a pair of parallel pliers (Fig. 2); and a pair of pliers of the kind just mentioned.

FIG. 1.

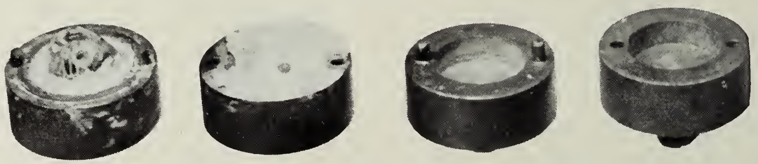


FIG. 2.

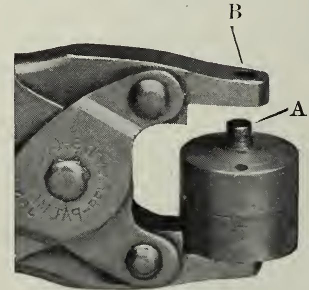

DETAILS OF PROCEDURE.

The procedure consists in—

(1) The preparation of the cavity as for an inlay of any kind—viz, made of gold, some other metal, or porcelain.

(2) The building of a wax model as

for a metal inlay, except that acute angles are not permissible.

(3) The coating of the model with oil, or copal or sandarac varnish.

(4) The coating of the interior of the flask with a thin layer of wax, to prevent or reduce to a minimum the adhesion of the investment. Warming the flask facilitates the flow of the wax, and effects its spread in the thinnest possible layer. Warming also aids materially in the release of the investment when the flask is opened.

(5) The investment of the wax model or pattern in plaster in one half of the flask, and, when the plaster has set, adjusting the other half of the flask, previously filled with soft plaster, bringing the two parts of the flask together by pressure applied by finger and thumb, or by means of the pliers described above. Care should be taken to provide for the separation of the parts without distorting the pattern or breaking the edges of the mold. In other words, the pattern should be invested in such manner that it will "draw" freely from each half of the mold.

(6) The flask should be warmed, opened, and the wax washed out by means of hot water poured from a dish at an elevation, as in the preparation of a mold in vulcanite work; then the mold should be given time to dry.

(7) The mold is painted with copal or sandarac varnish, and lined with No. 2 gold foil in order to produce a particularly dense surface.

(8) Each half of the mold is filled to excess with a so-called porcelain cement mixed and worked to such plasticity as is advised by the manufacturer.

(9) The lugs or trunnions of the flask are adjusted to the corresponding holes in the pliers, pressure is gradually applied until the parts of the flask have been brought together, and the flask is allowed to stand for the prescribed twenty minutes, or until the operator is ready to adjust the inlay to place. Twenty minutes is the minimum time prescribed in the directions that accompany porcelain cements; but, when allowed to set twice or thrice twenty minutes, or longer, a more lasting product is obtained. If the inlay is allowed to set over night, it becomes as hard as flint and correspondingly durable.

(10) The flask is opened, the inlay removed, the "bur" trimmed off by means of stones or sandpaper disks, the cavity sides are roughened, both inlay and cavity are dried, and the inlay is set with oxyphosphate cement, and trimmed and polished later in the usual way and by the same means.

ADVANTAGES.

By this method several cavities may be prepared at one sitting and wax models made thereof. The fillings may be made at the operator's convenience in the laboratory. They may be set one after another at the next appointment, and without the rubber dam—a feature that will commend itself in the filling of posterior teeth, for which the molded cement inlay is particularly adapted. The method generally in vogue necessitates the presence of the patient and the use of the dam from beginning to end; the method under consideration does not require the presence of the patient while the filling is being made, nor does it call for the rubber dam at any time.

CAN THE ILLEGAL PRACTICE OF DENTISTRY BE LIMITED BY LAW?

By R. OTTOLENGUI, M.D.S., LL.D., D.D.S., New York, N. Y.

(Read before the Dental Society of the State of New York, Albany, May 8, 1913.)

I BRING before you one of the most serious problems which confront the dental profession of this entire country, and one the solution of which is peculiarly difficult in our own state. In choosing my title, I had first in mind to ask, "Can the illegal practice of dentistry be *eliminated* by law?" but it occurred to me that, up to the present era, with all the laws that have been passed by all the countries in the world, the offender against the law has never been eliminated, so that the query seemed futile. For "eliminated" I then thought of substituting the word "controlled," but this in turn I set aside, because the control of that which in itself is offensive really means the toleration of it, as when the municipality licenses a liquor saloon. It has seemed to me, then, that the best that any law may accomplish would be the reduction of the number of offenses to the minimum, by rendering detection easy and by making punishment sure and swift. In this sense I ask, "Can the Illegal Practice of Dentistry be Limited by Law?" and I unhesitatingly answer, "Yes, it can!"

We have before us, then, the question of the limiting of the total number of illegal practitioners of dentistry to the minimum, and if we look upon illegal practice as an ulcer on the body politic we may think of it as a disease and consider for a moment the etiology thereof, for without a comprehension of etiology we shall never discover the cure of any disease.

THE ILLEGAL PRACTITIONER THE PRODUCT OF THE LAW.

The illegal practitioner is primarily the product of the law. Secondarily, he is the result of both laxity of law and lack of law. I may explain this statement very briefly. Before we had any dental statutes we had but two kinds of dentists—the ethical man and the quack. When the states began to enact dental laws the situation became complicated, because at once we literally created the illegal practitioner—for were there no law regulating the practice of dentistry, there surely could be no illegal practitioner. Furthermore, the complexity is increased when we consider that nowadays it does not follow that, because a man is practicing illegally, he is a quack, nor can we call all the charlatans illegal men. Some of the grossest offenders against the code are nevertheless legal practitioners—and to this extent at least the laws have injured the people, by giving countenance and legal standing to men who, in the absence of laws, would be readily recognized as quacks. I make this point at the outset because I desire to have it distinctly understood that I am in no sense studying this problem from the angle of ethics. In this paper I recognize the legal right of any licensed dentist to advertise if he chooses to conduct his practice in defiance of ethics and good taste. The man aimed at is solely and only the man who practices in defiance of the law, and it matters not whether he conduct his practice ethically or unethically, he is an offender in the eyes of the law, and as such cannot consistently rise and say that he is mistreated in this argument.

I have shown that the illegal man is the direct result of enacting laws, and I have said that he has increased in numbers because of laxity in law and because of lack of law. By *laxity in law*

I mean laws which, however well intended they may be, are ineffectual either because they are not or because they cannot be enforced. The law of this state is in this class. By *lack of law* I mean laws which permit things which should be prohibited. For example, the New York statute describes so-called mechanical dentistry, and permits the unlicensed man to practice that particular brand of dentistry. By this lack of law we have countenanced the laboratory in which is trained and from which is graduated, without diploma, the illegal dentist. This particular phase of the problem is one to which I merely allude, as it is not my intention in this paper to really discuss the laboratory man, or mechanical man, at all, further than to suggest that it is a problem in itself that well might be investigated by our Board of Regents, with the end in view that some just, proper, and effective statute regulating the practice of "mechanical dentistry" might be enacted. By effective, I mean that the statute should be effective in terminating the existence of these unlicensed schools of dentistry from which are turned out a steady stream of unlicensed dentists.

THE OBJECT OF DENTAL LAWS.

Before the discussion of any dental law, we should fully agree as to the object which the law is to serve, and I am sure that many statutes have proved ineffectual because drawn by men who did not have the true object in view. A dental law must obey the rule of all laws, which means that it should be enacted in the interest of the whole people, and not for the benefit of either the individual or any class of individuals. Thus the statute should not be intended to improve the status of the dentist, of the dental society, or of the dental school. On the contrary, if it be in the interest of the people at large, the law should unhesitatingly restrict the conduct of the dentist, the conduct of the dental society, and the conduct of the dental college.

With this purpose in mind, let us ask why it is requisite to protect the community against the dentist.

INTEREST OF THE COMMUNITY IN DENTAL LAWS.

To bring my argument to a point which can be quickly grasped by even the slowest mind, I will first compare the community at large to an automobile. Anyone who has ever seen an automobile completely dismembered knows that it is a marvelously complex mechanism, with a multitude of ingeniously constructed parts, so assembled that when all are in order we have harmonious co-ordination which results in the perfect working of a perfect machine; a machine that responds readily and promptly to all calls; that will travel fast or slow, up-hill or down-hill, and turn easily for every deflection in its course. Even the man who has never seen a machine taken apart, knows this in a general way—that an automobile must be in thorough order to render the highest service. We all recognize, therefore, that the slightest disarrangement of parts must interfere with the wonderful co-ordination of all the other parts—and to that extent, at least, efficiency is proportionately lessened. But we know another thing, and that is that a trifling accident, such as the loosening of a nut, if neglected, may result in a stoppage of the whole works, or at least may transmit damage to a more important part.

A perfect working community is composed of a similar co-ordination of numerous units all working for and aiding the work of one another. The harmonious working of all these units depends, of course, upon many factors, but the chief factor of all is *health,* and any disturbance of the health of the community causes a proportionate lessening of its efficiency—a depreciation of output. It might seem hard to show that the sickness of a single individual can be a matter of much concern to the whole community, but really it is not so difficult. A number of cases of scarlet fever occurring in a school frequently causes the closing of the school—and this outbreak must have originated in the illness of one child. Thus, perhaps, the education of a thousand or more children is temporarily stopped; the presence of these young people at home instead of at school disrupts the family routine by adding to the burdens of the parents, and this in turn may greatly interfere with the business interests of persons far removed from the original cause of disturbance. I could give many examples, but this one will serve: A man recovering from typhoid fever, about three years ago, was permitted to return to work in a dairy in New Jersey, and within a brief period there was an outbreak of typhoid on Washington Heights, New York city, which resulted in the death of two or three persons and the illness of a score. Thus the health or illness of one man was a matter of concern to a community in a different state.

I need not argue before this body of dentists that the condition of the teeth of a man bears a close relation to the man's health. But I wish now to compare the individual to the same automobile to which we likened the community. Like that wonderful machine, he is composed of hundreds of co-ordinating parts which produce the highest efficiency only when a state of health exists. A speck of dirt in a carburetor pipe may stop the best six-cylinder car from climbing a hill, and a piece of poorly masticated food may clog the digestive apparatus of a man and terminate his work in a quite similar manner.

Perfect health of the individual depends primarily upon the proper mastication of food, and secondarily upon the proper assimilation of food. The slightest accident to this masticating apparatus, as for example the loss of a cusp of a single tooth, lessens the efficiency of the entire body proportionately. But the neglect of caries in teeth often results in a diseased condition of the tooth roots, which if not cured causes a continuous contamination of the body itself, interfering with food assimilation and materially lessening the power of the body to resist infectious diseases. Thus in quick sequence we may have—First, tooth decay; second, exposure and death of the pulp; third, infection of the pulp and apical disease. If this be neglected, or what is just as vital to the community, if this be improperly treated or be left untreated by the dental attendant, then may follow—fourth, a continued draining into the system of infectious material; fifth, a lowering of the vital resistance of the body; sixth, the acquirement of some infectious disease, such as scarlet fever; seventh, the infection of other individuals, resulting in the closing of a school, the closing of a factory, the death of persons important in the business world, etc.

For these and allied reasons, the community has a right to pass laws which shall determine whether a man is sufficiently skilled in dentistry to be given a license to practice.

INEFFICIENCY OF PRESENT LAW OF NEW YORK.

Having shown that the community has a right to pass a law regulating the practice of dentistry, before we may logically ask for a change in the existing laws we should show that the existing laws are ineffectual. This is so abundantly true of the New York statute that there is scarcely an argument against the present law that I can advance that is not well known to all of you. However, I must point out at least the most flagrant flaws.

The chief difficulty is that the law does not provide any adequate means for its enforcement. The discovery and prosecution of illegal practitioners is placed in the care of this society. This is a compliment to the society, but is a gross injustice to the citizens of this state. The prevention of the illegal practice of dentistry should be one of the most sacred duties of a state to its people, and yet we find this Empire State of the great United States of America satisfied to free itself of this duty by turning it over to a private society, whose members have neither the time nor the money to properly safeguard the health of the people.

In other departments of police work we find regularly organized corps of efficient men, all receiving salaries, and with moneys provided for the expense of apprehending offenders against the law. But in this exceedingly vital department, the New York State Society is asked to furnish out of its own pocket the moneys needed for apprehending the offender, securing the evidence against him, and even for supplying the attorneys for prosecuting him. In case of conviction and fine, the fine is paid back to the State Society, and this is a double wrong. It is wrong, first, because the remuneration of the policeman should not depend upon the conviction of the man arrested, since this is bound to bring about an injustice either to the prisoner or to the prosecutor. It is wrong because, since the pay of the policeman, the witnesses, and the prosecuting attorney must depend upon the moneys collected in fines, it is a natural consequence that the appeal to the judge will be for a fine, when all arguments should be for the imprisonment of the convict. As an example, in the Second district we secured a fine of $500 against an illegal man, who smilingly drew out his check-book, settled with the court, and jumping into his big limousine, hurried down town to superintend the opening of a new office. The imprisonment of ten such men will better serve the people at large than the collection of ten thousand dollars in fines.

As the law has stood for years, and as it would still stand even if the amendments recently pending before our legislature had been passed, this society must have charge of this work and must furnish a committee to superintend it, which committee must give its services free. Why should our members work for the state free? Does the governor work without salary? Do the assemblymen and senators who make these laws, give their services gratis? Dr. Wm. Carr has rendered such service to this society and to this state for years, without very much thanks from either the society or the state. This is very honorable conduct on the part of Dr. Carr, but it is not so very honorable on the part of the society or the state to accept such service. For not only must Dr. Carr, and other members of the law committee, do this work at great sacrifice of time and money, and without remuneration, but they find themselves actually in a position of receiving threats on the one hand, and of suspicion on the other. I do not know about Dr. Carr, but Drs. Rogers and Johnson, who have done similar work in the Second district, have not only received many threatening letters themselves but similar letters have been sent to the women of their households.

"GRAFT" AND PROTECTION OF UNLICENSED DENTISTS.

Let me explain what I mean by suspicion. New York state, and particularly New York city, is fairly riddled with what is called "graft." The most lucrative form of graft is the exaction of monthly payments for the privilege of doing an illegal act without police interference. The collection of such money is usually made by some person in a very subordinate position, and he invariably explains that he is only acting for "a man higher up." This "man higher up" is a convenient cloak for the actual receiver, and the ingenuity of the scheme lies in the fact that it is never explained how much higher up the money actually goes. The limitation is left to the imagination of each person studying the problem. Thus, if you choose, you may decide that it goes no higher than the ward man; or you may believe that the captain gets a slice of the graft cake, with perhaps a bit of the frosting going to the inspector, and some of the filling to the commissioner. Then there are others who believe that some cakes are delivered uncut to party bosses, or even higher.

This is the sort of position that this society is asking its honorable members to occupy, when electing them to membership on our law committee. It is common belief in New York city that illegal men are promised immunity, protection, and even non-arrest, in exchange for a definite sum paid monthly. Dr. Carr does not believe that any such systematic blackmail exists. Some men are so highminded and honest themselves that they cannot believe that other men can be dishonest. But Dr. Carr is almost the only man in New York city who has at all studied this matter and still believes that graft does not exist. I am sure that both Dr. Johnson, the present law-committee man of the Second district, and Dr. Rogers his predecessor, will testify that graft exists in their district. For this reason Dr. Rogers has refused to serve longer, and Dr. Johnson has asked to be relieved.

Of course it is always difficult to prove the existence of grafting, though just at present enough of the truth is coming out to satisfy us all that the rumors of the past, even though no legal evidence existed, were founded on facts. So it is in the dental situation; I cannot give you legal proof, but I can tell you of the present system, and give you the rates. Formerly the charge for an individual illegal dentist was ten dollars per month, and each man settled with "the man lower down," the blackmail collector; by the way, sometimes "the man lower down" is a woman. At present there is an association, the members of which are assured protection at twenty dollars per month, the fee for having an unlicensed assistant being five dollars per month. Just how this immunity is obtained and to whom the money is paid, it is less easy than ever to discover. But this is the condition which is said to exist; perhaps it does, and perhaps it does not. The point of interest to us is that we are not and cannot be certain that it does not exist, because such is our law that it is possible—which is quite sufficient reason why we should make a new law that would render the continuance of such conditions as nearly impossible as we may.

Now I have that to say which I cannot say with too much emphasis. I myself am somewhat like Dr. Carr; I take an optimistic view of my fellows. I do not believe that all men are dishonest till proved honest; I prefer to think a man honest till proved otherwise. Hence I never have believed much in this mythical "man higher up." I have never thought of this straw man as anything but a cloak for the real crooks. Consequently, I do not believe there is any such person in the dental situation, but I do believe that our law is such that we are compelled to rely too much upon agents who are sufficiently unscrupulous to blackmail illegal men, taking money from them, and whispering as they take it, "Of course this goes higher up."

I have been asked, "How can this be, when the immunity is actually delivered?" The answer is simple. The members of our law committee are compelled to rely upon attorneys, and they in turn must leave the collection of evidence and the arrests largely to the work of agents. There is very little money in these cases for our attorneys, none at all for our law committee, and it is not strange that the real work should be left to the agents and sub-agents.

But, gentlemen of the New York State Dental Society, the situation has become intolerable. We have no longer the right to ask men to work on our law committee in the presence of such conditions. If this society has any self-respect, if it has any conscience, if it has any sense of its duty to the people, we should, before we adjourn, pass a resolution notifying the governor of this state that one year from date we will terminate our contract, and abandon this police work. We should notify this state that it may either leave our people unprotected prey to the illegal and incompetent dentists, or else place upon the statute a law which will adequately meet the situation. Can such a law be framed? It can!

THE ADEQUATE LAW.

That the limiting of illegal practice of dentistry is not easily accomplished is indicated by the fact that no law yet passed in any state has proved entirely satisfactory, nor has any law long remained unaltered, which shows a constant admission of inadequacy in the statute altered. But the later and apparently the better laws have certain features conspicuously present. The chief of these are—1. That the state shall prosecute offenders. 2. That all dentists shall register annually. For a solution of the difficulties in this state I would suggest that a committee should be appointed to frame a new statute which shall contain the following main features:

First: The illegal dentist being an offender against the health interests of the state, his prosecution should be placed in the care of the board of health. I make this suggestion because I have been informed that the boards of health may prosecute without appeal to county prosecutors. If this be not true, then my plan would be that the detection of the illegal man should be given into the care of the board of health, and the prosecution left to the county officers. When I refer to the board of health I touch upon a subject which will require some study. I would prefer that in large cities the work should be in the care of the local board of health, but as there are no local boards in suburban districts, it will be necessary to include the state board of health in this work in some manner. Perhaps the state may be divided as at present into judicial districts, and where there is a large municipal health board, as in New York city, that district might be cared for by the health board there. These boards of health should provide a sufficient number of inspectors to constantly investigate infractions which might be reported. If necessary these may be exclusively dental inspectors, or it may be possible to add this work to the duties of men already on the city pay-roll. But these men should be city servants and not private agents, as at present.

Second: ANNUAL REGISTRATION. Every dentist in this state, now practicing and hereafter entering practice, should be compelled to register annually, and his right to such registration should be the exhibition of his state board license, with proof that such license had been issued to him and to none other. False registration should be severely punished by a heavy fine or imprisonment, or preferably both. A fee of one dollar should be collected for each annual registration. Failure to register prior to a specified date should subject the dentist to a fine of one dollar for every thirty days of delay. Other states have adopted annual registration with advantage, but I believe that an improved plan of registration would greatly increase the effectiveness of the law, while decreasing the chance for evasion and the levying of blackmail. My idea is that while the supervision of the practice of dentistry should be in the care of the health board, the registration should be in the care of the board of examiners. This board issues the license to practice in the first place, and should care for the registration. They would be better qualified to prevent false registration, and moreover would serve as a foil against possible blackmail by the health board inspectors. One member of the board of examiners therefore, possibly the secretary, should have added to his duties the care of this registration, and perhaps might best be called the dental registrar. This man should have a salary, and all demands for money involved in the expense of prosecuting illegal men should be vouched for by him and should be paid upon such voucher by our State Society treasurer. To this extent, and to this extent only, should the State Society continue in this work. All registration fees, examination fees, and all fines, should be paid into a special prosecution fund, and this fund should be administered by this society as a further preventive against wrongdoing.

The most important part of this registration plan I have yet to outline. Once annually, at a given date, the list of men registered should be published in pamphlet form. This list should likewise contain a list of those who have died, and, as all deaths must be reported to the health board, this dead-men's list should be easily compiled, and thus many "dead men" now practicing dentistry would be compelled to return to their graves and attend to their own private affairs.

Each of these registration pamphlets should be sent to all registered men, and should contain, conspicuously printed on the first page, an invitation to all registered men to report to the registrar the names of any men known to be practicing dentistry whose names fail to appear in the Register. Such an invitation would remove all doubt of the legal right of a practitioner to lodge information against an illegal man, but, better still, the informer would not be making any accusation against the legal status of the other man. He would simply be reporting a fact, as for example "J. R. Smith is practicing dentistry, at ——— number, ——— street, and his name is not in the Register." Moreover, such information should be received as a confidential communication, just as at present a tenant in an apartment house may report that the plumbing in his apartment is not in order. Upon receipt of such notice, a health board inspector calls and inspects all apartments, thus protecting the informer. Upon report of the existence of an unregistered dentist, the dental registrar will report to the board of health, upon which the dental inspector will call. If the man can show a license, he is served with an order to register within thirty days, the fee being the legal one dollar, plus one dollar for every thirty days which had elapsed since he should have registered. Failure to register after receiving such notice should render the man subject to citation before the board of examiners, who may either fine him and permit him to register, or recommend him to the Regents for revocation of license.

I believe that such a law would greatly reduce the chances of practicing illegally, and would furnish at one and the same time both the machinery and the money needed for limiting the illegal practice of dentistry. I am prepared to present further argument if needed.

DEFINITION OF DENTISTRY.

We have seen the course to be pursued when the dental inspector calls upon a licensed man who has failed to register. We have now to consider his course when he enters the place of a man who cannot show a license for himself or for his assistants. It must be the legal right of the dental inspector to demand the exhibition of a man's license, failing which he should be liable to immediate arrest. At present the burden of proving that a man arrested has actually practiced dentistry lies with the prosecution, and the law has so protected the accused with technicalities, and judges are so little conscious of the seriousness of the offense, that it is most difficult to convict the first time, and well-nigh impossible to convict of a second offense. This is so true that a large proportion of the men who have been convicted, and so reported to this society, are still in practice; and it is this glaring fact that leads men to believe that these men who have once been convicted, who have not since qualified legally, and yet who are still in practice, must in some way be receiving immunity by the payment of graft. This is not legal evidence, but it is ground for a very logical suspicion.

It follows, therefore, that in some way these technical protections must be removed. I believe the remedy may be found in a definition of "legal practice of dentistry," in such terms that even the presence of a man in a room where there is a dental outfit would suffice for his arrest, the burden of explanation of his presence and his need of such an outfit being upon him. The definition of dentistry proposed in the law recently before the legislature is a great improvement upon any that we have heretofore had, but by studying all the definitions in the statutes of other states, I am sure that even this may be improved. The law should be so worded that a real offender may be easily arrested and convicted, and I am sure this can be done. If not, then it follows that the illegal men have more brains than the legal men.

REVOCATION OF LICENSE.

But our law should not stop with an attack upon the illegal practitioner. We need more drastic treatment of the legal man who employs, safeguards, and trains the illegal man. We already have in our law a rule that such men are liable to have their licenses revoked, yet I am credibly informed that only two such revocations have occurred, notwithstanding the fact that often in court the legal man comes forward and testifies that he is the employer of the accused. The remedy for this is a more rigid enforcement of this revocation clause. If ten or twenty licenses were revoked because of the employment of unlicensed assistants, there is no doubt that practitioners would be less willing to hire these men —saving a few dollars at the risk of losing their licenses.

THE CONDUCT OF DISTRICT SOCIETIES.

I have said that the conduct of societies is rightfully a matter for legal restriction. A fatally erroneous idea now prevails in our district societies to the effect that they are private dental clubs with social rights. Such is not the case, and should not be the case. If any of us desire to form dental societies for special purposes, and with social distinctions, it is our legal right to do this. But the highest duty of the district society should be, not to erect a barrier of ethics to keep men out of membership; the barrier should operate only to keep men in. In other words, a great service may be rendered to the people if we would throw open our doors to all legal practitioners, because all legal practitioners should have the advantage which the district society should afford in providing post-graduate teaching both in practice and conduct. Thus we should only ask the applicant for membership, "Are you a legal practitioner?" If he be, he should be permitted to enter. Having once signed the by-laws, however, he should be compelled to abide by them. Our committees on ethics should cease to be ornamental appendages to our stationery. They should comprehend that they have a real duty to perform. Let us suppose that each society member could have a printed certificate of membership which he could hang in his waiting-room, and which could serve as an announcement to his clients that he is not only a legal practitioner, but an ethical practitioner. Then suppose that a member were proved guilty of an infraction, his membership suspended or revoked, and his certificate taken away from him. Would not such a certificate be a business asset as well as a moral aid to a better conduct of the man's practice? I think so. Moreover, I think that in the past our state and district societies have not been sufficiently awakened to their duties. Let us, with the contemplated reorganization, arouse ourselves from this lethargy, and let us extend the hand of fellowship and brotherly love to our neighbors, and let us say in a Christian spirit, "Come thou and abide with me, that we all may be better men, better citizens, better dentists."

PYORRHETIC INSTRUMENTATION.

By WM. CRENSHAW, D.D.S., Atlanta, Ga.

(Read before the Piedmont Dental Society, Anderson, S. C., November 25, 1912.)

IF one should get together the various forms of pyorrhetic instruments on the market today, certainly the exhibit would—to the uninitiated, certainly—seem to constitute an ample armamentarium. Indeed, as to multiplicity of instruments the real need has been far exceeded. While many are capable of doing good service—particularly in their originators' hands—yet the various patterns, forms, and sets in vogue have proved the interest of the stomatologist in the malady which he treats rather than furnished efficient surgical means for the work.

INSTRUMENTS WITH CUTTING EDGE OBJECTIONABLE.

The writer is prompted to offer this paper in the hope of pointing out some dangers resulting from the use of improperly designed instruments, with reference particularly to the essential feature of the instrument, its working point—instead of its cutting edge, for except for very limited application in special cases pyorrhetic instruments should not have a cutting edge, *i.e.* an edge that cuts into the cementum or other tooth structure with which we deal in treating this disease. The writer is aware that some stomatologists in the surgical treatment of pyorrhea prefer to plane the roots, in order to remove the cementum to a depth that will remove the embedded spores which penetrate, as has been claimed, into the depressions and canals of the cementum that were once occupied by the prolongations of the pericementum. But this practice has not been successful, according to the observation of the writer at least, and he therefore bases his judgment on the idea that the cementum should not be planed, but only freed from calculus deposits or fragments of necrotic pericementum, and otherwise cleansed and left as smooth as may be.

If it is necessary to leave pyorrhetic roots smooth and unirritating to the gum tissue which is to readapt itself to the root, then the instrument with beveled or sharp edge should not be used, because of the ease with which it cuts into the cementum, leaving pits and nicks difficult to smooth out, and therefore unfavorable for gum adaptation. More harm is done with beveled instruments, therefore, which are sharp, than with those that are essentially dull, because, even in dry, hard teeth, the keen-beveled or chisel edge cuts into the cementum. Again, the sharp edge constantly misleads, because it becomes engaged with undulations of cementum of the slightest prominence, causing the operator to apply force in order to remove what he thinks is a calculus deposit, while in reality he is forcing his instrument into cementum, and as a result nicks and notches the root in this effort. Only a dull-beveled instrument should be used, because the object is to dislodge deposits, and the dull-beveled edge will do this with less danger of cutting into cementum than a sharp one. Both practical observation and theoretical deduction lead to the conclusion that the beveled edge, with few exceptions, should be used.

INJURY TO THE CEMENTUM AND SOFT TISSUES TO BE AVOIDED.

The chisel-edge instrument, for instance, inclined at an angle of 23 to 25 degrees, as illustrated in Fig. 1, makes one realize at a glance how easily the root may be cut into when a chisel is forced against it at any point along its length, and when firm pressure is applied. The root is scarified in this way when the operator discovers as he

Fig. 1.

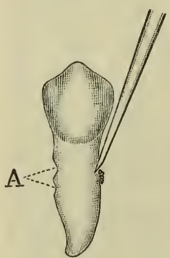

Fig. 2.

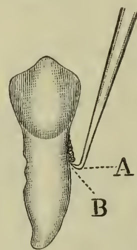

Fig. 3.

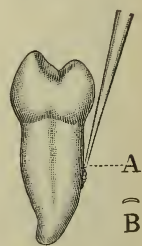


thinks a stubborn lump of calculus; but on finishing his work he leaves the scooped-out surface in about the condition shown at A, Fig. 1. Mistakes of this kind are made, and difficulties are created which are not easily overcome, in working at a point where the curvature of the root is known only by the tactile sense.

Take the action of the type of pyorrhetic instruments known as the plane (Fig. 2), which is less harmful than the chisel as far as injury to the root is concerned—but observe the distance from A at the back of the plane to the cutting edge B, and compare it with the thickness of the blade at the point of the right-angle edge instrument (A, in Fig. 3). It will be observed that the difference in the thickness of this form is hardly a third of that in Fig. 2. The clumsiness of the latter, and the unnecessary bulk at the point of such instruments cause unnecessary gum laceration.

In offering these instruments the writer is prompted by the need for such as will remove calculus deposits and other abnormal substances, and perform the work without injury to the root and with as little injury to the soft tissues as possible.

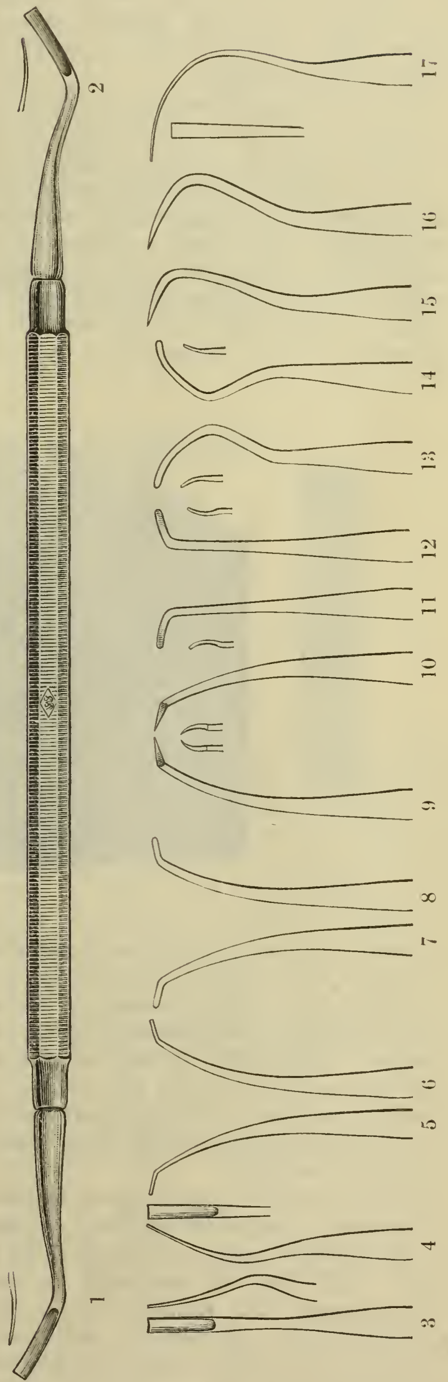
ADVANTAGES OF THE INSTRUMENTS DESCRIBED.

Bends of the shank are employed in some of these forms that are familiar because used in other sets of instruments; but the working end of the instrument is the essential point which the essayist is concerned about, viz, the right-angle working edge. (See Fig. 3, A, and B, the end view of same.) This form of point is, in nine-tenths of pyorrhea cases, the proper one to employ. The exceptions are instances in which no harm results from the use of beveled edges, owing to the position in which they are used and the application of the point.

Fig. 3 shows the application of a right-angle edge instrument. Theoretically and practically, it is impossible to injure the root with a right-angle edge working under the pressure necessary to dislodge salivary deposits, because, while such an edge will lodge and engage against deposits of whatever kind, it will not, under such pressure as is necessary to remove these, cut into cementum.

A right-angle edge, when clean and made of fine steel, will engage and break away scales of calculus, if the edge is applied with firm pressure and at the proper angle; it remains in working order longer than an acute or beveled one, and can scarcely be made to injure the cementum, because of the lack of the degree of acuteness of the cutting or beveled edge. It has two working edges on some forms and four on others, and works effectively at the front and back of the edge in almost all of the designs embraced in the list offered.

The new forms are made almost entirely in pairs of rights and lefts, and



The Set of Instruments.

mounted in double-end handles, so that whatever the form of instrument wanted, the right one and its alternate are together when the respective form of instrument is selected.

As long as pyorrhea specialists differ so widely in regard to their aim in instrumentation—viz, either simply stripping the roots of concretions and shreds or patches of pericementum, or using instruments which shave or plane off the cementum—so long must the armamentarium of the pyorrhea specialist be multiplied. The writer has seen enough of successful work accomplished by the removal of accumulations and cleaning the roots, in contradistinction to the chiseling and planing process, to induce him to advocate and practice the former method. The outfit should be simple, the instruments as few as possible in number, and of such design as to cause no more lacerations of the gum tissue than are inevitable.

Another desideratum in pyorrhetic instruments is delicacy of form, because of the delicate nature of the work to be done. The field of operation is close and cramped, the tissues delicate and sensitive, and instruments are needed that do not stretch, tear, or lacerate. Big instruments hinder and obstruct the view, and defeat the end to be accomplished.

DESCRIPTION OF PROPOSED INSTRUMENTARIUM.

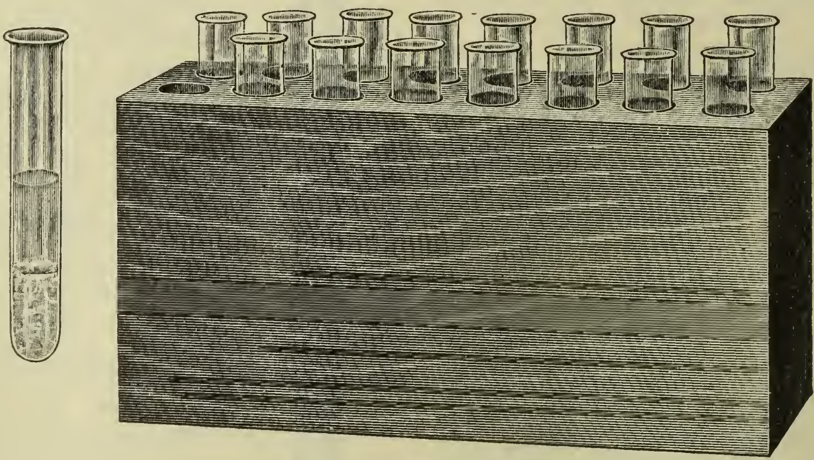
Nos. 1 and 2 are R and L instruments, adapted to scaling around lower incisors —anterior and posterior.

Nos. 3 and 4, adapted to the rounded edges labially and lingually of the lower incisor roots.

Nos. 5, 6, 7, and 8—two pairs—applicable between incisor roots and in the crotches of upper molars.

Nos. 9 and 10, R and L, are applicable at various points, but specially to the crotches of upper molar roots.

Fig. 4.



Nos. 11 and 12, R and L, apply to the roots of upper central incisors, canines, the palatal roots of upper molars, and other points.

Nos. 13 and 14, R and L, have beveled edges, and are adapted to the crotches and concave surfaces of the crotch side of the lower first and second molar roots.

Nos. 15 and 16, single instruments, applicable back of upper and lower third molars and between the teeth throughout the arch.

No. 17, to be used back of last molars —above or below.

PRACTICAL INSTRUMENT HOLDER.

Fig. 4 represents a holder which may be attached to the side of or placed on the bracket table; it is provided with test-tube bottles or phials of one-half inch diameter, and from four to five inches long.

These phials are provided with a cushion of cotton roll pushed to the bottom, over which is poured a gill or so of grain alcohol. One handle, carrying two instruments, is placed in each phial.

This contrivance for holding the instruments places them within easy reach of the operator, one point being placed upright so as to be seen, and so that the form of instrument wanted can be readily found, while the other point is resting in the phial on the cotton roll cushion, which prevents dulling the points by contact with the glass. Each instrument is sterilized, as often as it is used, by being returned to its place in the holder, and in this way confusion is prevented, and the table is left clear for other necessary appliances.

The holder shown provides sixteen phials, which hold sixteen single-point instruments, or thirty-two instruments in double-end handles.

THE NON-COHESIVE GOLD FILLING.

By A. W. SWEENY, D.D.S., Baltimore, Md.

(Read before the Academy of Stomatology of Philadelphia, at its regular monthly meeting, May 27, 1913.)

"Prove All Things: Hold Fast That Which is Good."

THE first three words of that well-known maxim seem to have appealed strongly to many of the profession who have been less attentive to what immediately follows.

OVER-ENTHUSIASM REGARDING INNOVATIONS.

The eagerness with which such dentists seized upon the many new departures and wonderful discoveries heralded as destined to revolutionize the practice of dentistry has betokened an attitude of hopeful expectancy, awaiting the advent of something which should render that practice easier and more remunerative; and the persistence with which those innovations have been exploited, despite many disastrous failures, has furnished a striking illustration of optimism and enthusiasm; but how, during all that search for something new, anything of long-known and demonstrated usefulness should have been largely forgotten is difficult to realize. Optimism and enthusiasm are admirable qualities, which have made greatly for the world's advancement, but there are other worthy qualities, among them prudence, caution, and conservatism. The spirit of modern progress is splendid, but there is still need for the wisdom of the ages.

Besides the tendency to rush into doubtful experimentation, we have also shown a tendency toward the over-employment of some standard resources. The vulcanite plate and the gold shell crown have both been shamefully over-exploited. The cast gold inlay now claims a large share of our attention, and it, too, is being greatly over-utilized. Kindly do not misunderstand your essayist. He is *not* the enemy of the inlay; he is its friend, and would but raise his voice in warning, in the hope of contributing some trifle which may assist in saving it from the unwise over-enthusiasm of many, who, though now its friends, are likely to become its bitterest enemies.

The opinion of Dr. Taggart regarding the appropriate use of the inlay should be entitled to respect. Before placing his casting appliance on the market, he stated that he had been fairly flooded with little scraps of wax from members of the profession, with requests to make inlays to go into cavities which could have been much better filled in the ordinary way. In the face of such testimony, what are we to think of the recommendation of some that we relegate our pluggers to the rubbish heap, and the statements of others that they rarely fill cavities with gold save by casting? Yet there is scarcely a doubt but that it has become the practice of many not only to allow the inlay to practically usurp the place of the gold filling, but also to permit it to encroach largely on the field long successfully occupied by amalgam.

PROVED AND TRIED USEFULNESS OF AMALGAM FILLINGS.

About ten years ago, a gentleman, now an enthusiastic advocate of the inlay, published an account of how he had treated and filled two large approximal cavities in molars, extending beyond the gingival margins and upon the occlusal surfaces of the teeth. He filled those cavities with amalgam, and stated his belief that he had rendered better service than if he had made use of gold shell crowns.

Knowing the care and skill which distinguish that gentleman's operations, your essayist does not hesitate to express his belief that, assuming the patient to have survived in the enjoyment of fair health, those amalgam fillings are now protecting the teeth perfectly, and will do so indefinitely. Most probably that man would fill two exactly similar cavities tomorrow with inlays, but why should he resort to the more difficult and expensive method unless absolutely convinced that it would give the better service? Far be it from your essayist's purpose to advocate anything which might tend toward a lowering of our fees, since he has long regarded them as too low already, save in favorable instances; but we must face conditions as they exist, not as we would prefer to have them, and as we have very eminent authority for the statement that we have the poor with us always, there must continue to be a great demand for an efficient service which can be easily and cheaply rendered. Furthermore, it will sometimes happen, even when the financial resources of the patient are most abundant, that the simpler service may be preferred. Twenty years ago your essayist was asked to fill a large distal cavity in a lower molar for a patient who was unquestionably a multi-millionaire. A gold filling had failed. All conditions were favorable, so a new gold filling was recommended; but the patient objected, saying—"That tooth was filled by Dr. Blank, a very eminent man, yet it has only lasted about two years. Now I would rather have you fill it with amalgam; it can be done much more easily and quickly, and very possibly it may last longer than the other filling."

The amalgam filling was inserted, and the patient carried it to his grave some twelve years later. In your essayist's own household there is a large amalgam filling on the distal surface of a lower third molar, extending well over on the occlusal surface. The operation did not require thirty minutes, but the filling has protected the tooth perfectly for over thirty-five years. Will someone engage to fill a similar cavity with an inlay in so short a time, and will anyone confidently predict a longer term of service?

At a health resort in the Rocky Mountains, your essayist had the pleasure of examining the teeth of a gentleman of New York, who had been a patient of Dr. Marvin's. There were no fillings in the anterior teeth, but a number on the distal surfaces of the bicuspids and the approximal surfaces of the molars, some of large size. They were simply ideal; not a trace of inequality could be detected as the explorer passed from the surface of the enamel to the highly polished surface of the metal, and your essayist realized that Dr. Marvin had displayed rare skill and consummate judgment, and that better service could not have been rendered—yet every single filling was of amalgam. Motives of economy could scarcely have influenced the choice of that preparation. The appearance and manner of the man and the fact of his stopping for pleasure at an expensive resort more than two thousand miles from his home tended to negative that conclusion. He stated that the fillings had been in service for a number of years, and had afforded the utmost satisfaction.

Such cases are not phenomenal; you have all seen similar ones repeatedly. They are merely cited in evidence of the fact that in the long familiar and often maligned amalgam we have a preparation of almost inestimable value, which should not be lightly thrown aside in favor of something else as to the extreme permanence of which we are not quite so certain.

DIFFERENT CASES REQUIRING DIFFERENT METHODS OF GOLD FILLING.

But a vast number of cavities must be filled with gold, therefore it is of the utmost importance to determine correctly which is the best preparation of that metal, and which the most appropriate method for its employment. Candidly, there is not, there cannot be, a single best method or preparation for all cases, just as there cannot be one best medicine for the treatment of all disease manifestations. The very quality which may constitute the cardinal virtue of a given one in a given case may prove its most glaring vice when the effort is made to use it inappropriately.

In the discussion of a paper, an operator stated that he had recently filled two large approximal cavities in molars with inlays, and that the two operations, complete, had required about two hours, whereas gold fillings would have required fully four hours.

SPEED IN GOLD FILLINGS AS EVINCED BY DR. BONWILL.

Twenty years ago the late Dr. Bonwill presented a patient at a meeting in Baltimore for whom he had made a very large number of gold fillings. Besides the incisors and canines, nearly every approximal surface of the bicuspids and molars contained a filling, many of very large size. The fillings were magnificent, fully equal in contour and finish to the highest class of inlay work. After all had examined them and praised them enthusiastically, Dr. Bonwill remarked casually, "Gentlemen, I filled all those teeth in one day." And when that statement was received with looks and expressions of incredulity, he added, "Certainly; why not? I would not ask more than fifteen or twenty minutes to make the largest of them." What would the gentleman who prided himself on the completion of his two large inlays in two hours have thought if he could have seen Dr. Bonwill fill two correspondingly large cavities in so splendid a manner in from thirty to forty minutes?

Doubtless some will reply, "Ah yes, but there have been very few Bonwills." And that is true; but not even the skill and genius of Bonwill would have sufficed for the attainment of such results, if he had not possessed a very broad and thorough knowledge of the art of filling teeth with gold, and it was that knowledge, added to his vast skill and enthusiasm, which enabled him to accomplish such prodigies. Furthermore, as it is conceded that what *has* been done *can* be done, if we would profit by that knowledge and use the same preparations as he used them, we could accomplish substantially similar results. Like so many more of the great men whose genius has shed luster on our calling, Dr. Bonwill has gone over to the great majority, but his patient is still living, and there is a gentleman in this audience who will tell you that those great gold fillings, made with such wonderful ease and celerity, are still in position, protecting the teeth perfectly, after the lapse of over twenty years. Why, then, the constant insistence that the use of the inlay saves so much time and discomfort? In some instances it does, surely, but in others it effects the reverse. A gentleman told a member of your essayist's household that he had just had a tooth filled with "one of those new-fashioned melted gold fillings," and expressed the hope that it would prove very durable, as the operation had been excessively painful on account of the cutting necessary to make room to get the filling into place! Another asked to have a distal cavity in an upper bicuspid filled with an inlay; but when it was prepared it was seen that considerable additional cutting would be required. The cavity chanced to be quite sensitive, and the patient objected, so it was filled in the ordinary way.

PRESENT PREPONDERANCE OF THE USE OF COHESIVE GOLD; LIMITATIONS OF THAT MATERIAL.

For some reason or reasons, which your essayist frankly admits his inability to fathom, the great mass of the profession have long confined themselves strictly to the cohesive preparations of gold. Conversing with a salesman for one of the large supply houses, your essayist expressed the belief that if a canvass were made of all the dental offices in Baltimore, in probably seventy-five per cent. no gold for filling would be found save some pattern of cohesive pellets. The salesman fully concurred in that opinion, with the proviso that he would say *ninety* per cent. of the offices. Now, a cohesive pellet is a thoroughly suitable and convenient preparation of gold for certain cavities, but a more inconvenient and unsuitable preparation for some other cavities could scarcely be devised. What wonder is it, then, if those who have steadily restricted themselves to that single preparation should have met with an excessively heavy percentage of failures? In an uncomplicated, readily accessible cavity, a man of very mediocre attainments can make a thoroughly reliable gold filling with cohesive pellets alone; but as the location of the cavity is found less accessible, conditions will prove different, and in many distal cavities of bicuspids and molars, notably when the crowns of the teeth are long, the difficulties and dangers will prove sufficient to tax the resources of the most skilful manipulator, and it is the belief of your essayist and others that very much of the great popularity of the inlay is traceable to the many disheartening failures long encountered by those who have been trying to treat those difficult cases with such unsuitable preparations.

INJUSTICE OF THE ABANDONMENT OF NON-COHESIVE GOLD FOIL.

But we all know that a half-century and more ago there were, relatively speaking, many men in the profession who could and habitually did fill just such cavities with gold, with very gratifying success. Were those men so vastly our superiors in manipulative dexterity that, with the few and crude appliances which they possessed, they could readily accomplish something which we, despite our vastly improved and amplified equipment, cannot equal? The proposition is unthinkable! They achieved their successes because they used a preparation admirably suited to their needs.

The statement has been attributed to someone that gold foil is "an antiquated and obsolete preparation for filling teeth." Antiquated it unquestionably is, as it is probably the earliest known preparation of that metal used for that purpose. Obsolete it has become in the practice of a vast number of the profession, but, in permitting it to become obsolete, many have done so to their own disadvantage and to the incalculable detriment of their patients. It was that antiquated preparation, gold foil, in its most antiquated form, the non-cohesive foil of our forefathers, which enabled them to achieve their highly satisfactory results, and if we would but lay aside some of our preconceived notions and use that same foil substantially as they used it, we could not only equal those results but could really go far beyond their most brilliant achievements. We need not confine ourselves to the flat surfaces and wide-open spaces which were the objectionable features of many of their operations; we can do far better, as has been demonstrated for years in thousands of instances. While the great mass of the profession have long been striving to force our most excellent cohesive preparations to do duty under conditions which have caused their very excellence to constitute the heaviest handicap to their successful employment, we have always had among us men of great skill and unquestionable standing who have steadily upheld the merits of non-cohesive gold foil, that splendid antique handed down to us as a precious heirloom by our forefathers. A half-century ago its merits were most ably supported, among others, by Drs. Maynard and Cockerille in the nation's capital. Much more recently, they were splendidly demonstrated by the brilliantly gifted Bonwill in this city, and until but little more than two short years ago those merits were steadfastly upheld, like a bright beacon light, by the lamented Harris in Baltimore, almost until the day when his hands grew cold in death, and it is with mingled feelings of pride and reverence that your essayist now invites your attention to the operations which serve so brilliantly to illustrate his paper, as examples of the highest point of attainment in the art of filling teeth with gold. He offers them as a silent, but splendidly eloquent message of good cheer and encouragement from beyond the grave, pointing out to all a safe and easy pathway to an assured success.

ADVANTAGES OF NON-COHESIVE GOLD FOIL.

Some of the useful properties of non-cohesive foil are strikingly illustrated by the occlusal surface fillings herewith submitted. [The paper was illustrated by fillings in the teeth of Dr. Niman. During the discussion a tooth containing a gold filling by Dr. Cockerille, in perfect condition after almost forty-eight years of service, was passed around, and as there was a later-developed cavity, it disproved the claim that such teeth remain immune to caries.] We have been repeatedly told that fillings of non-cohesive foil would be rapidly worn out on such surfaces. The most recent of those fillings have been in service for over five years, and your essayist is prepared to testify that not a particle of anything but Abbey's non-cohesive gold foil entered into their construction. The large contoured approximal fillings have been in service for seven years, and are mainly of the same foil. They serve also to upset the theory that non-cohesive and cohesive gold should not be used together, as there can be no homogeneous union between them. Some will remember the inquiry made years ago thus—"Why does a countryman wrap a rag around the bung before he drives it into the bunghole of his cider barrel?" The answer was—"Because he does not want to lose any cider." The impossibility of homogeneous union between the rag and the bung or with the periphery of the hole does not trouble him; he knows that the soft, pliable folds of cloth will be so tightly compressed that there can be no leak, so he goes to market with an easy mind and a clear conscience. And so it was when our beloved teacher performed those really remarkable operations. Finespun theories did not matter. He started with the old, familiar non-cohesive foil of Abbey, driving it to a thoroughly close adaption along the gingival margins, against the lateral walls, and freely into the occlusal portions of the cavities, and at the point which his mature and unerring judgment showed to be appropriate, he laid aside his non-cohesive foil, took up his cohesive preparation, and, driving it to an absolutely secure anchorage—homogeneous or mechanical, as you may prefer—in the masses of gold already in place, he built out the contours, rounded up the knuckles, and so completed the masterpieces which you have seen. And if it be true that the realization of work well done, of duty thoroughly fulfilled, constitutes the highest recompense of labor, surely he must have been enabled, at the conclusion of that splendid service, to sit down to the enjoyment of a munificent reward. Some practitioners who know the value of non-cohesive foil do not avail themselves of its advantages. Various excuses are offered. An intimate friend told of having watched the filling of an exceptionally difficult distal cavity in a lower third molar by a colleague who used Abbey's non-cohesive foil. The cavity was filled with ease, in but a fraction of the time which the narrator would have required to fill it with cohesive gold, and for years the filling rendered splendid service. Asked why he did not at once accustom himself to the use of non-cohesive foil, he replied—"Oh, I have always been too busy to spare time to learn new methods." Yet who but the busiest practitioner can so ill afford *not* to spare the time to learn all reliable methods which effect a substantial saving of time and labor?

MODE OF INTRODUCTION OF NON-COHESIVE GOLD FOIL.

Some imagine that the use of non-cohesive foil requires the expenditure of a vast amount of very fatiguing effort, whereas exactly the reverse is true. That idea prevails among some of the pupils of the late Professor Harris, whose college days date back for a third of a century. Professor Harris was a very tall man; his hands were large and gifted with tremendous power, and in his earlier days he used a great deal of heavy hand pressure, and many who then watched his demonstrations, while greatly impressed by his brilliant results, were discouraged by the thought that what was, for him, so easy, would be impossible for a man with hands of ordinary grasp and vigor. In his later years, however, he changed his method greatly, and nearly all the gold which he used was carried directly into the cavity and condensed with the old familiar automatic mallet, which even a girl's delicate fingers can manipulate. His method was strikingly shown in the case of the occlusal surface fillings already noted. A strip of gold was carried to the distal side of the cavity; several short folds were doubled over and pushed in, standing upright beside it; then, under rapid blows of the mallet, more gold was driven in, until, in a few minutes, the cavity was most substantially filled—and there was not the least suggestion of roughness in handling the patient.

LESS OBJECTION TO THE AUTOMATIC MALLET WHEN USED WITH NON-COHESIVE GOLD FOIL.

Objection has been made to the automatic mallet on the ground that its blow is most disagreeable. That is purely an individual matter. Our patients object to many of our appliances, and the automatic mallet would scarcely come under more general condemnation than would the engine bur, the disk, the separator, or the polishing strip; indeed, aside from the forceps, most patients would pronounce the bur the most objectionable of all our appliances. Certain it is that your essayist has sometimes been asked to substitute the automatic for some other style of mallet, and many of you have probably had the same experience. It is also a fact that the blow of a mallet on non-cohesive foil is not nearly so sharp and resonant as is the same blow upon cohesive gold, and while that fact will be seized upon as evidence of the superior density attained with the cohesive preparations, the fillings submitted herewith [demonstrating] do not show any discoverable lack in that direction.

Furthermore, it is now some years since a gentleman of Baltimore won an elaborate supper on a wager with a gentleman of this city by making a filling of Abbey's non-cohesive foil in a steel matrix, entirely by hand pressure, which, after an exhaustive scientific test, was declared to show "greater weight, greater specific gravity, and greater freedom from air-spaces" than did the cohesive gold filling of his competitor made in the same matrix with the help of a mallet.

THE OLD OFTEN THE BEST.

From the foregoing, the conclusion would seem but logical that many could, with great profit, spare sufficient time from their search for novelties to familiarize themselves with the properties and use of that preparation which was for so long the pride and main reliance of our forefathers. None need fear that the adoption of such a course would imply a retrogression, for it is not alone by keeping in touch with the best of what is new, but also in maintaining a firm grasp upon everything which has abundantly proved its usefulness in the past, that we may hope to realize in full the true spirit of progressiveness.

Because something recently introduced may prove highly useful, we must not jump to the conclusion that it should supersede everything long similarly used with great success. Though the trend of modern progress is ever forward, we are often forced to realize that some of our best recent achievements do not equal some of the triumphs of an earlier period. Notably is that true in the field of art, though illustrations are not lacking elsewhere. The ablest sculptors of our day have not equaled the sublime creations of their illustrious colleagues among the ancient Greeks and the Italians of the sixteenth century. No painter of our time has given us anything quite comparable with the masterpieces of Raphael and Correggio, of Titian and Rembrandt, Jacob Ruysdael, Holbein, Velasquez, and many others. Though the modern piano has utterly eclipsed the old-time spinet and harpsichord, and though in technique and tone the world has not seen the equal of such men as Liszt and Rubenstein, Paderewski and Mark Hamburg, no living composer has written anything which classes with the great works of Beethoven, of Mozart, Schumann, and Chopin, while in the field of the music drama the world is still waiting for the worthy successor of Wagner; and while the piano and its great exponents have scored such signal triumphs, no contemporary violin-maker has equaled a Stradivarius or an Amati, and no wizard of the bow now before the public will claim to be the rival of Paganini. The modern express train and the giant ocean liner are immeasurably ahead of the stage-coach of our ancestors and the galley of the ancients. The high-powered automobile has utterly outstripped the horse, and can easily distance the stoutest thoroughbred, yet there are no indications that that noble animal will be permitted to become extinct or to revert to the type of his diminutive prehistoric ancestor; and though by reason of certain very narrow and ill-advised legislation, notably in our Empire State, the thoroughbred has suffered a sad diminution in value, in England and some other countries where broader and more enlightened ideas and cleaner politics have prevailed, he is held in universal admiration, and the sport of kings still flourishes as of yore.

The foregoing random illustrations should remind us that, while we do well to remain alert and watchful for substantial improvements, we should hold on with a firm and unrelaxing grasp to everything which long experience has proved to be good.

RECENT INDORSEMENTS OF GOLD FOIL FILLINGS.

We have long been prone to mount hobbies, which we have often ridden far afield, to our detriment and humiliation, but happily a saving grace has always brought us back to safer and saner methods. Latterly we have again been indulging in that dangerous propensity, and many have gone "joy-riding" with the gold inlay, to the peril of all participants in those excursions. Happily, though, again there are signs of a better state of things; the breakneck speed has been reduced, and we may confidently expect, ere long, to see those venturesome riders turning again toward the safe and well-beaten highway. Some recent reminders have pointed clearly in that direction. In the DENTAL COSMOS for December 1910,* the gifted editor, commenting on a clinic held for the purpose of testing the relative efficiency of different styles of mallets for condensing gold, sees evidence that the making of gold fillings is not soon to be numbered among the lost arts. By an interesting coincidence, in the same issue of

* See DENTAL COSMOS, 1910, vol. lii, p. 1406.

that well-known journal, in the opening lines of his paper on the gold inlay, Dr. J. V. Conzett says:*

> In the opinion of the writer, there is no better filling than a good gold foil filling. Gold foil in the hands of the man who is an expert in its use is a material unsurpassed for stability and permanence; fillings made with it have demonstrated their perfection by the only test that is a fair one, the test of time. We *know* what gold foil will do in the hands of the master workman; therefore it requires no apologies at this late day.

About the time the above appeared in print, it became known through the dental-supply trade that the surviving partner of the old house of Charles Abbey & Sons, whose non-cohesive foil had long been the standard among users of the preparation, had retired from business, and that his product was no longer obtainable. By a few that information was received with feelings akin to consternation; but soon foil of similar properties was in the market, and, in the summer of the year 1911, the S. S. White Dental Mfg. Co. joined in the effort to perpetuate the excellent qualities for which the product of the old house of Abbey was so long and so justly famous. That latter fact is one about which there can be no difference of opinion, for all must realize that a house of such great and varied experience in catering to the wants of the dental profession may be absolutely relied upon not to waste its capital and jeopard its reputation by placing on the market any article which its management regarded as not only antiquated, but also obsolete.

As an additional evidence that the views herein expressed are not merely the unsupported ideas of your essayist, but that they are shared in by some whose opinions are entitled to respect, you will find among the writings of Prof. S. H. Guilford a passage wherein he likens the effort to fill a cavity with cohesive or non-cohesive gold to the attempt to stop a bottle with a plug of hard wood or with a rubber cork. He says that it *can be done* with the hard wooden plug, but can be much more easily and certainly done with the rubber stopper.

* See DENTAL COSMOS, 1910, vol. lii, p. 1339.

TIME AND LABOR REQUIRED FOR GOLD FOIL FILLINGS NOT OVERTAXING.

Though special mention has been made of Drs. Maynard, Cockerille, Bonwill, and Harris, men who stood as giants among their colleagues, their example should prove an inspiration rather than a discouragement; for, while the gift of genius has been vouchsafed to but a few, the capacity for honest work is the endowment of the many. A man of very modest ability can make a great number of most useful fillings with cohesive gold, if he will exercise proper care and patience, but in three-quarters of those cases he can do better work with far less labor if he will use non-cohesive foil; for he can dispense entirely with retaining pits and deep undercuts, largely with the rubber dam, and, if he prefers, with the mallet also. The constant insistence upon the great saving of time and discomfort effected through the use of the inlay must come chiefly from those who have forgotten that large gold fillings were most successfully made over a half-century ago, while little was said about their proving such a tax upon the nervous resources of either the operator or the patient. Many do not realize that an eighth-ounce book of non-cohesive foil can be thoroughly packed into a cavity in from ten to fifteen minutes, and while that feat will call for the services of a master, if one less highly gifted should require from twenty to thirty minutes for its accomplishment, it still could not fairly be termed a fearfully taxing, nerve-racking experience. The inlay is a splendid thing; in its proper place, it is well-nigh ideal, but its legitimate field is by no means so wide as many seem to have imagined.

FINAL APPEAL FOR THE NON-COHESIVE GOLD FOIL FILLING.

Gentlemen, whatever may be its deficiencies and limitations, your essayist feels a firm and positive conviction that his paper contains food for your very serious thought, and that it is worthy of something more than your passing and casual attention. We all recognize the obligation resting upon us to render for those who intrust themselves to our hands the best service of which we are capable. At the same time we realize the duty we owe to ourselves and those dependent upon us to neglect nothing which may assist us to conserve our time and lighten our labors, so long as the attainment of those ends shall not cause a lowering of the standard of the services which we render. Often it has appeared a difficult problem to reconcile those seemingly conflicting claims; but how freely, how joyfully may we embrace the opportunity held out in a vast number of instances, not only to effect a notable saving of our time and lightening of our labors, but also to make our services of greater and more enduring value! Surely that prospect must prove most alluring; its consummation must constitute a goal toward which all may strive with great zeal and earnestness, knowing that, in its realization, we shall accomplish a great and worthy work indeed.

And, if it be true that in another and a higher sphere of existence those who have gone on before us retain a consciousness of what takes place here below, possibly some may find an added incentive to the prosecution of that good work in the thought that they may be resting under the approving smiles and sharing in the benedictions of the great forefathers of our profession and some of the most illustrious of their successors—among the latter who have recently left us, one of the ablest, one of the kindest, one of the most charming and lovable men whose presence among us has served to grace and ornament our calling.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE ARCHOGRAPH: AN INSTRUMENT FOR DETERMINING AND RECORDING ARCH VARIATIONS AS APPLIED TO TOOTH MOVEMENTS.

By ROBERT H. W. STRANG, M.D., D.D.S., Bridgeport, Conn.

(Read before the Alumni Society of the Angle School of Orthodontia, at its seventh annual meeting, New London, Conn.)

WITH the advent of the "new appliance," so recently introduced by Dr. Edward H. Angle for the treatment of malocclusion, comes a marked demand for an accurate method of determining and recording arch changes in their relation to tooth movement. Previous to the use of this form of appliance the force was transferred from arch to tooth by means of the ligature, so that it was possible to gage its application with a fair degree of accuracy. With the "new appliance" the attachment is direct, and any change in the curve of the arch or in the angle of the pins must result in tooth movement, and the question is—"In what direction, and how far?"

THREE FACTORS TO BE DETERMINED FOR SUCCESSFUL EMPLOYMENT OF ANGLE'S "NEW APPLIANCE."

Three facts must be known before accurate and uniform results can be obtained. First, the direction of the force applied; second, the effect of this force at the point of application and at all other points, including especially the anchorage; third, the amount of force. Without a means of answering these questions, this wonderful little appliance is bereft of much of its value as an instrument for scientific tooth movement.

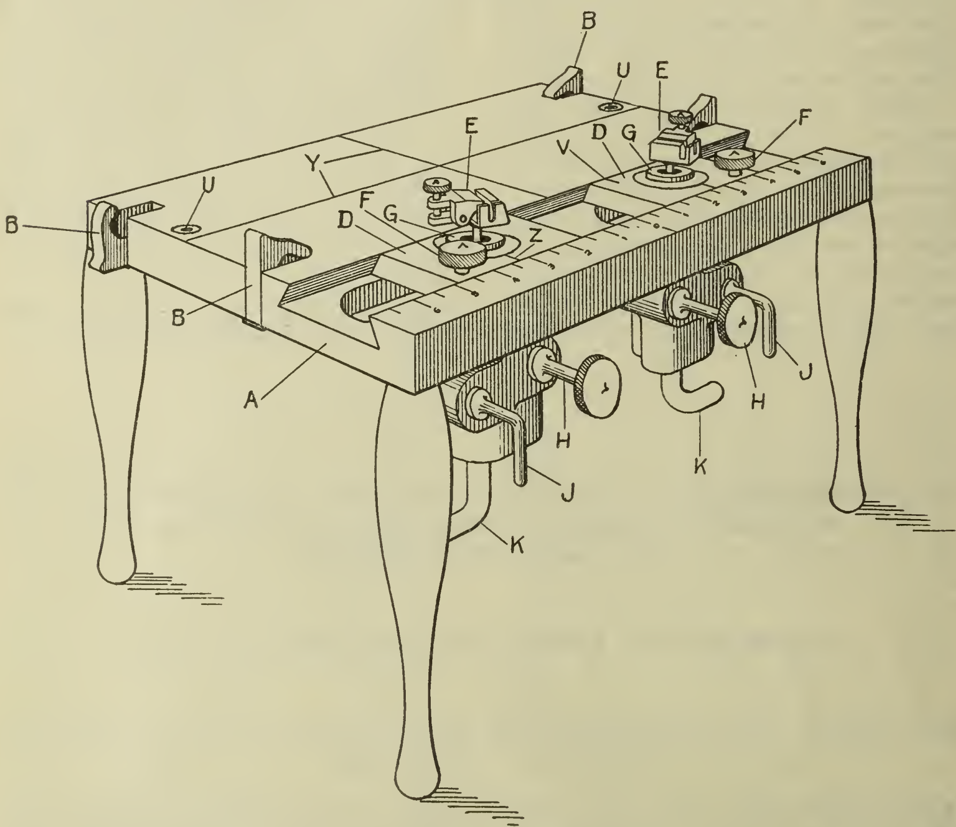
After much experimenting, the instrument that appears in the illustrations here shown, and which we will call an "archograph," has been devised for this purpose. Through its agency we are able to determine and record accurately the direction of force as produced by changing the shape of the arch wire or by bending the pins, and the effect of such force upon each tooth attached to the arch and upon the anchor teeth. We are further able to judge the amount of force by the extent of these changes as shown upon our record sheet.

DESCRIPTION OF THE "ARCHOGRAPH."

A brief description of the instrument is now in order.

This consists of a stage A, Fig. 1, mounted on four legs in table-like effect. For convenience of description, we will designate the side corresponding to the upper part of the illustration as the *top* of the instrument; its opposite side as the *base;* the two remaining sides as the left and right sides respectively. On the latter two sides are spring clasps B, for holding the recording paper in position. In the center of the right and left sides and in the center of the top are placed scratch-marks Y,

Fig. 1.



to be used as indicating lines. The recording paper is to be correspondingly marked, so that it can be replaced in the same position at any subsequent time.

At the base of the stage are the two slides D, moving freely to right and left, and locked by the set-screws F. These also carry scratch-marks, V to record on the paper the position of the slides, and Z to measure distances on the millimeter scale below the slides.

Each slide has attached to it a telescoping tube G, which can be raised or lowered to any desired height by means of the screw H, and locked by the lever J. Surmounting these tubes are the chucks E, of such design that they will hold any of the various styles of anchor tubes used in the different forms of appliances. Each is attached to its tube G, by means of a ball-and-socket joint, which can be set when at the proper angle by turning the lever K.

Fitting upon the stage A is the removable platform R, in Fig. 2, which is held in position by the dowel pins W, fitting into the sockets U, in Fig. 1. On R are placed six pointers S, Fig. 2, which have three adjusting screws L, M, and N. The position of these indicators on R is subject to variation according to the case in hand, by using any of the screw-holes O as desired. Each pointer has a hinge joint at P, so that the end can be lifted away from the top of the little pin on the arch after adjustment has been made.

FIG. 2.

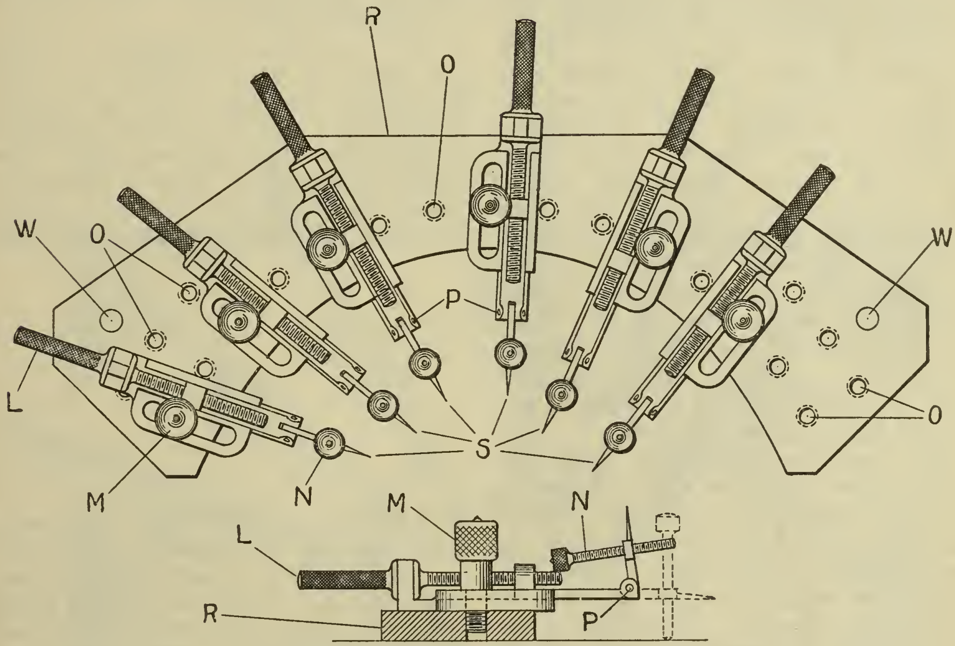


FIG. 3.

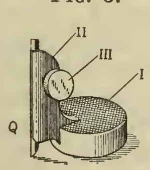


The tracing pencil Q in Fig. 3 completes the equipment. It consists of a round body I, attached to which is the lead-holder II, controlled by the binding screw III.

MODE OF ADJUSTING THE ARCH TO THE ARCHOGRAPH.

In adjusting the arch to the instrument, making records and arch changes, we proceed as follows: Let us suppose that the arch has been adjusted to the mouth, has been in position passively for the usual period to allow the patient to accustom himself to the appliance, and that the time has now come for the application of force. In the chucks E in Fig. 1 are placed buccal tubes and end sections of duplicate form to the ones used in the case in hand. Of course, if some other means of attachment, such as the Young-Angle lock, has been used on the anchor bands, this must be duplicated and placed in the chucks. In our description, we will consider that the sectional arch, as described by Dr. Angle in the DENTAL COSMOS for January 1913, is the appliance in use. The platform R is removed from the stage A, and the recording paper adjusted.

The arch is then taken from the mouth, and placed in the end section on the instrument, and the correct lateral separation given to the slides D, as indicated by the width of the arch wire, after which the slides are fixed by turning the screws F. The tubes G are now raised or lowered by turning the screws H, until they are in that position whereby as much of the arch as possible is brought in contact with the recording paper. The proper height being thus ascertained, they are locked by the clamping levers J. The final step is the locking of the ball-and-socket joints at the base of the chucks, which is accomplished by turning the levers K. The buccal tubes in the chucks of the instrument are now in the same relationship, the one with the other, as are the tubes on the anchor bands in the patient's mouth. It is well at this point to test our adjustment. This is readily done by removing first one end of the arch, and then the other, allowing each in turn to fall passively upon its receiver, over which it should lie in perfect alignment. Having ascertained that the adjustment is correct, we are ready to make a tracing, which is quickly done with the pencil Q in Fig. 3. This is designed so that the lead is always brought to bear upon the arch at the same angle of inclination. Without this precaution the tracings would be valueless. The position of the pins at their points of attachment to the arch is now indicated on the paper with a dot made by piercing the sheet with the point of a common pin. Later this mark is recorded in ink.

As it is usually impossible to bring the arch in contact with the paper throughout its entire length, there are some of the pins also not in immediate relationship with the recording sheet. Upon each one of these is slipped an accurately fitting tube, 1/32 in. in length, to which has been soldered with the flat side against the tube, a small, half-round wire, .030 in. in diameter and 1/4 in. in length. This is pointed at the end. (See Fig. 4.) When this tube is placed upon the pin, the wire will extend down and touch the paper. The flat side of the wire rests against the arch, prevents rotation of the tube on the pin, and makes the indicating point accurate and positive. (See Fig. 4.) Two of these are seen in position on pins 3 and 4 in Fig. 5.

FIG. 4.

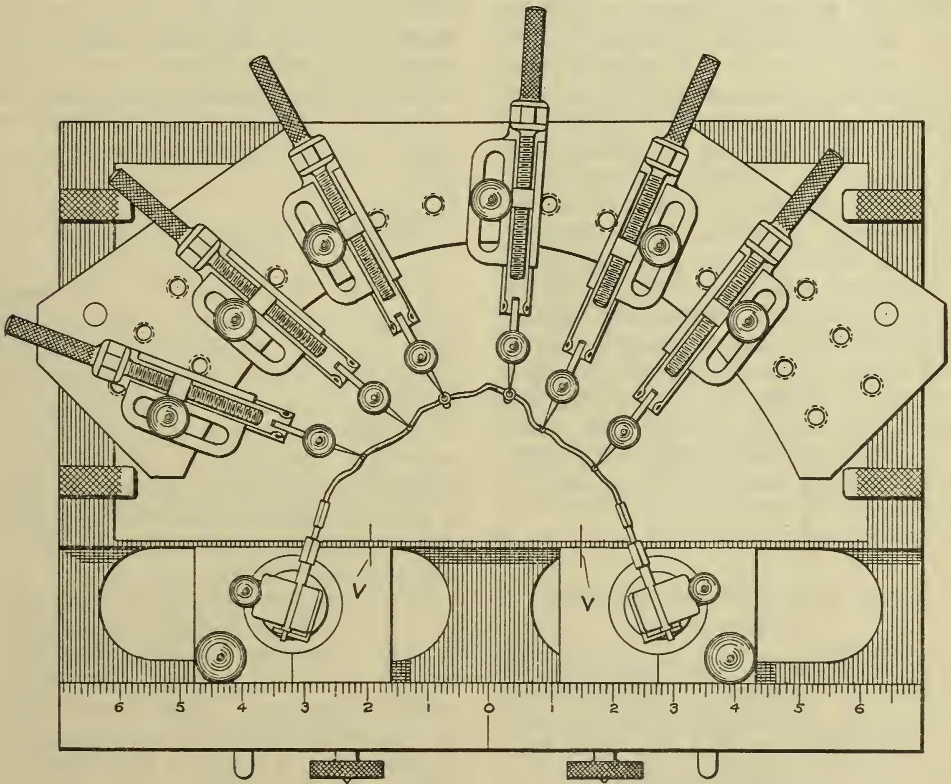
The platform R, holding the pin indicators S, is now placed upon the instrument, and a marker adjusted to the end of each pin. We now have fixed indices on the most vital points of the arch, *i.e.* the anchor ends and the places of attachment for each tooth, while the whole arch is accurately outlined on the record sheet. The completed adjustment is shown in Fig. 5.

MAKING AND RECORDING READJUSTMENTS OF THE ARCH AND PINS.

Now we are ready to change the form of our arch or the inclination of the pins so that tooth movement may be accomplished. Such changes should be exceedingly delicate, and, until one is quite familiar with this appliance and with the archograph, should involve the movement of but one tooth. After acquiring the necessary technique, variations can be made affecting the movement of several teeth with absolute safety and accuracy.

and the unchanged pins brought in contact with the pointers. Immediately the character and amount of variation at the altered area is detected, together with its effect upon the anchorage of that side and all positions on the arch between the point of bending and this anchorage end. If this variation is too great, is in the wrong direction, or has produced a faulty inclination in the pin, we are able to

Fig. 5.



detect and readjust it before harm has resulted. The proper variation being completed at one point upon the arch, the necessary readjustment is made to correct the disturbed relationship at the anchorage end. It is now well to determine whether the amount of force has been well calculated, and is within the physiological limit. This the patient alone can tell, so we apply the altered arch to the teeth. There should be absolutely no discomfort when it is in position, nor should it feel "too tight." Hav-

Each individual pin-marker is now thrown back, and the stage R lifted from the instrument. The arch is then slipped out of the end sections, and the bend made at the point desired. The end of the arch farthest away from the point of bending is then replaced in its end section. This end of the arch is used in order that as many unchanged points as possible can be brought in contact with the previously adjusted indicators. These are now placed in position by adjusting the stage R to the instrument, ing ascertained that we are also correct in this detail, we replace the arch on the archograph, and make a tracing of the change for record. The new position that the pin at the point of variation has taken should also be registered. These records can be retraced to advantage in different colored inks, and the dates recorded on the paper in the corresponding color. In this manner the writer usually registers four different series of changes on the one record sheet. Before the recording paper is removed from the instrument, indicating points are marked upon it at the junction of the scratch lines, Y and V, Figs. 1 and 5. This permits replacing the record at a future sitting, and the readjustment of the arch to its previous tracing.

When several changes are made at different points upon the arch the technique is the same, but each individual variation must be completed, perfect readjustment made in the disturbed anchor relationship and the pin indicators again fixed before another alteration is begun. Thus constant points are maintained as guides, so that each change is made accurately and scientifically. The number of changes is then limited only by the demands of the case and the skill of the operator.

RANGE OF USEFULNESS OF THE ARCHOGRAPH.

While this instrument was devised for use with the "new appliance," it has been found to be exceedingly helpful in making adjustments of the old style arch. With its help perfect adaptation to anchor tubes is made certain and much displacement of anchor teeth avoided. Such movements as parallel expansion or contraction of molars, rotation of molars, and tipping of molars can be planned with absolute accuracy.

MANIPULATION OF THE ARCHOGRAPH WITH OLD STYLE ARCH.

The technique of adjustment and use with the old style arch does not differ materially from that of the "new appliance," but is of course easier to acquire because of the one-piece arch. The arch is taken from the mouth, the ends are placed in the tubes held by the chucks E, the various adjustments made and the chucks locked. Tests are applied to see that the relation of the tubes to the ends of the arch is correct. A tracing is then made. Whatever changes are desired in the shape of the arch are then made in the mouth, using one end of the arch as a fixed point, and testing the changes frequently by placing this end in its anchor tube. When the proper form has been reached, this same end of the arch is placed in its coresponding tube in the instrument, and the opposite end is bent to fit its tube perfectly, thus assuring accurate adjustment to anchor teeth. A record is then traced of the new arch form.

ACCURACY OF TOOTH MOVEMENT INSURED.

It is the belief that this instrument has been simplified as much as is possible, but even now it undoubtedly appears quite complicated, until one has familiarized himself with it. Therefore it is not to be expected that it can be used with perfection immediately. As these appliances are extremely delicate, so must be the adjustments made on the recorder, and it requires considerable practice to master the technique.

To the operator who feels that he has but a few minutes to spend on each case, this instrument certainly will not appeal; for it is not a time-saver as related to the individual sitting. However, when used as a guide throughout the entire period of treatment, it will save both time and energy, for it makes tooth movement positive and always toward the normal, thus avoiding any prolongation of treatment through wrong application of force. Furthermore, by obviating all guessing, inflammatory reaction is precluded, and hence treatment is made most comfortable for the little patients.

As a final word, the writer would express the sincere hope that the archograph will be found of help to the orthodontist in his problems of treatment, and will be of particular aid in the scientific application and effective use of the "new appliance."

Correspondence.

SCIENTIFIC ALLOYS.

To the Editor of the Dental Cosmos:

Sir,—In view of the articles which have appeared in the Dental Cosmos advocating alloys, for amalgam, in which the metals are in atomic ratio, I beg to ask the following questions:

(1) If an alloy in which the metals are in atomic ratio is the best alloy for any purpose, why is it that the proportions of copper and tin differ so widely in speculum metal, bell metal, and gun metal?

(2) Does not the fact that the proportions of the metals differ so widely in the above-mentioned alloys prove that the proportions of the metals in an alloy depend on the purpose for which the alloy is made?

(3) Is it not admitted that the amount of mercury necessary to add to an alloy, in order to produce an amalgam for filling teeth, precludes the possibility of the *amalgam* being an alloy of metals in atomic ratio?

(4) If a primary alloy is made of metals in atomic ratio, which is then made into a secondary alloy, in which the metals are not in atomic ratio, by the addition of mercury, is there any proof that the secondary alloy, or amalgam, is necessarily better *because* the metals in the primary alloy were in atomic ratio?

I should also like some information on another point.

If an amalgam is made with an alloy of silver, tin, and copper, and it is admitted that, in the presence of air and moisture, certain antiseptic or tooth-preserving salts will be formed, is it wise to state that this is of no value, because these salts cannot be formed in the cavity unless the filling leaks?—and then in the same breath state that it is more difficult to make a moisture-tight filling with amalgam than with cohesive gold? If that be the case, how many perfectly moisture-tight amalgam fillings are made in the mouth? and in how many cases can the formation of the more or less tooth-preserving sulfates be despised, as of no account, because the fillings are so tight that they (the sulfates) cannot be formed between the filling and the dentin?

I believe it has been found difficult to make a perfectly adapted amalgam filling in a Wedelstaedt steel tube, even if the sides are roughened with a carborundum stone. It is still more difficult to produce perfect adaptation in a glass tube. Provided the amalgam does not contract, and provided it is an adaptable amalgam, fillings *can* be made in glass tubes which show no leakage after immersion in an aniline dye or a penetrating ink. But the careful and accurate manipulation necessary to produce a moisture-tight filling in a glass tube makes one doubt one's capacity to produce the same result in the mouth in all, or even in the majority of cases.

Yours faithfully,

Wm. Cass Grayston.

Scarborough, Eng.

PROCEEDINGS OF SOCIETIES.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

Forty-fifth Annual Meeting.

FIRST DAY—*Morning Session.*

THE forty-fifth annual meeting of the Dental Society of the State of New York was opened on Thursday morning, May 8, 1912, in the assembly room of the Educational Building, Albany, N. Y. The president, Dr. C. F. Baylis, Oneonta, called the meeting to order at 10.30 o'clock.

The Rev. J. V. MOLDENHAWER, Second Presbyterian Church, Albany, invoked divine blessings on the deliberations of the society.

The vice-president, Dr. W. W. Smith, Rochester, took the chair while the president, Dr. C. F. BAYLIS, read his annual address, as follows:

President's Address.

We are again assembled to attend the annual meeting of our society, the forty-fifth anniversary of the organization. I trust it is well that another year has passed and we can again meet the friends we have learned by close association to esteem and respect. Our surroundings are most delightful as we are privileged for the first time to hold our meetings in this beautiful building, devoted exclusively to educational purposes. It is an experiment, holding our meetings in one place and having the clinics and exhibits at our hotel headquarters. I trust it will be profitable to all concerned.

As your presiding officer, I extend a cordial welcome to all, and I trust that you will have a pleasant and profitable time, and return to your several localities with a feeling that you are better prepared to serve your patients, and yourselves, for having been with us.

This society and its allied district societies for the past forty-five years have succeeded in making our profession a representative one in this state. It is now looked upon by the members of other professions, and by people generally, as an educated, skilled, respectable, and progressive profession, of which any man may well feel proud to be a member.

To every ethical practitioner of our profession in this state I wish to say that he owes a great debt of gratitude to the men who have been the pioneers in building up these societies, and our profession, and I invite you to come with us and give us your co-operation and support, that we may not only be a leading society, but a progressive one, with every representative ethical member of the profession with us, all moving forward for the good of the society, the profession, and the public to whom we strive to give health and happiness.

REORGANIZATION.

The adoption this morning of new By-laws makes this meeting a marking-stone in our onward and upward progress as a society. The old order of conditions has passed away, and we enter the future under a new and progressive form of government and an unlimited membership.

We have reorganized—or, as I term

it, we have moved forward from the small to a large dental society. This reorganization makes no change in the management of the district societies, except that their active members become members of the State Society and of the National Dental Association, and that they must collect dues from their members sufficient to enable the district society to pay the dues of the State Society, and that the State Society is to pay the dues of the National Dental Association. The district societies at their annual meeting are to elect a representative on the Executive Council and an alternate, a member of the Law Committee, a member of the Legislative Committee, two members of the Oral Hygiene Committee, and are to recommend two members for appointment on the State Board of Dental Examiners.

For a number of years the business of the society, except election of officers, has been transacted by the Executive Council. Under our new by-laws, they also elect the officers of the society, thus placing us entirely under a "commission" form of government. All sessions of the Council are open to members of the society, and any member may be heard on any subject under consideration.

DISTRICT SOCIETIES.

It has been my privilege to be the guest of the several district societies, except the Second and Ninth, which I regret not being able to visit because I had no definite knowledge of the dates of their meetings.

My visits to the several sections of the state convinced me that there is a deep feeling among the members of the several societies for the welfare of the organization and its members, and that good-fellowship and harmony permeate the local organizations. The evident progressiveness seemed more along the lines mentioned than that of increasing the membership. I would recommend that we do a little missionary work, and go out and induce our ethical brother practitioners to come with us. Let us try to make them see that to do so would be for their good, for the good of the local society, for the good of the State Society, and above all for the good of the profession. Every ethical dentist should feel that the societies are entitled to his moral and financial support, in return for what they have done for his profession.

The presidents of the several district societies are endeavoring to create a closer relationship with the various sections of the state, and to this end they have arranged a dinner for the retiring and active presidents of the several societies, at six o'clock, May 8th.

SCIENTIFIC RESEARCH.

The Scientific Research Committee have been very fortunate in having Prof. Wm. J. Gies, of the department of biological chemistry, Columbia University, to continue the direction of their investigations. With the splendid facilities of Columbia University back of him, he is able to go about his work with the best equipment available to science at the present time. Many of the stock preparations and appliances have been supplied by the university without cost to the committee. Professor Gies has not accepted personal remuneration, and the money appropriated has been expended in employing associates of Professor Gies who are willing to devote their time in carrying out the experiments under his direction.

I would recommend that the society appropriate at least three hundred dollars for the use of the Scientific Research Commitee for the coming year.

STATE LIBRARY.

I am informed that the State Library does not contain any books on dentistry. I recommend that the Dental Society of the State of New York appoint a committee of three to select a list of dental books for the State Librarian to have purchased and placed in said State Library, at Albany, N. Y.

INTERNATIONAL CONGRESS.

The Fourth International Congress of School Hygiene will convene at Buffalo,

N. Y., August 25 to 30, 1913. This congress is one of the most important conventions ever held in this country from the standpoint of public health. Our society has been very active in inducing the Public Health Commission of this state to introduce Oral Hygiene in our public schools. It seems a most opportune time for this society to be represented at such a congress, and I recommend that the Oral Hygiene Committee take steps toward affiliation with this congress.

HONORARY MEMBER.

It gives me great pleasure to recommend the election of Wm. J. Gies, M.D., Ph.D., as an honorary member of this society. Dr. Gies for the past several years has been doing a great amount of scientific investigation inquiring into all the possible factors in the causation of dental caries, and I believe his investigations toward the solution of this great problem are of concrete and substantial value to the society. He has been nominated by Wm. B. Dunning, seconded by Ellison Hillyer, Arthur H. Merritt, L. M. Waugh, and other members of the society.

THE PROGRAM.

The Business Committee have succeeded in securing for us some excellent papers by prominent men in the profession, from without as well as within our state; and prominent members of the medical profession have consented to read and discuss papers and also to give clinics. With the very complete reports that the several committees have prepared on timely subjects, I feel confident that very interesting and profitable sessions await you.

CLINICS.

The Committee on Clinics have been a very hard-working and efficient committee. They have succeeded in securing a very large and excellent list of clinicians for the two sessions assigned to this section of our meeting, and I trust their efforts will be rewarded by a large attendance.

CONCLUSION.

In conclusion, I wish to state that the hearty co-operation tendered me by the members throughout the state has been very gratifying, and that every request made by me of a member of this society has been cheerfully granted.

Dr. Smith appointed the following as the Committee on the President's Address: Dr. Louis Meisburger, Dr. A. R. Cooke, and Dr. W. B. Dunning; after which the president, Dr. Baylis, resumed the chair.

The next order of business was the report of the Business Committee, by Dr. H. J. Burkhart, chairman, who reported the program for the day.

Dr. G. B. Beach, secretary of the Executive Council, presented the amendments to the By-laws brought over from the last annual meeting, and, on behalf of the Council, recommended their adoption.

Dr. Beach moved the adoption of the amendments as read. [Motion carried.]

Motion was then made and carried to adjourn until the afternoon session.

Thursday—*Afternoon Session.*

The meeting was called to order Thursday afternoon, at 2.30 P.M., by the president, Dr. Baylis.

The first order of business was the reading of the minutes of the previous meeting—which was dispensed with until a later session.

The next item on the program for the afternoon session was the reading of a paper by Dr. Ellison Hillyer, Brooklyn, N. Y., entitled "The Development of the Anatomical Articulator."

[This paper is printed in full at page 989 of the present issue of the Cosmos.]

Discussion.

Dr. H. L. Wheeler, New York. This description of the development of the articulator has been so complete that it is unnecessary for me to comment upon it. I wish, however, to call attention to one or two points. The articulators that are very largely in use today may be said to be, first of all, the Twentieth Century Articulator (Dr. Snow's), the Gritman articulator, and that of Gysi. Professor Gysi, of course, in his articulator has obtained practically two features that are wanting in other articulators—that is, the retention points and the ability to produce lateral motion. As the condyle slides down over the glenoid fossa, over the eminentia articularis, there is the protrusive movement which brings the jaw outward and forward, and the lateral motion, and these motions are obtained in the Gysi articulator. With this feature we have had practically no experience, and Professor Prothero, in a paper read before the First District Society this winter, did not place as much dependence on that as upon having an adjustable condyle path. The Gysi articulator is a complicated one, and probably represents as perfect a means for reproducing the various movements desirable in the mandible as has been or will be obtained for some time by any mechanical appliance. In the Simplex articulator, which is within the means of, and which can be operated by, the average dentist, one of the most vital necessities of a good anatomical articulator has been eliminated—that is, the adjustable condyle path. This articulator has a condyle path which allows for the protrusive movement and for the lateral movement, to be sure, but this is set at a certain fixed degree on the scale—I believe the essayist said it was at 33°. Since there is, however, a wide difference in the angle of the condyle path in different mouths, also a difference in the angle of the condyle path on either side in almost all individuals, I believe it to be essential for obtaining the best results, and up to date, that the condyle path be adjustable. The Snow articulator possesses this feature in the most simple and readily understood form. Of course it is desirable, if possible, to get the other movements, but it is also desirable to have the articulator simplified so that the average practitioner may understand it, and it has been found difficult to embody in an articulator all the movements of the mandible.

I wish to further speak of one or two items in relation to the setting up or properly articulating the teeth in or upon the anatomical articulator. At the present time the profession is greatly interested in, and very enthusiastic over, the probability of obtaining what are called perfect anatomical molds of porcelain teeth. To a certain extent, of course, that is desirable, but there is one feature, so far as my observation goes, that has been neglected in considering the question of obtaining correct anatomical occlusion in artificial teeth. The average individual who needs a complete upper and lower artificial denture has arrived at the age when the cusps and grinding surfaces of the teeth are comparatively well worn; the high, well-marked cusps of the anatomical artificial teeth, which are obtained from very perfect natural teeth that have not been worn, will therefore not work in the mouth of the average individual who needs a denture! There are reasons for that. The natural teeth are set in bony sockets and in cushions of peridental membrane, and, as the teeth move forward, backward, and laterally, there is a certain amount of motion which allows each tooth to give, and allows for the changing of the direction of the movement. So far we have found no means whereby it is possible to make artificial dentures in any other way except so that the teeth stand in relation to each other in a perfectly rigid manner. There is no individual motion whatever in the approximal relationship of artificial teeth. The teeth in an upper and lower denture in moving over each other are incapable of reproducing the movements of the natural teeth in their alveoli, and that means that artificial teeth must have lower and flatter cusps. If the teeth of a man of eighteen, twenty, or twenty-five years of age, the cusps of which are very little worn, are reproduced in porcelain and set up rigidly in an artificial denture, they will interfere with the movements of the mandible. Even though the idea of anatomical teeth be theoretically correct, allowance has to be made for the rigidity of the artificial denture. Besides this, another feature has to be taken into account: The average edentulous individual has lost his teeth at different times, and this progressive loss generally results in a decided change in occlusion, which will inevitably bring about a change of the condyle path sooner or later. Nature will adjust herself to that change—which is very fortunate, for if it were otherwise, dentures made on a plain-hinge articulator would not work. Most patients could not adjust themselves to dentures made without any consideration of the proper anatomical movements of the mandible; but because nature makes an effort to readjust the relation of the condyle to the glenoid fossa, and its movement over the eminentia articularis, mankind finds it possible to go on chewing with less movement and less convenience, and so the average wearer of a denture manages to get along somehow.

I wish to emphasize Dr. Hillyer's plea that artificial dentures, as far as possible, should be made so that it will be easy for the patient to adjust himself and to enjoy as easy a use of the mandible as when he had a complete natural denture. In the dental colleges the classes are now being strongly impressed with the necessity of understanding the principle and practical use of the anatomical articulator, and in the course of time, I believe, a large number of dentists will solve these problems in such a manner that their patients will be very much better served than they have been in the past.

Dr. L. M. Waugh, Buffalo. I should prefer to discuss this paper reversely, and speak first of the Gysi articulator, because with this apparatus the condyle movements may be most nearly registered and reproduced, and the technique of application of this apparatus is not as complicated as we have been led to believe. The Gysi articulator has not been practicable until the construction of the recent Gysi scientific articulator. The first one was not practical, because it was made of soft metal. The face-bow was made too soft, and if, in attempting to register the movements of the condyle, any resistance was met, its parts would yield so that a sufficiently accurate movement of the condyle was not obtained. For that reason I believe that the Snow face-bow, in combination with the New Century articulator, while it does not attempt as much as the original Gysi articulator, will yet give uniformly good results for practical work. In the new scientific articulator of Gysi, the softness of the metal has been overcome, and it has been made sufficiently rigid for it to effectually register the movements of the mandible. Those who wish to come near the ideal in prosthetic work will find the Gysi articulator to give the best result that can be obtained, but the New Century articulator together with the Snow face-bow, with which we are perhaps more familiar than with any other anatomical articulator, will give sufficiently accurate results for practical purposes. The Gritman articulator with a fifteen per cent. descent condyle path, and with a fixed path, gives excellent results as compared with older articulators, but the teeth require more grinding than if we set the general direction of the condyle path to suit the individual case, as may be done with the New Century articulator.

When any new invention is brought before the profession, there are a few enthusiasts whose attempts are beyond the practical, and that has been the case with anatomical occlusion. Some men attempt what is away beyond the practical, and they have developed and advocated a technique so complicated that it frightens the average practitioner out of the hope of ever mastering it. Anatomic articulation is not a difficult process; it is simple if we use the Gysi articulator, and still more so if we use the New Century and the face-bow. I feel that in the hands of the average practitioner the apparatus which does not require too much scientific measurement will give better average results than one that does.

Dr. Wheeler has spoken of one or two items in relation to occlusion, the topography of the teeth, and temporo-mandibular articulation. The argument is often advanced that the Snow face-bow is not absolutely accurate. That is true, but can we get anything absolute? If we examine a skull we find the bony head of the condyle fitting in the bony depression of the glenoid cavity, and for years the question of anatomical occlusion was based upon this more or less fixed bony structure. Upon a closer study of the skull, however, we find that, interposed between the condyle head and the glenoid fossa there is a yielding fibro-cartilaginous tissue. In articulation this fibro-cartilage moves more or less back and forth with the movement of the condyle, and there is more or less play in the joint. It is not fixed, like a machine, and there is a certain power of accommodation to which Dr. Wheeler referred, and which largely facilitates our work. In trimming the bite-plate, unless we have the proper amount of wax so that when the patient brings the jaws together there will be sufficient stress to cause the yielding of the ligament in the joint, we shall find a slight opening sufficient to reduce the masticating power necessary for the reduction of foods that offer resistance, such as meats. This factor must be borne in mind, and no matter how accurate our measurements are, and what scientific possibilities an apparatus offers, we may still not obtain the maximum efficiency. There is a certain amount of accommodation in the parts that allows nature to adjust matters. It is common knowledge that dentures are constructed without consideration of the condyle path and the distance of the models from the joints. Yet patients become accustomed to dentures thus constructed—for two reasons: First, they learn to masticate without the use of the lateral motion; secondly, owing to the yielding of the tissues mentioned, during articulation, the denture becomes more comfortable in a year or so.

So much has been said with regard to anatomical occlusion that I do not know which phases it would be best to discuss in detail. The establishment of the retention center is possible with the Gysi, but not with the Snow articulator, and is important in many cases. The incisal guide, while, in my opinion, it is not of much use, gives a little rigidity. One objection to the New Century articulator is that, if one has not learned to use it carefully, he may spring it just enough to throw the bite off, and this is prevented by the incisal guide. This is a feature of the Gysi articulator that the New Century articulator does not possess.

It was my good fortune to know Dr. Gritman when he first had the inspiration of constructing an articulator. I have followed the development of this work, and in studying the different kinds of articulators I have become convinced that the possibilities for producing anatomical occlusion with any one of the anatomical articulators will permit us to make dentures which are efficient from the beginning, and which the patient may learn to use correctly with a minimum of discomfort. With the anatomic method of articulation we are able to obtain results that we could not obtain with the old method.

One point is essential, and I cannot emphasize it too strongly, namely, that we must use a face-bow of some sort and establish the proper cuspal relationship. In other words, we must have the proper occlusal planes of the teeth in artificial dentures, and just in proportion as we do that will our patients find themselves able to accommodate themselves to the plate. But unless we use the face-bow and establish proper articulation, we shall lose one of the most important advantages that anatomical occlusion affords. It does not matter so much what anatomical articulator we use; but we must be acquainted with the method of its application. Its use decreases the tendency to failure; still, obstacles remain that it will not overcome, although it promises to do much better work than has been accomplished before.

We hear so many practitioners say

that they are not interested in this work, that their aim is to care for people who appreciate their teeth and want to save them. These practitioners are closing their eyes to one of the greatest possibilities for the improvement of our efficiency. The aim of modern dentistry lies in prophylaxis, and in the recognition of the fact that the deciduous teeth must be saved from their eruption up to the time when artificial dentures become necessary. The lesson learned in using the anatomical articulator teaches us to recognize a new meaning of the contacts of the occlusal surfaces of the teeth. It teaches us that the proper relationship of the inclined planes is a feature of prime importance, and that the grinding and incisal edges of the teeth mean more than we realized in the years gone by.

Dr. Hillyer (closing the discussion). I do not think it is necessary for me, in closing, to add anything to the discussion, which has followed natural lines.

Report of Fellowship Committee.

The next order of business was the report of the Fellowship Committee, through the chairman, Dr. R. H. Hofheinz, as follows:

Mr. President and Members of the Dental Society of the State of New York,—The Committee on the Fellowship Medal, at a meeting held in Albany last year, unanimously decided to recommend that Dr. James Truman of Philadelphia become a Fellow of the Dental Society, of the State of New York.

R. H. Hofheinz, *Chairman,*
A. L. Swift,
W. J. Turner,
A. R. Cooke,
L. Meisburger,
Committee.

Presentation of Fellowship Medal.

Dr. Baylis, the president, asked Dr. Hofheinz and Dr. Cooke to escort Dr. Jas. Truman to the rostrum. He then presented the metal to Dr. Truman, with the following words:

Members of the Dental Society of the State of New York,—With each passing year the members of this society appreciate more and more the value of the fund placed at its disposal through the generosity of the donor, Dr. Wm. Jarvie, by which the society is enabled to prepare and have suitably inscribed a medal to be presented to some distinguished practitioner of dentistry who by his ability, labor, and self-sacrifice has attained eminence in the profession. The special committee whose duty it has been to select the person to whom the William Jarvie Medal should be awarded this year has made a most happy selection, not only because of the eminence and distinction of the gentleman who will be the recipient, but more especially on account of the very high personal regard in which he is held by all who have been honored with his acquaintance. It is not only a pleasure but also a great honor for me to announce that the William Jarvie Medal will this year be awarded to Dr. James Truman.

For many years as an instructor he has had much to do with shaping the minds and lives of students who have been fortunate enough to come in contact with him. As a writer he has been devoted to the elevation of the literature of the profession. His many valuable contributions to the science of dentistry are well known and appreciated by the profession. Throughout a long and active life he has been a leader in every activity in which he has been engaged, bringing to every subject an energy and enthusiasm which inspire everyone brought in contact with him with the desire to strive for better things and to labor for the uplift of the profession. It may be fitting to enumerate the positions of trust he has held.

James Truman, D.D.S., LL.D., was born in Abington, Pennsylvania, a suburb of Philadelphia, in 1826. He was educated in the public and private schools of Philadelphia. He received his degree in dentistry at the Philadelphia College of Dental Surgery; received the honorary degree of LL.D. at the University of Pennsylvania in 1904. He was demonstrator and professor of operative dentistry in the Pennsylvania College of Dental Surgery from 1864 to 1876; was professor of dental pathology, therapeutics, and materia medica in the University of Pennsylvania in 1882; dean of the University of Pennsylvania from 1883 to 1895, and professor emeritus since 1909. Was editor of the *Dental Times,* 1865–1869; editor of the *International Dental Journal,* 1890–1905, and has been a contributor to various dental publications. He is a member of the American Dental Association, honorary member of the Dental Society of Europe, member of the Pennsylvania Dental Association, the Academy of Stomatology of Philadelphia, and of the Biological section of the Academy of Sciences. He has been in active dental practice for sixty-one years in Philadelphia, with the exception of four years in Waterloo, N. Y., and four years in Germany, at Frankfort, Hanover, and Dresden.

This, briefly, is a partial history of the activities of a most remarkable man. It is a rare privilege to honor one who has been so eminent in his profession, and also has been so faithful in maintaining high standards and ideals. May he live many years to enjoy and receive the honors due him from a profession that he has done much to create, and for which he has devoted many years of ceaseless toil.

As president of the Dental Society of the State of New York, I take great pleasure in presenting to you, Dr. Truman, this medal, which expresses in a small way the love and esteem in which you are held by our members, and in so doing permit me to say that we feel highly honored in having an opportunity to confer this compliment upon one so modest and deserving.

DR. TRUMAN'S RESPONSE.

Mr. President and gentlemen of the New York State Dental Society,—Let me thank you for this unlooked-for appreciation of my efforts. I would hesitate, and do feel a delicacy in taking up your time, but I cannot allow this meeting to pass without a recognition of the deep feelings that stir my inner life today.

I consider myself as an adopted son of New York state. Here I practiced my profession for a period of several years. Here I married my wife. Here two of my children were born. Here I tried to reform the politics of the state, but I must confess with very poor success. Need I say I love this state? Nature has marked it for scenic beauty beyond comparison. I have wandered by the beautiful and placid waters of Lake Seneca; have gazed and acquired poetic inspiration as I have viewed the beautiful hillsides of Lake Skaneateles; have sailed the broad bosom of that great inland sea, Ontario; have stood enthralled amidst the roar of Niagara's mighty waters; have floated down the great river that flows by your doors and have been inspired by the picturesque mountain scenery—have watched as I approached the Highlands, and they seemed ready to embrace the mighty waters as they passed them by; have taken lessons from the Palisades, lessons of geological interest, as these towering walls gave evidence of the mighty power of the waters as the Hudson passed onward to the sea. Amid these manifestations of beauty and power, I said to myself: Our friends the Germans may properly sing of their historical Rhine with its castled and baronial-dotted mountain sides, but give to me, in preference, the American Hudson with its legendary lore, its Sleepy Hollows and Rip Van Winkles, its romance of Indian traditions, as it passes onward in silent grandeur, the most beautiful and majestic of all the mighty rivers that float upon the fair bosom of our great Republic.

I have labored with the mighty men of the past in this state—men from the North, South, East, and West—to rouse dentistry from its crude beginnings. I have seen, in day dreams and night visions, the great Royal Arch of Dentistry, beginning in the crude uprisings of a profession; have seen it magnificently arching the zenith of life and fading away in that seven-hued robe of glory and beauty into infinity; but it remains incomplete, the keystone is not in place—it lies prone and contemned. On it is inscribed this legend: MEDICINÆ DOCTOR. Not that I value degrees would I ask you, men of New York, to assist in placing this stone in position; but for that higher ideal that our profession should stand for—the scientific, the broader culture that this legend represents.

Here, receiving from your hands this beautiful gift, it represents to me, in its radio emanations, the future yet in store for us as one of the important factors in the healing of the nations. In memory I bow in reverential adoration of the men of the past. Here I stand in gratitude to you for this splendid recognition of my very imperfect work. Here I hopefully look into the future as the sands in my hourglass are running low, and patiently await the evolutions and developments of time. [Long-continued applause.]

The next order of business was the reading of a paper by Dr. R. Ottolengui, New York, entitled "Can the Illegal Practice of Dentistry be Limited by Law?"

[This paper is printed in full at page 1008 of the present issue of the COSMOS.]

After the reading of Dr. Ottolengui's paper, the secretary, Dr. A. P. BURKHART, read the following resolutions passed by the Allied Dental Council of Greater New York, together with a telegram:

At a regular meeting of the Allied Dental Council of Greater New York (being the federation of the Eastern Dental Society, the Harlem Dental Society, and the Kings County Dental Society), which was attended by nearly 500 dentists, among whom were some of the most prominent men in the country, the following resolution was unanimously adopted:

Whereas, quackery in dentistry has assumed proportions hitherto undreamed-of; and

Whereas, this quackery is foisted upon an unsuspecting public, jeoparding their health and well-being; and

Whereas, we hold it is the duty of the dental profession to protect both the good name of our profession and the welfare of society in our branch of the healing art; and

Whereas, in the lecture delivered by Dr. Ottolengui before this gathering he has outlined legislation which if carried into effect promises to stamp out this evil, which casts such a slur upon the good name of our profession; therefore be it

RESOLVED, That this gathering most heartily indorses the policy outlined by Dr. Ottolengui, and urges that the State Dental Society, being the official representative of the dental profession in the state, start its machinery in motion to the end that these suggestions be placed on the statute-books and thus become the law of the state.

ALLIED DENTAL COUNCIL, G. N. Y.
S. H. FILLER, *Sec'y.*

Dr. Ottolengui's paper was then discussed by the following gentlemen: Drs. A. S. Johnson, Brooklyn; W. H. Rogers, Brooklyn; Wm. Carr, New York; F. W. Proseus, Rochester; T. P. Hyatt, Brooklyn; L. Meisburger, Buffalo; M. L. Rhein, New York; H. E. S. Chayes, New York; with closing remarks by Dr. Ottolengui.

Motion was then made and carried to adjourn until the evening session.

(To be continued.)

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held May 27, 1913.

The regular monthly meeting of the Academy of Stomatology of Philadelphia was called to order by the president, Dr. Joseph Huggins, in the lecture hall of the College of Physicians, Tuesday evening, May 27, 1913, at 8 o'clock.

The President introduced Dr. A. W. Sweeny, Baltimore, Md., who read the paper of the evening, entitled "The Noncohesive Gold Filling."

[This paper is printed in full at page 1019 of the present issue of the Cosmos.]

Discussion.

Dr. L. Ashley Faught, Philadelphia. I am sure that I voice the thought of all the members of the Academy when I express the gratification with which I have listened to this most admirable paper of Dr. Sweeny. He has not only brought to us a symphony in diction to which it has been most pleasant to listen, but he has written it to a most timely keynote—"Prove all things! Hold fast that which is good."

Dentistry is no novice in progress, and it is not a far cry from the early fathers to the present twentieth-century dentist. In an extremely short period of time the operative dentist has been caught by three successive waves of revolution, and forced to a mental halt and readjustment, that out of revolution might come evolution: First, the wave of cohesive or adhesive or sticky gold; second, the "new departure"; third, the inlay, particularly the gold inlay.

Without any attempt to become chronological, I will ask you to prolong the vision backward, and for a few minutes to study with the essayist of the evening these periods of revolution and evolution.

The early operative dentist was most concerned with an exceedingly simple proposition—a cavity in a tooth, and the development of some means of filling the void. To this operation the term obturation has been applied; the etymology of the word justifying its use, viz, from the Latin *obturare,* to stop; a stopping placed in an opening or hole, just as a glass stopper or cork is placed in the hole of a bottle.

Various substances were used, the most advanced operators—perhaps the most skilful—pronouncing in favor of gold. The main idea was a durable stopping, a replacement as far as possible of that which was lost, possibly the stopping of further decay. The essayist has attended to ringing all the changes, and referred vividly to what was accomplished by the fathers—to the durability of their work. It is quite unnecessary for me to weary you with repetition. Such were the conditions of 1835. As I have stated—and to avoid controversy, I shall avoid chronology—but about that time, or possibly much later, certainly in the decade from 1850 to 1860, came the first revolution, a welcoming of the cohesive property of gold, the renaissance of operative dentistry, a new era of restoration, the drawing of a line between what was, at best, mutilation and disfiguration, and the development of form and beauty.

The war was on, and Robert Arthur's treatise on "The Use of Adhesive Foil" was studied with the deepest interest. In place of flat, broad, approximal fillings came the evolvements of the contourists. To the mere *saving* of teeth *in situ* was added the attempt to restore a useful organ. Almost all here present are young enough—I dare not say old enough—to know of the men who did what was gigantic work, viz, imitating nature—in the language of that greatest of all contourists, "The building of golden mansard roofs upon the priceless pearls, within the ruby portals, for the tooth-spirits to dwell in." The art developed, and thousands became proficient, until in 1893 a prominent manufacturer of gold foils said: "At the present time, the sale of non-cohesive foil is very limited, and grows less every year. Those who use it are old practitioners; in fact, we do not know of any young practitioner who uses it at all."

The revolution was complete, and the establishment of approximal contact and the restoration of approximal contour were the greatest gain of this epoch. The restoring of the typal form of the organ and restoration to its normal position in the arch, perhaps to normal occlusion and normal functioning, were the contributions of ideal effort. Much was gained, but the conservative watchmen noted that much was lost—often the teeth! The exacting nature of cohesive foil, which would not change its inherent working qualities to suit the dentist's theories, had now paved the way to the second revolution in dental progress, namely, the "new departure," its slogan being the same as in the early days, viz, the saving of teeth. More properly speaking, this rebellion was heralded by such statements as—"In proportion as teeth need to be saved, gold is the worst material to use." None, even today, will question the truth of the assertion of the great apostle of the new departure that —"Hundreds of thousands of teeth have been lost, years before their time, from no other cause than that, in using gold, impossibilities were attempted in defiance of incompatibility of material, and despite the unsurmountable physical characteristics which precluded its working." Knowledge, based upon observation, led many in this rebellious period of dentistry to confirm the saying of Dr. C. C. Allen that—"If my life and fortune depended upon the saving of a tooth merely, without regard to its appearance, I *would fill it with amalgam.*"

War was waged against accepted doctrines, until this second revolutionary period led to thoughtful consideration, with the cohorts in dentistry much divided in their struggle for professional place and precedence. In this connection, it is truly remarkable that cements, so utterly unreliable as filling materials, were admitted to be a good material under gold, and well worthy of much consideration.

Now burst upon the horizon my friend and old college classmate, Dr. W. H. Taggart, with his cast gold inlay process, promising the attainment of the highest achievement, viz, the saving of teeth, approximal restoration, and a still further advance—restoration of occlusion. A prophecy has been lately made that "The time has now arrived when the dentist must awaken and grasp the need of making occlusion the fundamental principle of his everyday work." I was much pleased to read this statement, for it has been the primary theme of my own class teaching for the last ten years.

Thus, by the three great epochs I have sketched, has progress in operative dentistry been made, revolution being quite prominent, and evolution the possible attainment. To the query, What is the object to be attained in filling teeth? evolution has developed the classic answer: To exclude agents of decay, to protect the tissues of the tooth, to prevent fracture, to restore shape and function, and to produce cosmetic effect;—a twentieth-century answer, and quite different from that of the nineteenth century. Completeness seems to have been attained. While, with the essayist of the evening, I bow with respectful deference to the forces by which such progress has been reached, I feel with him that there is danger in the alluring possibilities of attainment. And I plead with you for the acceptance of his message that the filling of teeth with gold foil be not allowed to become obsolete; that inlays, gold and porcelain, and silicate cements be not allowed to banish gold foil, and particularly, non-cohesive gold foil, from up-to-date dental offices. They have almost succeeded, but not wholly so, for as Dr. H. B. Tileston has said—"Whoever would practice dentistry in this twentieth century, with the lofty purpose of giving his patrons the best possible service, must be a man of judgment. He cannot afford to be a faddist; decidedly, he should be an eclectic. He will still find many cases in which gold foil can be used to best advantage, and many also in which foil of the non-cohesive variety will give the most satisfactory results."

Did I hear someone inquire where and when non-cohesive foil should be used? I have already spoken too long, and I cannot permit myself to turn this meeting into an occasion for a rostrum lectuie, but an outline answer may be permitted: Non-cohesive gold foil should be used in all occlusal and other pit cavities; in labio- and bucco-gingival cavities, wholly or in part; in the gingival third of all approximal cavities, except in large contour restorations in incisors; against the labial enamel plate in incisors.

It is just these places that I, with the essayist and a few others, plead that we "hold fast that which is good," for, to my mind, the gold inlay has not been proved. Good work with it involves a difficult technique, and it is as weak as its weakest link in the chain, which is the cement. Gold has the one great faculty of "staying put." With the proper redevelopment of the old gold technique, no operator need worry as to the results of his operations, but this cannot be said about any other and later developed method of operating.

Dr. R. Ottolengui, New York. I feel very much embarrassed in approaching the discussion of this paper. When I read it in the manuscript, I thought it would be rather an easy matter to discuss it, but after I have heard it read with all the oratory and enthusiasm of the essayist, I find it difficult to answer, because I am impressed with the fact that this is almost a religion with the essayist, and I was early taught that it is a great deal safer method in life never to argue a religious subject with a religious man. I am therefore going to expose the rift in my armor at once, so that whatever I may say, he may find his answer readily, and I tell him frankly that I know nothing about non-cohesive foil, because I have never used a leaf of it.

I wonder if the essayist would mind my asking if he has any objection to mentioning the name of the man to whom he alluded in the paper as having published an account of filling two teeth with amalgam.

Dr. Sweeny. I omitted the mention of the name purposely, but I will say that it was someone you know very well.

Dr. Ottolengui. That is what I thought. I rather imagined he meant myself, except for the eulogistic manner in which he alluded to the man, until I remembered that everything courteous comes from Baltimore. I want to say a word about these two fillings which were described. These fillings were not, strictly speaking, amalgam fillings, they were amalgam inlays. They were made by burnishing gold foil into the cavities, packing them with amalgam, removing them and keeping them twenty-four hours to set, after which they were polished and put into place, so that, in that sense they were not amalgam fillings, but inlays. I hope the essayist's prophecy that they are still doing service is true, but I doubt it. [Laughter.]

Now I must say a word about amalgam, before I say anything of gold. The essayist has said that the poor are always with us, which evidently is a plea for some kind of filling that will be inexpensive. In my practice, if I were to measure my service by time, leaving out the element of cost of material in any complicated cavity which I had ever filled with amalgam, I would find it necessary to charge more than if I had used gold. And this is where the patient suffers when amalgam fillings are used as a cheap substitute, for he obtains cheap service. So much has been said about amalgam and what amalgam has done—and it is a curious fact that we always find some isolated example cited by some successful practitioner to prove the efficiency of amalgam, as was the case tonight—that, when I hear so much about what amalgam has done, I feel tempted to show what it *has* done. I threatened to write a paper on this subject years ago, and collected from different practitioners who extract teeth a large number of teeth filled with amalgam. I remember that one of these colleagues sent me one hundred such teeth, and out of these only ten of the fillings had ever been polished in any way whatever, and those not on the approximal surfaces. I need not tell you why; you know the difficulties of making amalgam fillings and polishing them, especially in a patient who cannot afford to have it done right. If the patient cannot afford to pay for this work, the dentist cannot afford to have him come back the next day to have the filling polished, and, if the filling is not polished, there are spaces left for food to accumulate. If I could show you some of these teeth, and the masses of amalgam which must have been under the gum, extending almost as far over the margins as into the tooth—these teeth being supposed to be saved, but the cavities being out of sight —you would lose some of the faith in amalgam that is being engendered.

There, then, lies the problem that must be solved in regard to the inlay; we must find a substitute for gold, and here is a curious fact that, when amalgam is used as a substitute for gold foil, we do not necessarily displace the gold foil filling, but, if we find a substitute for gold, good enough for use in inlays, it will make gold inlays necessary. This problem is being attacked now in two or three quarters, and I believe that, in the not distant future, a perfectly good casting metal at a cost of $4 an ounce will be on sale, by the use of which the cost of cast inlays will be considerably reduced.

The aim of this whole beautiful paper has been to point out the need of a filling with which to *save* teeth, and we are just arriving at an appreciation of what the inlay can do, and that in the future we must do something more than save the teeth. We must absolutely restore the masticatory function, and while the credit for pointing out the possibility of this work must go to Taggart, we must also give credit to Dr. Young for pointing out to us that occlusion is of just as much importance to the operative dentist as it is to the prosthodontist and the orthodontist, and this is the message that I want to bring to you tonight.

A great many practitioners are drifting into specialties, and presuming to charge large fees for their specialist services; why should we not imitate the specialist's method? The orthodontist starts by making a set of models, studying the case and explaining to the parents what he must do, if he is to produce in the child a proper masticatory apparatus. The beautifying of the child is a secondary aim; the primary object is to put the teeth in such a position that the patient may masticate food, and the orthodontist points out that a proper masticatory apparatus will be conducive to proper nutrition, and that with such an apparatus the patient will possess a higher resistance to diseases that attack the body—thus, perhaps, by having his teeth correct, he may avoid the necessity of an appendicitis operation. The whole thought is that the correcting of malposed teeth means more to the patient than mere appearance.

Then comes the prosthetic specialist. He takes a set of models, studies the case, and then, with a certain amount of metal and porcelain combined, produces a denture with which the patient can "chew as well as ever" (which was never true once), but for that he is able to charge a specialist's fee, like the orthodontist.

Why do not the operative men do the same? I will pass around a set of models of the mouth of a lady who came to me because she had broken off the corner of a tooth that had been filled. I examined her teeth and found that she had paid an orthodontist a fancy fee to have her teeth regulated—and I knew therefore that she had an appreciation of occlusion. I asked her to let me take a set of models and show her what a poor masticating apparatus she had; and so, instead of patching an amalgam filling for her, I have undertaken to remove a number of shapeless amalgam fillings and large gold inlays, so that I might be able to restore these teeth by reconstructing the occlusal surfaces of eight molars. I am sorry to say that I have only finished one side at the present time, but some day I hope to have the models of the finished case to show you. This is only one example that I bring to your notice of the way in which I think we should treat these cases, viz, start in and take out all those amalgam fillings that may be *saving* teeth, all those cohesive gold fillings that may be *saving* teeth, all those non-cohesive Baltimore fillings that are *saving* teeth, but which are interfering with proper mastication of food by presenting flat occlusal surfaces.

In this connection I must emphasize that whoever says that the gold inlay is the quick method of filling teeth, does not understand the gold inlay method; and whoever says that the gold inlay must be used to the exclusion of every other method of filling, does not understand the purpose of the gold inlay.

We should "prove everything and hold fast that which is good," but just as we appreciate the fact that we must in the future do something more than simply save teeth, that we must cease being mechanics, and become physicians instead, and attempt to save the lives of our patients, just so much will we enter into a more perfect field of work rendered possible for the first time in dentistry.

Proper occlusal planes cannot be made with gold foil, because we cannot carve out the sulci and build up the cusps in the hard metal in the mouth. During the last winter I have re-carved, to the best of my ability, more than forty inlays that had been satisfactory to me when I inserted them, but since Dr. Young has shown us the proper appreciation of occlusal planes in a perfect masticatory apparatus, I have become ashamed of such work, and am attempting to undo it, and so have learned the difficulty of carving teeth as they should be.

While what Dr. Flagg said—"In proportion as teeth need saving, gold foil is the worst material to use"—may have been true, the reverse is true now, viz, exactly in proportion as teeth need saving, we must turn to gold, and such gold must be cast—and if we cast our bread upon the waters, it will come back to us after many days.

Dr. Rhein, New York. I wish to say at the outset that there are a great many of the essayist's aphorisms, if I may use the term, with which I am in thorough accord. I do not believe there is only one way to accomplish anything, and I believe good dentists, men who are really fitted to practice dentistry, can obtain very good results by several different methods. With regard to amalgam, I believe that as perfect a filling for saving teeth can be made with amalgam as with any material we have, but I believe it to be the most difficult material to properly work that we have at our command. Dr. Kirk, who is in the room, very likely remembers a very painful incident that occurred between us some years ago. I agreed to write the chapter on amalgam for the "American Textbook of Operative Dentistry," which I did; but for some time afterward I was a most unhappy individual—for two reasons: I had been giving clinics with amalgam, demonstrating the magnificent results that could be produced by it, but during that time I realized the fact which Dr. Ottolengui has so vividly portrayed to us, that amalgam as generally used means a needless destruction of teeth, because it is employed in dealing with caries in the teeth of the poor. I maintain that operative dentistry is nothing more nor less than a luxury, and that it is impossible to rightfully administer it to the poor, and when that is attempted, instead of becoming a blessing it is an absolute detriment to the people we are endeavoring to serve in this unworthy manner. So when I saw myself going down in history as the "amalgam man," standing sponsor for what I considered the most dastardly thing perpetrated on the human race, I wept bitter tears and put my manuscript in the furnace. This little chapter of history Dr. Kirk will probably recall; it occasioned some unpleasantness between us, and I am glad to make this explanation of my actions at that time.

I have amalgam fillings in the mouths of patients that I inserted thirty years ago that are as good today as they were then; whole buccal walls of molar teeth standing up as smooth and polished as a pane of glass, but this is simply due to the care and time taken in the insertion of these fillings. Speaking of the preservation of teeth for thirty years brings up the most interesting portion of the essayist's paper—the length of time that certain fillings will preserve teeth. There never was a more misleading impression produced upon the minds of people than in regard to this matter—for the reason that the great majority of people between the ages of twenty and forty-five are immune to caries, and it makes no difference what kinds of fillings are inserted—unless inserted in such a way as to produce some unnatural conditions—they will preserve the teeth. Cited cases of fillings mean nothing unless backed up by evidence that the individuals in whose mouths the fillings were inserted were not immune to caries. The gentleman whose mouth we had the pleasure of examining for a few moments this evening is a man who certainly in my judgment is absolutely immune to caries, and has been so for some time past, so that the fillings shown here before the meeting mean nothing in regard to their saving qualities in these particular teeth.

Getting down to the gist of the paper, which is the use of non-cohesive gold: I have used it, but I do not like it. As I said at dinner tonight, there is only one occasion on which I am in favor of the use of non-cohesive gold foil, and that is when I find it in a tooth in which the pulp has died and I want to get to the pulp quickly; under such conditions the filling is so soft that I can get into the pulp very quickly. These are the only occasions on which I am glad that non-cohesive gold may be used. While that statement represents my own individual feeling, successful operators like the essayist have found non-cohesive gold of great value. I wish to point out some of its defects as I see them. Dr. Ottolengui mentioned its greatest defect, and that is the difficulty of properly restoring the masticatory surfaces of the teeth. Reconstructive gold work was never properly understood until two years ago, when Dr. Young of New York enunciated the theory of anatomical restoration of the masticatory surfaces. In what it means for tooth preservation this transcends anything ever presented to dentistry up to that time. To be sure we have spoken of masticatory restoration in a general way. Taggart spoke of it when he brought out the casting process, but not in the absolute restorative sense in which Dr. Young has brought it to our attention.

The essayist says that at a competition between a Philadelphian and a Baltimorean, the Baltimorean succeeded in introducing more non-cohesive gold into a matrix than the Philadelphian who used cohesive gold. I do not know who the Philadelphian was, but I feel sorry for Philadelphia if her reputation is going to rest on such an operator. I am ready to enter a contest and agree to insert more cohesive gold into a given matrix than can any man with non-cohesive gold. I will put more cohesive gold into a given form than any man can cast with the inlay process with the same character of gold. I will agree to put in cohesive gold with a higher specific gravity than non-cohesive gold, and even higher than gold is ordinarily supposed to have. I have with me a plaster model of three teeth in which I inserted cohesive gold fillings several years ago, and since that time I have not disturbed these teeth except that from two of the fillings I have removed portions of the gold and at many different clinics have packed fresh cohesive gold on the original fillings—having done this to illustrate that when a person has mastered the art of manipulating cohesive gold it is easy to make a solid homogeneous filling with it. I have no use for pellets or for cylinders, and years ago I gave up the use of gold foil for this purpose, because I feel that I can best accomplish my purpose with rolled gold. The only essential is that the gold shall be absolutely pure and the operation clean from beginning to end.

As to the question of the time consumed in inserting a filling, I do not think that element should enter into the discussion, for the reason that the saving of teeth properly is a luxury. If it can honestly be made one of the necessities of life and given honestly to the poor, well and good; but we have not reached that time as yet.

This is what we find when non-cohesive gold is used in simple occlusal cavities: As soon as the patient loses immunity, at some point in the margin our explorer will crawl up between the gold and the wall of the cavity. It would not do this, however, a year or so before that, when our patient was in a condition of immunity.

Dr. Black in his able treatise on operative dentistry—and I do not approve by any means of a great many things he says on the subject—brings out with great emphasis the liability to recurrence of caries at gingival and approximal sites, as the result of what he calls the flow of gold from masticatory stress. We do not get that if the teeth are not in occlusion—of course not. I have seen most beautiful operations done by expert operators, and when I have said that the patient could not receive much benefit from these teeth in mastication, the operator has replied, "I am not going to have my work marred by having it chewed upon." It is strange how much work of that kind is to be found if you look for it. This is not operative dentistry, gentlemen, and when Dr. Black speaks of the compound approximal filling under stress as liable to give way at the gingivo-approximal angle he gave the advocates of non-cohesive gold their death-blow so far as its value as a tooth-preserver is concerned—and yet he went on advocating its use, and so do his disciples today. It is the lack of proper specific gravity in that portion of the filling which produces that flow of gold to which he had his attention called, and which I defy him or anyone else to show in any filling of cohesive gold when properly condensed. I use today the electric mallet the same as many men in this room, and have seen its use demonstrated many times by Webb. So it was with astonishment that I heard the essayist speak of Dr. Bonwill's using non-cohesive gold. He may have done so, but I saw Bonwill clinic hundreds of times and I saw him give clinics with the electric mallet, and I never saw him make a non-cohesive gold filling. I watched him closely packing cohesive gold more rapidly, I admit, than any man I ever saw use it. Did you, Dr. Darby, ever see Dr. Bonwill use non-cohesive gold?

Dr. Darby. I saw him use Abbey's non-cohesive gold, but heated to redness.

Dr. Rhein. Then it was cohesive! What difference does it make what gold we use?—it is cohesive gold when one piece sticks to another, no matter what gold we use. I do not use gold foil; I use rolled gold from sixty to one hundred and twenty thickness and with all the dexterity that I think one can display with No. 4 foil. It is simply a question of the individual. It is absurd, however, to speak of Dr. Bonwill clinicing with non-cohesive gold, for the reason that he used Abbey's gold and made it cohesive by annealing. I understand by non-cohesive gold that it is gold which, when not put into the flame, will not stick one piece to another, but instead one piece will slide over the other. There it is that the men in the Wedelstadt district place their greatest stress—on the kind of gold that they use. It must not cohere, so that there is space between the different cylinders.

In conclusion I wish to say that I am not an advocate of cohesive gold fillings as opposed to the cast inlay. I use the cast inlay every day; I use cohesive gold fillings every day, and I inserted an amalgam filling today, but I spent two hours in inserting it. I knew of nothing that would take its place in this particular case, and it was in the mouth of one of the most fastidious patients I have. I say this to emphasize one of the beautiful things the essayist brought out, namely, that every material has its proper place, and that all depends upon the judgment of the man using it. As to cast inlays, the unfortunate thing is that just as dentists seized upon amalgam and wrought all this terrible havoc, they are doing the same with the inlay. I claim that it takes more skill to put in a perfect inlay than it does a gold filling. I claim that the preparation of the cavity must be absolutely on geometrical lines or else the fillings will be imperfect. No cohesive gold filling will take the place of the cast inlay on the masticatory surface, when the inlay is properly made. I wish to emphasize strongly what Dr. Ottolengui said in that direction, because no living sculptor can be found who can carve out from a rough gold block a surface that will reflect the anatomical sulci so perfectly as can be done with the wax model before the inlay is cast—and there alone is where the superiority of the inlay rests, and where the inlay will gain adherents more and more as the point made prominent by Dr. J. Lowe Young, with regard to anatomical restoration of the masticatory surfaces, is more thoroughly understood.

Dr. Darby. I shall say but little, because the ground has been well covered. I am glad that Dr. Rhein called attention to the fact that Dr. Bonwill used gold in the cohesive form. I knew Dr. Bonwill before he came to Philadelphia, and saw him make a great many fillings, but his gold was always well annealed. He used Abbey's soft foil, but he was in the habit of heating it to redness, and it was just because of the cohesive property which the high heat imparted to the gold that he was able to work it so successfully with the electric and mechanical mallets.

In the earlier years of my practice I used nothing but Abbey's gold foil, usually of the non-cohesive variety. In all simple cavities it was used in the form of tape, and often the gold was not annealed until the last piece or two was applied to the filling—simply in order to give the filling a hard surface for finishing. I think Dr. Rhein is wrong in supposing that fillings made of non-cohesive foil are more often defective at the margins than those made of cohesive foil. My own observation would lead me to believe that as perfect adaptation can be made with non-cohesive as with cohesive foil. It is adaptation, not hardness of material, that saves teeth. Dr. Edward Hudson probably knew nothing of cohesive foil, and yet I have seen fillings of his that had lasted seventy years. Dr. Elisha Townsend used non-cohesive gold in making his beautiful fillings—although it has been said of him that his gold was placed on a plate and put in the oven of the kitchen range to heat it, before he packed it into the cavity.

Dr. F. D. Gardiner. I am very glad to have heard Dr. Sweeny's able paper. There are very many suggestions in it with which I heartily agree. The ground has been so well covered in the discussion that there is very little left for me to say. I would state, however, that I believe a filling material should be prescribed to meet the existing conditions; that we should treat caries of the teeth as a disease, and not as merely giving occasion for mechanical intervention. I would say also that I was taught to use non-cohesive gold on the wedge principle, and that I used it with a great deal of satisfaction and success for several years. Later I changed my methods of operating and used cohesive gold exclusively, because it was better adapted to my methods of cavity formation. Either will preserve the teeth equally well. Few operators learn to manipulate cohesive gold accurately. I was taught to use unannealed soft gold in connection with cohesive gold. I have seen operations performed by my preceptor, as beautifully as I have ever seen anybody make them, entirely of unannealed gold on the wedge principle, every layer of gold going to the bottom of the cavity and extending to the surface, and I defy anyone to distinguish those operations from the most perfect cohesive fillings ever made. I have inserted some myself over thirty years ago, and when I see them occasionally, it is only by looking at my records that I can tell whether these fillings were made of soft or cohesive gold.

Dr. C. C. Harris. I had hoped, on coming here this evening, that I would not be called upon to speak upon this subject. The discussion seems to have so completely covered conditions met with in the posterior teeth that there is hardly anything for me to add, except that I would like to emphasize, for the sake of the young operators present, that the building out or contouring of posterior teeth with non-cohesive gold was never advocated. I think all advocates of non-cohesive gold—of whom I am naturally one—intend, as far as possible, that all cavity surfaces should be covered with non-cohesive gold. Into this gold, cohesive gold can be introduced, particularly if the tooth is to be built out at an angle or is to be brought out in contour. I have been practicing over thirty years, and it is very rare and unusual for me to introduce an entirely non-cohesive gold filling. I line the walls well with non-cohesive gold, and then I introduce and pack cohesive gold. The one part of the mouth to which non-cohesive gold is especially adapted is the approximal surfaces of the six anterior teeth. I do not see how anyone who has ever learned the first principles of non-cohesive gold manipulation, and has any sense of the artistic and esthetic, can ever hope to get away from the use of this gold. There are few cases that come to my hands—if I get hold of these cases early enough—in which any gold will be displayed, and with that thought in mind I am going to pass around a case that may interest you, viz, a couple of fillings done by my father twenty-eight years ago. That is my style of work in anterior teeth.

The advantage of non-cohesive gold, after one becomes familiar with it, is that one can save the very thinnest of walls. I care not how thin or frail the walls may be, though they may be as thin as paper, I can cover them with non-cohesive gold and into that pack cohesive gold that will preserve the teeth indefinitely.

I had last summer—pardon the conceit of this remark, because it is not meant in any vainglorious attitude, but simply to prove the principle—a woman who said to me, "Doctor, those fillings are still standing in my front teeth. Do you remember that you told me it would be well worth the time and expense if they lasted only two years, and then, if necessry, to pursue whatever course might be required?" I looked at those fillings with some admiration, and asked how long they had been in the teeth, and she said about twenty-five years. Those walls were as thin as paper; you could see the gold through them, and probably you would not admire that work because of the fact that the walls were so thin, and it might be objected that they should have been cut away. We have a gentleman in Baltimore, Dr. Gingrich, who is quite an adept in and enthusiast for non-cohesive gold, and who uses non-cohesive foil exclusively, while I use cohesive gold in the body of the filling. I sent this lady down to him that he might see this work. He called me up later—and this is the part of his remarks that I hope you will forgive me for repeating—and said, "I want to say that the man never lived, does not live, never will live, who can duplicate that work. You know I think I am something of a non-cohesive gold worker myself, but I would never attempt such as that, nor do I appreciate how anyone else could attempt it. But while I say this, I have something else to say. I do not want you to feel hurt or think that I mean to depreciate your efforts, but I believe that is the only time you ever did it." Within the same month, a woman patient called with similar work in her mouth, even more beautiful as to clearness of margins, and I asked her how long ago the filling had been inserted. She said the work was done thirty years ago, when I was quite a youngster.

Do not understand me to say that my father never used cohesive gold; he used as much of one kind as of the other. Dr. Tucker, for whom in 1878 he built up a bicuspid into occlusal contact with the upper teeth, recently wrote me that this filling and porcelain fillings set with gold are still perfect. I think Dr. Sweeny will bear me out in the statement that this filling has every appearance of a shell crown.

If I can be allowed a few minutes further, I want to say a few words in demonstration of the value of this kind of work: Two years ago a lady came to my office inquiring for my father. I gave her his address, to which she went, and I regret that I did not keep her name and address, for the reason that I lost sight of her afterward. She had in her mouth twelve fillings in anterior teeth, some quite large and as beautiful and absolutely perfect as any operator could possibly make them. She told me that a portion of the work was done by him in 1860, and the rest in 1861, in Harrisburg, Va. Not one filling showed any imperfection or any sign of failure. Within the year past I had a young man in my office with exquisite non-cohesive gold fillings in the masticating surfaces of the lower and upper molars, and likewise such beautiful amalgam fillings as I had never seen before, and if amalgam will accomplish such results as that, it looks to me as though the inlay is a useless acquisition to the profession. These gold fillings were so perfect that I remarked to this gentleman, "You have as perfect fillings, with as beautiful margins, as I have ever seen. This work was evidently done by someone who was graduated more than twelve or fifteen years ago, because graduates of the last fifteen years have not done such work as this." I then asked him who did the work, and he said, "Dr. Darby, of Philadelphia." [Applause.]

In those cases, I do not care whether you pack cohesive gold into the center or not—I personally succeed by packing cohesive gold into the center—but I insist that every cavity shall have the saving lining of non-cohesive gold. I used Abbey's gold for this purpose as long as it was available to the profession.

Dr. Darby alludes to Abbey's gold being made cohesive by annealing. I would feel awkward and foolish not to agree with Dr. Darby, but I will say that one cannot make Abbey's gold cohesive in the sense of other cohesive gold, by annealing. It is, however, possible to do the following: If one is inserting a large filling, he can line the cavity with non-cohesive gold and then run the next ribbon through the flame, which helps the cohesive gold to take hold, but does not render it cohesive in the sense that cohesive gold is adhesive.

Dr. Sweeny (closing the discussion). The hour is very late, and in view of the fact that the only gentlemen who have really offered any contention have left, it hardly seems charitable to say much in rebuttal of their testimony.

It is useless for me to say how thoroughly I appreciate your reception of my effort—it is a great gratification to me. But, great as that gratification is, there is another which vastly transcends it, viz, that arising from the very hearty and unmistakable manner in which so many have testified to their appreciation of a scientific fact. By your testimony in that direction you have simply added to the long chain of evidence that you are indeed exactly what you claim to be, namely, a body of true scientists and true professional men, and that, as such, you desire above all else knowledge and truth, and you want that knowledge no matter what theories may be affected by its promulgation—that is what affords me that greatest satisfaction. If I could afford to take up your time, I might say a little in rebuttal of the statements of Dr. Rhein, but I will answer briefly.

Here is a tooth [demonstrating]—a very commonplace-looking affair as you look at it casually; it has a fair-sized, plain-looking filling in the center, such as all of you have seen thousands of times, and, on the face of it, it does not mean anything at all, but when you realize that it was put in by Dr. Cockerille in 1863, and that the tooth was extracted by Dr. Gingrich in 1911, it is a pretty good rejoinder to Dr. Rhein's statement that, if conditions tend to the production of caries, we will be very apt to find little pits around the margins. My experience has always been that one is more apt to find them around margins of cohesive gold fillings. I want to pass this around, and wish you to observe that conditions which promote caries exist, because there is a cavity on the side of the tooth.

I can scarcely refrain from saying a word or two in reply to the two gentlemen from New York. That was a pretty fair and reasonable statement by our friend from New York, but it hardly measures up to the standard of what he has before announced to you as to his views on this subject.

I have not been as long or as actively engaged in the practice of dentistry as some of my *confrères,* but I have spent quite a little while at it, and, if there is any consideration whatever in filling teeth that is of greater importance than saving the organs, then I am under a sad misapprehension of my duties. If it should be proved in time that we can get this restoration of occlusal surfaces and possibly more restoration of contour and an equal, or even, if you like, a greater amount of efficiency in the direction of tooth preservation, then indeed the passing of the gold filling will have been fully accomplished. But we have not advanced to that stage as yet, and I am strongly inclined to think that, no matter what advanced ideas we may take up, when we attempt to inculcate those ideas into the minds of our patients, and tell them that there is any consideration whatever which can outweigh, or that all other considerations combined can outweigh, the saving and preservation of their teeth, we will be likely to find a tremendous majority coming from Missouri, and they will want conclusive and substantial evidence.

Though I regret to have to tire you on personalities when there is no opportunity for rejoinder, I am almost of the opinion that if our distinguished colleague, who unfortunately was compelled to leave us, had in his own molars some such fillings as those which Dr. Niman has so kindly offered for your inspection, or some like those of Dr. Bonwill's patients—conscious though they may be of the fact that the missing portion of the occlusal surfaces of the teeth were not reproduced in ideal perfection, but in so thoroughly practical a manner that they were never conscious of any deficiency in the performance of the act of mastication—I think it would be safe to say that he would hesitate a long time before he would consent to the removal of a single filling in order to make place for the most perfectly formed inlay that could be made.

My chief object in coming before you was not to exploit anything whatever to the exclusion of anything else of value, but simply to try and impress upon your minds, with all the earnestness possible—and especially on the young men, who are to be here long after many of us have gone—the importance of the fact that, while they are waiting for the perfection of the inlay process—waiting for that long-sought panacea, the perfect filling—they may avail themselves during that interval of something which has so long succeeded as a preserver of the teeth. That, gentlemen, is the principal object of my coming before you.

Again I do not wish to be personal, but there is a dear young friend of mine, sitting in this audience, who holds a teaching position in one of our colleges, and who told me not long ago that he did not know anything about non-cohesive gold; that he had never used a scrap of it, and had never seen a particle used, and when I told him that an entire book of non-cohesive gold could be packed into a tooth in a quarter of an hour, he raised his eyebrows, and although he was too polite to say so, looked very much as though he thought I was romancing. But, gentlemen, you can do it, and for the benefit of these young gentlemen I would say that until you know that you have something better, hold fast to that which has proved itself to be very good. You cannot hope to become, in a short while, as proficient in the use of non-cohesive gold as were the old masters—maybe not one of you will attain such perfection, but that does not really matter, because anyone who will bestow the same amount of care and attention that is being bestowed today on inlays, can learn to make thoroughly substantial and durable operations.

The meeting then adjourned.

EDITORIAL DEPARTMENT.

THE INTERNATIONAL DENTAL FEDERATION—"F. D. I."

IT is now thirteen years since the F. D. I. was organized, at the close of the Second International Dental Congress, held in Paris in 1900; its annual meetings have been uninterruptedly held each succeeding year, the latest having convened at the Hague, August 27th, 28th, and 29th of the present year. As we have pointed out in these pages on previous occasions, this international body came into being not as the expression of any selfish or local professional interest, but as the spontaneous materialization of a generally felt need for an arena in which might be threshed out in debate those fundamental problems affecting the progress and development of dentistry as a whole, and especially the relations of dentistry to society at large and to the public service.

In the very nature of the case, because of the international character of the organization and its cosmopolitan membership, it was at the outset understood and clearly specified in the organic law of the body that its functions were purely consultative and advisory—that it did not desire nor could it acquire any legislative attributes effective outside of its own membership; that its usefulness, apart from the opportunities which its meetings afforded for the discussion of problems of international interest, rested solely in the weight which its conclusions might derive from the character and professional reputation of its members and such value as would attach to their findings as expert authority. In short, the sole influence which, in the nature of the case, it is possible for the F. D. I. to exert upon dental professional advancement is a moral influence, directive and advisory in its method. Upon that basis, and without legalized authority to enforce its conclusions, the work of the F. D. I. has proceeded during the thirteen years of its existence, showing each year an increasing and enlarging influence in its harmonizing and unifying effect upon the policy and activities of dentistry as manifested in the several nations of its constituent membership.

Each nation has felt that its dental professional activities required the stimulation of comparison and competition in order to shake off the incubus of provincialism that inevitably impedes progress in any direction where a nation or an individual lives, or attempts to live, a self-contained life. The process of evolution of dental training, dental legislation, dental procedure and practice, in the several countries of Europe and America respectively had developed peculiarities of method characteristic of each, and it was generally felt that opportunity for discussion and comparison of ideals and methods would not only be mutually helpful, but would tend to put the world's dentistry upon a more stable and uniform basis. The creation of the F. D. I. supplied the forum in which dental professional problems could be discussed from an international viewpoint; and since its establishment its members have had the great satisfaction of witnessing the ever-increasing influence which it has continued to exert in advancing the ideals and purposes which brought it into existence.

It is worthy of note that wherever the F. D. I. has met in Europe it has always been under the highest governmental patronage or under the auspices of the constituted educational authorities of the country. It has thus contributed to improve and advance the social relations and status of professional dentistry in a way and to a degree not possible for any less cosmopolitan organization to do. If the F. D. I. had done nothing more than what it has accomplished in a purely incidental way for the larger social recognition of the dental profession it would have amply justified its existence. It has, however, done more than any other single influence to modify and unify the standards of dental education in the several countries represented in its membership. Its earlier period of activity was concerned more particularly with the great underlying question of the educational features of the dental professional curriculum—for it is a self-evident proposition that divergences of method in the professional education of practitioners result in corresponding differences of ideals and methods in dental practice; hence a fair degree of unanimity in educational methods becomes an essential prerequisite for the unification of standards of professional practice. The discussions of the educational problem by the F. D. I. through several annual sessions resulted in the concerted recommendation of a plan of curriculum which has since been either wholly adopted or at least has served to extensively modify the curricula of the dental educational institutions whose nationalities were severally represented in the membership of the international organization. In the accomplishment of this purpose the F. D. I. has promoted a step which has distinctly advanced the work of unification of the standards, both educational and legislative, of the dental profession of the world.

The universal interest which has been aroused in the public service relations of dentistry is a question with which the F. D. I. has been definitely concerned, and with which at the present time it is most prominently occupied. The conditions which determine or modify the relations of dentistry to the public service in the several countries of the world are extremely varied and complex, being the reflex of social and governmental conditions in each of the countries concerned. The F. D. I. therefore logically becomes the arena in which these differences may be best studied, and where the influences may be put in motion leading to their proper adjustment. The meetings of the Hygiene Commission have constituted a clearing-house of ideas in relation to the public dental service in all countries, and for the present the deliberations of this commission are the most important and valuable activity of the F. D. I.

The public service question has not been allowed, however, to overshadow certain other activities of this important international body. Its established purpose of stimulating scientific research is practically manifested in the creation of the Miller prize annually awarded for the highest attainment in dental science or practice, constituting an honor not second to any within the gift of the dental profession and a stimulus to scientific and professional attainment in dentistry throughout the world.

The official relation of the F. D. I. to the authorized series of international congresses was early established, having been confirmed by the congress at St. Louis in 1904 and at each subsequent international dental congress;—for which reason, together with the others already referred to, it is important that in the consideration of our national and state organizations and their multifarious relations and interests we do not lose sight of the significance of this great international organization, in which our own national body is officially represented. It is especially pertinent at this time that the leaders of our national body keep in touch with the activities of the F. D. I., in view of the approaching congress to be held at San Francisco in 1915, in connection with the Panama Pacific International Exposition—for if that congress is to have a *de facto* "international" character it should become officially allied with the F. D. I. in order to avail itself of the general and weighty influence of that body, especially throughout Europe.

Note.—Dr. VAL. MACDONALD, whose article, "A New Method of Treating Empyema of the Antrum," was published in our May issue, calls attention to a typographical error on page 501, viz: *For* "salol solution" *read* "SALT solution." Referring to the method he mentioned, of placing the indifferent electrode *under the chin,* and employing a special headgear for its application, he writes that he does not now consider the plan to possess any special advantage. He says: "In all ionic treatment I now apply it to the wrist, or even allow it to be held firmly into the palm of the hand."—ED. DENTAL COSMOS.

The Ontogeny of the Primate Teeth.

Die Ontogenie der Primatenzaehne. [Odontologische Studien I.] Versuch einer Loesung der Gebissprobleme. Von Dr. L. Bolk. Ss. 122, 2 Tafeln, u. 74 Abbildungen. Jena: Gustav Fischer, 1913.

This is a comparative study, concentrating on the very earliest steps in tooth development. The results, if confirmed, will necessitate a radical revision of the usual descriptions based on Röse's classic of 1891.

In this study, Bolk has examined the several teeth, at different ages, in eight primate species, including man. He has used the wax-plate reproduction method to confirm the study of serial sections.

He describes four structures which may almost unconditionally be said to have been hitherto absolutely unknown. These are (1) the lateral enamel ledge, (2) the enamel crypt, (3) the enamel septum, (4) the enamel navel. These structures are seen in both deciduous and permanent teeth.

The lateral enamel ledge is a wing-like or buttress-like outgrowth from the dental ledge, arising separately for each tooth. It projects laterally (labially or buccally) and attaches to the lateral side of the enamel organ in all cases. In isolated transverse sections the lateral ledge and dental (mesial) ledge give the impression that the enamel organ is connected with the oral epithelium by two strands.

The enamel crypt is a niche, having the dental ledge for its mesial wall, the lateral ledge for its lateral wall, and the top of the enamel organ for its floor. Its cavity is filled with mesenchyme, which is in wide connection with the jaw mesenchyme. In the incisors this opening is directed proximad, in M_3 distad. Between these teeth the transition is gradual.

The enamel septum we must describe from a different viewpoint. Instead of one center for the differentiation of the enamel pulp, Bolk has found two—one mesial (lingual) and one lateral (buccal). Between these, for some time, exists an area of undifferentiated cells in the form of a septum running in an approximo-distal direction. In transverse sections it stretches from the external epithelium of the enamel organ to the stratum intermedium. This septum divides the body of the enamel organ into a mesial and a lateral division.

The enamel navel is a groove or depression in the external epithelium of the enamel organ, just at the point where the septum touches this layer. This groove further accentuates the division of the enamel organ into a mesial and a lateral half, suggested by the septum.

Bolk offers a semi-hypothetical account of the process by which the above structures and their relations are produced. He interprets these facts as meaning that each primate tooth arises by the fusion of two separate *anlagen*—that is, each primate tooth is a double structure, equivalent to two reptilian teeth. The theory is therefore termed the Dimeric. The lateral division of the mammalian enamel organ is the *protomere,* the mesial division the *deuteromere.*

There are three principal objections to this theory. Bolk takes up each separately and decides that none of them is insuperable.

To generalize his theory for the mammalia, he studied series from four other orders, and finds therein these same structures.

Chapter III deals with the "accessory ledge." This is almost a side issue to his main argument, but is introduced to make clear some points in Chapter IV. This ledge is generally interpreted as evidence of a prelacteal dentition. Bolk homologizes it with that ledge from which the glandulæ labiales are developed in certain reptiles. He has found no evidence in favor of a prelacteal dentition, and doubts its existence.

The fourth and last chapter deals with the relation between reptilian and mammalian dentitions. In its essence it has been already abstracted (see DENTAL COSMOS, January 1913, p. 102). Bolk has in the course of this monograph reported many other very interesting observations, but they are relatively details and cannot be given here.

Bolk's theory is a praiseworthy attempt to compromise between the theories of differentiation and concrescence. In brief, this compromise is as follows: In the reptilian ancestor of the mammals a triconodont *differentiation* had been instituted. So much is in agreement with the views of Cope, Osborn, etc. Two such triconodont teeth—one buccal, one lingual—became fused. This is the peculiarly mammalian process, and therefore, is the origin of the mammalian tooth. Bolk allies himself essentially with Röse. This fusion of two triconodont teeth, the lingual side of one to the labial side of the other, would yield a six-cusped element as the typal mammalian tooth. The principal variations in cusp topography among the mammalian orders arise by a secondary reduction of this six-cusped tooth.

This supposition of Bolk's permits the utilization of much paleontological evidence collected by Cope, Osborn, etc. It employs all the embryological evidence advanced by the classical concrescence theory, and it eliminates the confusing and unwarranted assumption that each cusp of the mammalian tooth represents a single reptilian cone tooth.

However novel this Dimeric theory appears, it is nevertheless interesting to note that in 1911 d'Éternod read a paper before the twenty-fifth meeting of the German Anatomical Society, in which he held that "Toutes les dents humaines sont des bicuspidées modifiées," and promised later to publish researches of thirty years in support of this view.

Of more immediate interest to the dentist are the structures newly observed by Bolk. His report demands a restudy of the initiation of tooth development in man, and if found warranted, prompt revision of our present text-book description.

As the second study in this odontological series, Bolk promises to report on "The Anatomy of the Primate Dentition."

SILVER NITRATE AND ITS APPLICATION IN DENTAL PROPHYLAXIS. By DR. F. BROSIUS, BERLIN.

The various uses of silver nitrate and its generally acknowledged though not generally enough used advantages are discussed by the writer under a classification of six groups, the first being the deciduous teeth and the first permanent molar. In these teeth, a from 30 to 40 per cent. solution is applied with cotton and a pointed orange-wood stick to all pits and fissures, which have been previously freed of any adhering food débris by an explorer. The tongue and lips are protected with a linen napkin. In carious teeth, any portions of leathery decay are removed with sharp excavators, care being taken not to come too near the pulp, as silver nitrate, if applied to an exposed or nearly exposed pulp, invariably produces a purulent pulpitis. The fundus of the cavity is saturated with the silver nitrate solution, which is allowed to act for several minutes, and the cavity is filled with oxyphosphate cement. In very sensitive teeth a twist of cotton saturated with the solution may be laid in the cavity, and sealed-in temporarily with Fletcher cement. The second deciduous molar should be cleansed mechanically, as well as by silver nitrate chemically, in order to prepare the field for the eruption of the first permanent molar, which in turn, when erupted, should be carefully observed, and the fissures of which should be treated prophylactically as described.

The writer applies the silver nitrate to the cervico-approximal, cervico-buccal, and cervico-lingual cavity margins before inserting fillings, thereby preventing the recurrence of caries in these most vulnerable areas. If the drug is applied carefully and the cavity preparation is correctly made, the discoloration at the cervical margin cannot be seen.

During periods of great nervous tension, as in pregnant and hysterical women, men suffering with nervous breakdown, convalescents, and during puberty, the progress of caries and the hyperemia of the gingivæ can be prevented to a great extent by painting the lingual tooth surfaces, especially their cervical portions, with the silver nitrate solution, and observing a strict dental hygiene.

In atrophy as well as hypertrophy of the gingivæ, painting with silver nitrate solution, in the former condition combined with massage, is favorably indicated.

Single teeth in old persons, abutment teeth, teeth in contact with artificial dentures, and teeth which bear clasps, can be successfully preserved for a long time by repeated silver nitrate treatment, which is also indicated as a prophylactic measure against the formation of chemical erosions.

The black discoloration can be removed by touching with tincture of iodin or sal ammoniac.

[*Therapeutic Gazette*, Philadelphia, July 15, 1913.]

UNTOWARD RESULTS OF QUININ AND UREA HYDROCHLORID AS A LOCAL ANESTHETIC. REPORTS OF THERAPEUTIC PROGRESS.

This abstract contains an interesting report of several cases of untoward effects of quinin and urea hydrochlorid, the danger of the application of which as a local anesthetic in dental practice has been pointed out before in these columns. (See DENTAL COSMOS for February 1913, p. 169.) In every case cited, extensive sloughing was noted, and the healing process was considerably retarded. In one case of Dr. Arthur Hebb's an extensive abscess followed the use of a one per cent. solution. Again, in another case, the injection of a two per cent. solution of this anesthetic mixture was followed on the third day by a rise in temperature to 103° F., which continued daily for four or five days. Not until the fifth day did the wound show any sign of breaking down; on the fifth day, there was a distinct slough of considerable size beneath the mucous membrane which, after a few days, broke down, followed by a discharge of liquid pus. A similar result has been reported by Dr. H. H. Rightor. Though the anesthesia was perfectly satisfactory, considerable discoloration of a violet hue was observed on the day following the operation, lasting for five days. The anesthesia of the tissues persisted all this time. On the seventh day there was a foul odor and well-marked localized gangrene, extending to the line of infiltration entirely around the line of incision, but no suppuration, necessitating the removal of the gangrenous mass with tissue forceps.

The cases reported surely warrant extreme care in the daily as well as casual employment of this solution in dental practice.

[*Zanaerztliche Rundschau*, Berlin, May 4, 1913.]

THE PROBLEM OF ROOT-CANAL FILLING IN CONNECTION WITH ROOT RESECTION. BY DR. B. MAYRHOFER, INNSBRUCK.

Opinions are still divided as to whether, in a tooth the root-apex of which is to be resected, the canal should be filled before, during, or after the operation. The last method has practically been abandoned, since after resection of the root, the wide aperture of the apex allows the invasion of blood and serum into the root-canal, and irrigation of the root-canal with strongly antiseptic solutions is not only insufficient, but very harmful to the healing process of the alveolo-gingival wound. Whenever possible, Mayrhofer fills the canal before resection with balsam of Peru and round gutta-percha points sterilized in alcohol. These points are introduced by means of sterile pliers, the beaks of which are oval and allow of easier manipulation of the points than flat-nosed pliers, and packed as tightly as possible by means of a strong, rigid root-canal probe of suitable angle. In this way the mechanical obturation combined with the bactericidal action of the balsam of Peru prevents the recurrence of bacterial growth. If any gutta-percha is forced through the apical foramen, it does no harm, as the apex is resected subsequently; on the contrary, any protruding gutta-percha acts as a guide during the operation of resection. If a root-canal cannot be filled to the apex, owing to its tortuous form or its narrow lumen, or if blood or serum persistently invades the root-canal, Mayrhofer finds root-canal filling during the operation excusable. Even in such cases, however, he prefers to obturate the uppermost portion of the root-canal, which is subsequently resected; he then carefully cleanses and sterilizes the remaining portion of the root-canal, and fills it with balsam of Peru and gutta-percha points in the manner described. If, as it sometimes happens, the filling of the canal causes excessive pain, an anesthetic can be forced through the root-canal. It is always advisable to make the root-canal filling and apical resection in one sitting, and to close the gingival wound by suture, thereby insuring a very rapid process of healing.

[*Journal of the American Medical Association*, February 22, 1913.]

THE SERPENT'S TOOTH IN FORMALDEHYD. BY DR. W. E. MORGAN.

[*Le Laboratoire et le Progrès Dentaire*, Paris, March 16, 1913.]

SEVERE FORMALDEHYD INTOXICATION. BY J. WATT.

The reckless freedom with which formaldehyd solution and its derivatives are used in hospitals, by surgeons, dentists, boards of health, and food preservers, leads the writer to call attention to the dangers attendant on the use of this most insidious drug, which have been pointed out in former issues of this journal. (See DENTAL COSMOS for February and September 1913, pp. 147 and 957.) There is no doubt that a personal susceptibility has much to do with the effects, but the number of unfortunates who, with the best intentions, have been using this drug, especially since Dr. Buckley's introduction of tricresol formalin, is becoming so great as to place formaldehyd at the head of the list, not excepting the X rays, of irritants of the skin and the mucous membranes, while its results are so serious as to leave those tissues peculiarly weak in their resistance to other irritants.

Since formaldehyd has been announced as the proper ingredient for the denaturing of alcohol, the amount designated being one part of the forty per cent. formaldehyd solution to 250 parts of alcohol, the use of this denatured preparation for surgeons' and dentists' hands and in the operating room in general has produced an appalling number of untoward accidents of the kind described above. The writer relates his own experience with a chemical dermatitis of four weeks' standing, due to formaldehyd, the affection assuming very disagreeable and extremely painful proportions. Like all other chronic forms of dermatitis, the affected surfaces are peculiarly susceptible to heat and cold, alkalis and acids. Soaps made of animal fats, ointments containing animal fats such as lanolin or lard, emollient preparations like cold cream, and the viscid liquid preparations so universally used for chapped hands and face, should not be employed in these conditions; are all intensely irritating and provocative of profanity, while the soaps made of vegetable oils and the vegetable or mineral oils themselves are very soothing.

Solutions or ointments containing lead, zinc, tar, oil of cade, ichthyol, and the various combinations of salicylates and pyrogallates are all temporarily beneficial in formaldehyd dermatitis, but seem to be provocative of new circles of intensely burning and itching, red, minute papules of acute character at the margins of the old. So many members of the medical and dental professions have been invalided physically, incapacitated for professional work, deprived of livelihood and rendered nervous wrecks by this peculiarly subtle and all-pervading vaporous poison, that it should be relegated to the uses of the undertaker and pathologist only, and only then used with extreme care. Every practitioner should be as careful in the use of formaldehyd as he would be with a bottle of bromin—for, once stung, repentance is vain.

In view of the fact that formaldehyd is now known by experience to be so dangerously irritant, not only to the skin but also to the mucous linings, as in the eye, mouth, and nasal passages, and because its efficacy as a germicide and disinfectant is now seriously questioned by some of our best pathologists and masters of sanitation, and since its special use in root-canal treatment can be supplanted by that of several other and no less efficient drugs, may we not wisely discard it altogether?

For the benefit of his fellow sufferers, the writer outlines the best attitude toward formaldehyd thus: (1) Avoid it entirely. (2) Wash the hands or affected parts not more than once a day with lukewarm water and a vegetable oil soap, such as Castile. Avoid green soap made with a fish oil or any animal oil soap. At other times use olive oil or cottonseed oil for cleansing purposes. A little phenol added to such oil—ten minims to one ounce—keeps it from becoming rancid and adds to its soothing quality. (3) Apply to the affected parts, two or three times daily, an ointment made of zinc oxid one part, starch two parts, and petrolatum eight parts. During the vesicular and acute stage this should be applied without friction; but after the epithelium becomes dry, and the derma somewnat thickened and scaly, the ointment can be rubbed in, and the zinc reduced somewhat. (4) Avoid all powders except sterilized starch, and then during the vesicular stage only. (5) Rubber gloves cannot be worn for more than from three to five minutes without producing marked irritation by reason of the confined perspiration. (6) Wear a cotton protecting sleeve or glove, or both, night and day, until thoroughly healed. Silk or woolen goods cannot be allowed to touch or rub the affected part without producing irritation.

Watt investigates the effects of commercial formaldehyd, viz, a 40 per cent. aqueous solution, when taken internally, and remarks that the toxicity and symptomatology of this irritant poison are still little known. He reports the case of an alcoholic of sixty-three years of age who had taken about 28 grams of commercial formalin intended for purposes of disinfection. He was brought to the hospital in a state of complete unconsciousness, and died despite syringing of the stomach, administration of stimulants, and artificial respiration.

The symptoms observed in the various cases described by the writer differ greatly, evidently according to the quantity of the drug ingested. Tendency to vertigo, loss of consciousness, and more marked involvement of the respiratory apparatus than the circulatory system are noted in almost all cases. The predominance of cerebral symptoms which are rapidly followed by death does not allow enough time for the phenomena of irritation of the heart and digestive system to develop fully, except for initial vomiting. In conclusion, Watt places the toxicity of formaldehyd on a par with that of phenol.

[*Zahnaerztliche Rundschau*, Berlin, January 19, 1913.]

PHYSICAL STUDIES ON IMPRESSION COMPOUNDS. By Dr. F. Schoenbeck, Leipzig.

The plastic impression materials used in dentistry are composed chiefly of resin and stearin, to which, for the sake of obtaining a certain consistence, fillers such as talcum are added. Some dyestuff and a few drops of an ethereal oil improve appearance and taste. Under a low-power microscope these materials present the picture of a uniform surface, permeated with fatty acid needles, particles of coloring matter, and grains of the filler employed. Besides these we observe more or less dissolved resin particles, which are easily recognized by their yellow color. The size of these resin particles directly influences the plasticity of the material, which should possess the following properties: It should soften at a temperature higher than that of the mouth, should possess great plasticity, uniform structure, should give a sharp impression, should not stick, should harden quickly in the mouth, and should not contract or expand to any great extent, though a slight expansion is not detrimental. The temperatures at which the various impression materials tested became soft and workable varied between 41° and 45° C. The size of the grain of the filler employed greatly influences the plasticity of the material. The amount of contraction in an impression compound can be determined—First (and unsatisfactorily), by a ruler and calipers; second, by the micrometer. The tests carried out by the writer with the micrometer method showed in the various brands examined a variation in contraction of from 0.005 to 0.035 mm. For very delicate measurements he uses a telescope the lens of which is provided with a micrometer scale. A rod of impression material, about 5 cm. in length and ½ cm. in diameter, is fastened to an upright glass rod. After cooling, the length of the impression material is marked on the glass rod, which is immersed in a square water-bath. The temperature of the water-bath must be regulated so that the impression material will soften but will not become distorted. The mark made on the glass rod is observed through the telescope and noted, and the same observation is repeated after the water-bath has cooled down to room temperature. A comparison between the two observations will determine the amount of expansion or contraction that has taken place. For still more accurate measurements, a combination of the telescope described and two micrometers has been used by the writer.

On the whole, the volumetric changes in impression materials do not differ very widely, since a difference in temperature of only about 20° is to be reckoned with, the various materials being workable at from about 40° to 60° C.

If placed in boiling water, the composition of modeling compound is altered entirely. Fatty acids and resin particles are dissolved or melted out, and the change in the quantitative ratio of the materials contained in the compound naturally alters the physical behavior of the mass.

In order to obtain a homogeneous, plastic mass, the softened compound should be kneaded thoroughly, microscopic examination showing a much more uniform distribution of the filler in the kneaded mass. Kneading also discloses any large particles of resin which may be embedded in the compound, and which can be easily removed before taking an impression.

[*L'Odontologie,* Paris, May 15, 1913.]

IODIN IN DENTAL THERAPEUTICS.

By Dr. Siffre.

With all its excellent qualities, iodin has one great fault, viz, it is volatile, and even the greatest precautions cannot prevent the dispersion of its vapor, which attack metals such as steel, nickel, silver, or German silver, and produces discoloration even in porcelain. But this very quality of vaporization renders this drug valuable in dental therapeutics, especially in dental caries. First of all, iodin does not produce pain when applied to hypersensitive dentin or to pulp. In fractures in children's teeth, the continued daily application of the alcoholic tincture of iodin stimulates the pulp to the formation of secondary dentin, disinfects the fractured surface, and saves the tooth for ulterior restoration by an inlay, a filling, or a pivot tooth, the iodin preventing suppuration and death of the pulp, or chronic pericementitis, which would otherwise follow such an accident. Iodin is especially favorably indicated in carious teeth of children who are unwilling or unable to have fillings inserted. In cavities in deciduous teeth, the writer recommends the introduction of a pellet of cotton saturated with ordinary tincture of iodin, or oil of geranium with 10 per cent. iodin, this application being very simple and abating the pain in pulpitis. After a few daily applications, the tooth is sterilized, and gingival fistulæ disappear.

In order to insure full benefit of the iodin, which in the alcoholic tincture volatilizes too rapidly, the aqueous solution is preferable. This is obtained by adding iodin crystals to an aqueous solution of potassium iodid, in which iodin can be dissolved in all proportions. As an excellent formula, Siffre recommends the following: Iodin crystals 1 gram; potassium iodid 0.50 centigram; glycerin, a few drops, to cover the I and KI, which are allowed to dissolve by stirring from time to time. The resultant liquid is thick and very stable, and emits only very little vapor, so that it can be preserved in a bottle covered with a bell jar. Repeated application of this iodin-glycerin on cotton sealed in cavities with gutta-percha and left for a week prevents recurrence of caries. The glycerin is removed from the cavity before final filling, by wiping with alcohol and drying with hot air. If any other metal but gold, which is not attacked by iodin, is used for the filling, such as amalgam, silver, tin, or copper, an iodid of these metals will be formed which, by its antiseptic action, prolongs the life of the tooth. For treating root-canals, a paste of iodin, glycerin, and tannin, which hardens and produces relatively little discoloration, can be used advantageously. At any rate, any stains can be removed satisfactorily by repeated washing with alcohol and drying with hot air.

Periscope.

Preventing Solder from Flowing.—Any portions of a crown or bridge to which it is undesirable that solder should flow are coated with ordinary ink, after heating the piece. The borax is subsequently applied, and the solder will be confined to the desired areas.—*Journal Odontologique*, per *Sud-Est Dentaire.*

Clasps of Cast Gold Contra-indicated.—The casting of gold clasps is not to be recommended. The elasticity of the gold, essential in a clasp or spur, is destroyed by casting, while in drawing or swaging this quality of the material is preserved.—*Le Monde Dentaire,* per *Revue Trimestrielle Belge de Stomatologie.*

Desensitizing Hypersensitive Dentin.—If, in excavating a cavity, hypersensitive dentin prevents further progress of the operation, a solution of equal parts of zinc chlorid, tincture of iodin, and distilled water is applied on a pellet of cotton to the cavity for from two to three minutes. If necessary, the application is to be repeated.—*Oesterreischische Zeitschrift fuer Stomatologie.*

Preventing the Sticking of Modeling Compound.—In order to prevent the sticking of softened modeling compound to the fingers of the operator and burning them, the hands should be thinly coated with vaselin oil. By applying a thin coat of the same oil to the surface of the soft compound, its adhering to the teeth or mucous membrane, hence distortion of the impression, is avoided.—*Journal Odontologique,* per *Sud-Est Dentaire.*

Leukoplakia Cured in Four Days by an Injection of Salvarsan.—In the case reported, the patient, a smoker, with syphilis of five months' standing, was unable to take food or use tobacco. The injection of the salvarsan was but slightly painful, and the patient was able to go about his business without interruption. Healing ensued within four days. A similar remarkably rapid cure of smokers' patches in a syphilitic by salvarsan was reported in 1910 by Balzer.—*Revue Dentaire,* per *Revue Trimestrielle Belge de Stomatologie.*

Inserting a Shell Crown on Posterior Teeth.—In adjusting a shell crown on upper or lower molars, fingers and thumbs are much in evidence. To overcome this a strong spatula of steel, ivory, or bone about five-sixteenths inch wide is selected, and a piece of base-plate gutta-percha large enough to engage the occlusal surface of the crown is stuck on one end of this spatula, thus holding the crown for adjustment and final setting.—G. A. Bowman, *Dental Brief.*

Articulating Paste.—A very convenient and useful means for ascertaining the points of contact in setting porcelain inlays and articulating artificial dentures by the anatomical method may be supplied by mixing ivory black and glycerin to a thick paste. The opposing surfaces are wiped dry, and a small quantity of the paste is painted on the occluding tooth. On closing the mouth, the point of contact will be plainly marked.—D. W. Barker, *Dental Digest.*

Advantage of the Decimal System in Measuring Fluids.—The selling of fluids by weight is really the simplest. It is only necessary to place the bottle in the scale, counterbalance it, and then, after placing the required weight in the one scale, to pour the fluid into the bottle till the scales balance. This is a great saving of labor, as there is no subsequent washing of measures, and one fluid after another can be served out in rapid succession.—*Edwards' Dental Quarterly.*

The Uses of Barbed Broaches.—Barbed broaches are designed to serve several purposes: (1) To cut off or excise the pulp at the end of the tooth-root; (2) to remove the pulp after it has been severed, or to remove the remnants of a decomposed pulp, or one devitalized by arsenous acid; (3) to carry medicaments, with or without the aid of cotton, to or through the apical foramen; (4) to pack dressings or the various plastic materials used in making the root-filling. In the last case, the operation is sometimes facilitated by snipping of the point of the broach, and making the blunt end smooth by stroking it once or twice on an oilstone.—*Dental Dispensary Record.*

Eau de Cologne in Applying the Rubber Dam, Taking Plaster Impressions, or Cleansing Root-canals with Soda Solution.—The application of the rubber dam can be rendered considerably more agreeable in regard to taste and odor, if it is washed with soap and water, rinsed, and then immersed in water containing a little eau de Cologne. After drying, the rubber dam is sprinkled with talcum powder.

A few drops of eau de Cologne added to the water in which plaster is mixed renders the taking of an impression less disagreeable, and reduces the tendency to nausea.

As an addition to a soda solution which is highly recommended for rinsing root-canals, eau de Cologne is greatly appreciated by patients with a delicate sense of taste.—*Monatsschrift fuer Zahntechnik und Verwandte Gebiete.*

Inlay Anchorage for Bridges with Removable Pivots.—The retention of inlays, or of inlays used as anchorage for a bridge, can be considerably enhanced by passing a bur through the inlay in such a way that a platinum or gold pivot can be passed through the hole into the root-canal of the tooth. The direction of these pivots should be arranged so as to make the pivots converge. In bridge work, the inlays and pivots are removed together in an impression, a model is poured, and the bridge finished. The inlay or bridge is cemented to place, the pivots are introduced into the holes while the cement is still soft, and ground off after hardening of the cement. In many cases the pivots can be made so short that devitalization of the pulp is superfluous, while at the same time increasing the retention of the appliance.—*Monatsschrift fuer Zahntechnik und Verwandte Gebiete.*

Tumors of the Carotid Gland.—Sinushin describes the carotid gland and its tumors. The gland is situated at the bifurcation of the carotid artery, and its tumors are usually single, of the size of a hen's egg, reaching sometimes as high as the mastoid process. Sometimes they are pierced by the artery. When compressed, all pulsation stops. Laterally they can be moved, but not vertically, nor during the act of swallowing. The sympathetic and vagus nerves are not involved. Such tumors have never been observed before the age of eighteen; they occur usually between twenty-five and thirty, mostly in women, and on the left side. The growth is slow, causing no objective symptoms. Operation gives a high mortality—20 per cent.—owing to the cerebral complications liable from ligation of the carotid artery. Yet the possibility of malignant degeneration of the carotid tumor and metastasis renders imperative their operative removal. The carotid artery can be compressed, but must not be ligated; only the external carotid should be ligated during the operation.—*Medizinskoe Obozrienie,* per *Journ. Amer. Med. Association.*

Treatment of Vincent's Angina.—Treatment is satisfactory in mild cases, most unsatisfactory in the serious ones accompanied by toxemia, prostration, and mechanical obstruction to breathing. In the mild cases, in which the ulcer resembles syphilitic lesions, best results are derived from the use of trichloracetic acid. The membrane is first removed by hydrogen dioxid, wiping off with a cotton swab. A 10 per cent. solution of cocain anesthetizes the ulcer, after which, in a few minutes, trichloracetic acid is applied. Three or four applications—sometimes but one is needed—at intervals of two or three days, are sufficient. Tincture of iodin is not so efficacious as the trichloracetic acid, but in an extensive ulceration, involving much surface, it is preferable. Orthoform relieves the pain. The teeth must be cared for, and no progress will be made so long as carious teeth and abscesses remain. The patient's general condition must be improved. In the more serious cases, local treatment is not satisfactory. It is hoped that a specific antitoxin may soon be produced, or that possibly salvarsan might prove efficacious against this spirochete, as it is against that of syphilis. —T. H. HALSTED, *Lancet-Clinic.*

Selection of a Cement Spatula.—The spatula is too often lightly considered or entirely overlooked as an important factor in mixing cements. Both its form, for mechanical reasons, and its composition, for chemical reasons, must be considered. Cement powder and liquid do not mix, like many other substances, by the solid dissolving in the liquid, and then combining atom with atom or molecule with molecule, nor are they like a lot of glass marbles mixed with glue into a mass, a simple mechanical mixture, but each granule of powder coming into contact with the liquid has a thin layer on its surface dissolved by the liquid to form the cementing substance that binds the undissolved portion of the granules together. This process must be accomplished in a short time, and the more intimately every surface of a granule comes in contact with the liquid, the better will be the resulting mix.

To accomplish this quickly and evenly, a correctly shaped spatula must be used.

This we find in the heavy, double-edged, uniform-width German silver spatula on the market. Presenting an oval surface to the slab, the granules of powder are caught under it and rolled forward and back into the liquid, thereby more nearly coating all surfaces of granules with liquid than could possibly be done with a flat, springy spatula mixing with a patting motion. Vigorous, thorough spatulation is necessary to secure a good mix, whether it be thin and creamy for an inlay or thick for a filling.

The composition of the spatula is an important factor. Owing to the hardness of the granules of the powder, particles of any metal spatula—with the possible exception of tantalum—will be ground off and enter the mix, thereby discoloring and changing its composition to a greater or lesser degree. An iron spatula will produce a great amount of discoloration, if thorough mixing is accomplished, but a German silver or coin silver spatula will not only give very slight discoloration, but will be a benefit to the mix chemically.—G. C. POUNDSTONE, *Dental Review.*

HINTS, QUERIES, AND COMMENTS.

ANOTHER CHARGE AGAINST FORMALDEHYD.

LAST winter I treated myself for colds with vaccine, hypodermically administered. I had been disinfecting the syringe employed by various methods, usually by placing it in the dry, formaldehyd sterilizer, or by combining this with other familiar methods. I found the pain from the vaccine treatment to be long-continued, in one instance lasting over one month, and noted that a sore spot formed at the place of insertion of the hypodermic needle. Naturally enough, I attributed this mishap to infection, and consequently was more and more careful in cleansing and disinfecting the syringe and the area of skin surrounding the place of insertion—but to no avail. All my efforts to discover the cause of the sores were unsuccessful, until I suspected the formaldehyd chamber, and then the trouble ceased. At present a number of purplish spots still persist at the places where injections were made, which I can attribute to no other cause than formaldehyd. Perhaps the pains in the gums of which patients so often complain after hypodermic injection for the extraction of teeth are in part due to the same cause.

I have become greatly interested in Dr. Grove's "Warning Against the Indiscriminate Use of Formaldehyd Preparations" (published in the DENTAL COSMOS for February, p. 147) in which he relates certain experiments, and concludes that Dr. Buckley's mixture of formaldehyd and tricresol is injurious to the tissues. This statement, if true, is very important, and my own experience, as related above, seems to bear out Dr. Grove's conclusions. On the other hand, teeth treated by the tricresol-formalin method do not have to be extracted in after years as frequently as Dr. Grove's statements would lead one to surmise. For this reason, I am still using Dr. Buckley's treatment, though with some trepidation. Dr. Grove concludes by saying "There are other methods for the correction of these conditions equally satisfactory, and free from the dangerous properties of formaldehyd." It would have been of great interest to know to what other methods Dr. Grove refers. What other method of treatment will abort an abscess as well as that indicated by Buckley? Is it vaccine therapy, which has been claimed by a manufacturer of vaccines to be most efficient? Is it sodium and potassium? Even if this last combination reached the microbes which have passed beyond the apical foramen, how can it be applied to a distal cavity in a second or third molar, when the tooth is almost too sore to be touched? In many such cases, pain prohibits the application of the rubber dam—indispensable in sodium and potassium treatment—and even the slightest amount of instrumentation is hardly bearable. If Dr.

Groves knows any treatment that will curb the demon of alveolar abscess as readily as Dr. Buckley's mixture, thousands of dental practitioners, in my opinion, would be delighted to hear of it from him.

STEWART J. SPENCE.
Chattanooga, Tenn.

OCCIPITAL PAIN DUE TO GINGIVAL LESION.

I WISH to report a case in my practice which may possibly be of interest to the profession in general.

Some time ago, a patient, Mrs. M., age about sixty, came to me complaining of pain in the alveolar portion of the upper jaw, right side. She wore two plates, upper and lower. She had a deep cut in the gum on the same side, which was undoubtedly caused by a sharp projection in the upper plate. She mentioned casually that she had suffered of late from pain at the back of her head, in the region of the lower part of the occipital bone, and was being treated for it by a nerve specialist, but so far without material results. The doctor had diagnosed the condition as a nervous trouble, constitutional in origin.

On questioning her I learned that the pain had started synchronously with that in the gum. Naturally I concluded that the cut might be the cause of it—which proved to be the case.

After remedying the defect in the plate, and applying curative treatment to the wound, I sent her home, cautioning her not to wear the plate for a day or two. All pain disappeared, and so far there has been no recurrence.

GEO. G. WEINSTEIN, D.D.S.
New York, N. Y.

DENTAL COLLEGE COMMENCEMENTS.

PHILADELPHIA DENTAL COLLEGE (TEMPLE UNIVERSITY).

At the annual commencement exercises of the Philadelphia Dental College (Temple University), held in Philadelphia, Pa., June 1913, the Degree of Doctor of Dental Surgery was conferred upon the following graduates:

Avelino Abalo	Cuba
William J. Averbuch	France
Elizabeth Beatty	New Jersey
Elmer H. Brown	New Jersey
Francis J. Conlin	Massachusetts
Joseph A. Corriveau	Massachusetts
Russell B. Cunningham	New Jersey
Gastaos R. Da Costa Ramos	Brazil
Louis B. Dennett	New Hampshire
Leon Desbaillets	Switzerland
Alexander Duchange	France
Roger Duchange	France
Fritz Egger	Switzerland
George H. Elliott	Maine
Paul W. Eves	Pennsylvania
Axel G. D. Fischer	Sweden
Edward K. Graham	Pennsylvania
Walter Grandage	Connecticut
William J. Greene	Massachusetts
Luiz F. Guimaraez	Brazil
George T. Holt	Rhode Island
Guy S. Ingram	Pennsylvania
George A. Jenkins	Connecticut
Israel Kine	Pennsylvania
Terra W. Leach	Australia
Charles D. Leidy	Pennsylvania
John H. MacDermott	Massachusetts
Clarence E. Morton	Pennsylvania
Gordon D. Peters	New Brunswick, Can.
Mogue S. Power	Newfoundland, Can.
Hugo Renfer	Switzerland
Alfred L. Robinson	New York
Benjamin Rouslin	Rhode Island
Francisco A. Sabater	Porto Rico
William J. Scheifley	Pennsylvania
Ida Slutchefsky	Russia
Winfield V. Stafford	New Jersey
Benjamin Stein	Pennsylvania
William Stoehr	New York
Frank M. Stout	Pennsylvania
Robert G. Stringer	Pennsylvania
Elsie B. Struppler	Pennsylvania
Charles J. Timmins	Pennsylvania
Norman W. Trimpi	New Jersey
Isaac Unger	Connecticut
Maria H. Verheyden	Holland
Isaac L. P. Wilson	Costa Rica, C. A.
Ernest M. Woodcock	Maine
Philip H. Woods	Pennsylvania

Society Notes and Announcements.

INTERNATIONAL DENTAL CONGRESS, 1914.

The Sixth International Dental Congress will be held in London from August 3 to 8, 1914, at the invitation of the British Dental Association.

His Majesty King George V has graciously consented to be the patron of the congress, which will take place at the University of London and at the Imperial College of Science and Technology, South Kensington.

The president of the congress will be Mr. J. Howard Mummery, and the joint general secretaries are Mr. Norman G. Bennett and Mr. H. R. F. Brooks. Mr. H. Baldwin is honorary treasurer.

A Committee of Organization, under the presidency of Mr. W. B. Paterson (president of the International Dental Federation), with Mr. F. J. Pearce as honorary secretary, has been busily engaged for some time in making the preliminary arrangements.

Previous congresses have taken place in Paris, 1889; Chicago, 1893; Paris, 1900; St. Louis, 1904; and on the last occasion at Berlin, in the Reichstag, in 1909, when the German Emperor took a personal interest in the meeting, delegates attended from twenty different countries, and the governments of many of them were officially represented.

Invitations are being issued to dental organizations throughout the world, and it is hoped thus to secure the co-operation of leading specialists and representative authorities in all branches of dental surgery.

The rules of the International Dental Congress provide that all ethical practitioners of dentistry possessing the qualification of the country in which they receive their professional education, or of the country in which they practice, are eligible for membership.

The subscription for members of the congress will be 30s. ($7.50; 38 fr.; 31 mks.), and for members of their families accompanying them 15s. (19 fr.; 15½ mks.; $3.75).

The offices of the congress are 19 Hanover Square, London, W., to which address all communications should be sent.

THE PANAMA PACIFIC DENTAL CONGRESS.

As one of the attractions of the Panama Pacific International Exposition, a dental congress, international in character, to be known as the Panama Pacific Dental Congress, is to be held in San Francisco, California, beginning on the last Monday in August 1915, and continuing for ten days.

A committee of Organization has been perfected, including representatives from the Pacific Coast states—California, Oregon, Washington, Utah, Idaho, Colorado, and Arizona.

This committee is now actively engaged in perfecting the work of organization, including the establishment of executive committees in every state of the United States and in every foreign country where dental organizations are known to exist, which will be empowered to promote the business of the congress by bringing it to the attention of their national, state, and local societies, and securing memberships and contributions to the program.

The American Society of Orthodontists and the National Dental Association, of the United States of America, have already made arrangements to meet in San Francisco in 1915 as a part of the congress, and invitations will be extended to other dental societies to take similar action.

The Panama Pacific Dental Congress is the first organization to apply to the Exposition management for space for exhibits, and to ask that a definite time be set aside for its meeting.

Manufacturers of dental goods have signified their intention to maintain during the congress the greatest exhibition of dental supplies ever held. Ample space for this purpose has already been promised by the Exposition authorities, and we are assured of their hearty co-operation in all things pertaining to the success of the congress.

The membership fee has been fixed at ten dollars, and the finances of the congress are being cared for by a corporation, formed within the Committee of Organization, and known as the "Pacific Dental Congress Commission of 1915."

Over $8000 has already been subscribed for promotion purposes by the dentists and dental societies of the Pacific Coast states, and this fund will be increased by many thousands of dollars before the congress meets.

Ample funds for promotion of the congress are assured, and in due time committees on Local Arrangements, Transportation, Exhibits, Clinics, Program, etc., will be appointed, and everything possible will be done to insure the success of the congress and make it in attendance and scientific and professional interest the greatest dental congress ever held.

The whole world is coming to San Francisco in 1915 to participate in and enjoy the Panama Pacific International Exposition, which will commemorate the completion of the world's engineering masterpiece, the Panama Canal.

Never in the history of the profession has there been so auspicious a time for holding a great dental congress, and the Panama Pacific International Exposition Company and the Committee of Organization of the Panama Pacific Dental Congress unite in a cordial invitation to the members of the dental profession to come to San Francisco in 1915 to attend the congress and view the wonders of the Exposition and the Pacific Coast of the United States of America.

FRANK L. PLATT, *Ch'man,*
Committee of Organization.

NEW JERSEY BOARD OF REGISTRATION.

AT a special meeting of the New Jersey State Board of Registration and Examination in Dentistry, held at Newark, N. J., on Saturday, June 14, 1913, the resignation of Dr. Charles A. Meeker as secretary-treasurer was announced; also the retirement of Dr. Meeker from the board on account of ill health, after twenty years of faithful service.

Governor Fielder has appointed Dr. Cornelius Kiel of Hoboken to fill Dr. Meeker's unexpired term. Dr. Alphonso Irwin of Camden, N. J., has been elected secretary-treasurer. Hereafter all communications concerning the granting of licenses to practice dentistry in the state of New Jersey should be addressed to Dr. Alphonso Irwin, 425 Cooper st., Camden, N. J.

The office of the New Jersey State Dental Commission has been transferred to Camden, N. J.

NORTHEASTERN DENTAL ASSOCIATION.

THE nineteenth annual meeting of the Northeastern Dental Association will be held in Footguard Armory Hall, Hartford, Conn., October 14, 15, and 16, 1913. Every effort is being put forth to insure a most attractive meeting. All ethical members of the profession are invited to attend, and those eligible are requested to join the association and help sustain the meetings.

FREDERIC T. MURLLESS, JR., *President,*
EDGAR O. KINSMAN, *Sec'y,*
Cambridge, Mass.

PENNSYLVANIA STATE DENTAL SOCIETY.

OFFICERS AND COMMITTEES—1913–14.

THE officers and committees of the Pennsylvania State Dental Society for 1913–14 are as follows:

Officers—Howard S. Seip, Allentown, president; Jas. G. Lane, Philadelphia, first vice-president; H. E. Friesell, Pittsburgh, second vice-president; Luther M. Weaver, Philadelphia, recording secretary; Geo. S. Schlegel, Reading, corresponding secretary; W. A. Spencer, Carbondale, treasurer.

Council—For one year: A. E. Bull, Wilkes-Barre; W. C. Scott, Lansford; C. B. Bratt, Pittsburgh. For two years: Victor Cochran, Philadelphia; C. O. Booth, Pittsburgh; C. E. Peters, Pittsburgh. For three years: Joseph Huggins, Downingtown; C. A. Bachman, Emaus; F. L. Davenport, Wilkes-Barre.

Board of Censors—D. B. Williams, Wilkes-Barre; C. M. Bordner, Shenandoah; E. W. Bohn, Reading; A. S. Koser, Harrisburg; F. W. Allen, Philadelphia.

COMMITTEES.

Program—S. P. Cameron, Philadelphia; J. D. Whiteman, Mercer; V. S. Jones, Bethlehem.

Local Arrangements—A. E. Bassett, Philadelphia; E. R. Sausser, Philadelphia; J. A. Standen, Philadelphia.

Exhibits—H. B. McFadden, Philadelphia; Geo. F. DeLong, Reading; F. L. Davenport, Wilkes-Barre.

Clinics—F. R. Stathers, Philadelphia; C. A. Bachman, Emaus; C. S. Van Horn, Bloomsburg.

Publication—L. M. Weaver, Philadelphia; W. W. Booth, Pittsburgh; B. B. Sprout, Williamsport.

Dental Science and Literature—E. S. Filbert, Pottsville.

Ethics—C. M. Bordner, Shenandoah; J. M. Crosby, Bradford; W. H. Lowell, Lancaster.

Enforcement of Dental Law—L. M. Weaver, Philadelphia; H. Zimmerman, Annville; W. C. Middaugh, Easton.

Necrology—W. H. Trueman, Philadelphia; W. H. Scholl, Reading; Geo. W. Klump, Williamsport.

Legislation—C. B. Bratt, Pittsburgh; W. H. Fundenberg, Pittsburgh; Geo. R. Root, Philadelphia; V. H. McAlpin, Warren; Geo. W. Klump, Williamsport; H. E. Trostel, York; J. C. Reed, Harrisburg; A. J. Heffernan, Wilkes-Barre; W. C. Scott, Lansford.

Oral Hygiene and Public School Dental Education—Geo. S. Schlegel, Reading; H. W. Heckel, Pittsburgh; S. B. Luckie, Chester; W. B. Mausteller, Harrisburg; P. B. McCullough, Philadelphia.

Reorganization—J. G. Lane, Philadelphia.

GEO. S. SCHLEGEL, *Corresp. Sec'y*,
Reading, Pa.

INDIANA BOARD OF EXAMINERS.

THE next meeting of the Indiana State Board of Dental Examiners will be held in the State-house, Indianapolis, Nov. 10 to 15, 1913. All applicants for registration in the state will be examined at this time. No other meeting will be held until June 1914.

Notice. All persons legally registered for the practice of dentistry in Indiana are required, under Section 9 of the new statute, to register with the secretary of the State Board of Dental Examiners, ANNUALLY, on or before the 31st day of December. The annual registration fee is $1.00. Blanks will be mailed to each qualified dentist on December 1st. This act applies to those dentists who have left the state or are now not in practice, the penalty being the revocation of said persons' license within ninety days, upon failure to re-register. The annual registration certificate is necessary to entitle one to practice.

For further information apply to

F. R. HENSHAW, *Sec'y*,
508 K. of P. Bldg., Indianapolis, Ind.

MASSACHUSETTS BOARD OF REGISTRATION.

A MEETING of the Massachusetts Board of Registration in Dentistry will be held in Boston, October 22, 23, and 24, 1913. For applications and further information apply to

G. E. MITCHELL, *Sec'y*,
14 Water st., Haverhill, Mass.

MARYLAND BOARD OF EXAMINERS.

THE Maryland Board of Dental Examiners will meet for examination of candidates for certificates November 6 and 7, 1913, at the Baltimore College of Dental Surgery, Baltimore, at 9 A.M. For application blanks and further information apply to

F. F. DREW, *Sec'y*,
701 N. Howard st., Baltimore, Md.

DENTAL COMMISSIONERS OF CONNECTICUT.

THE Dental Commissioners of the State of Connecticut hereby give notice that they will meet at Hartford on Thursday, Friday, and Saturday, November 13, 14, and 15, 1913, to examine applicants to practice dentistry. Application blanks, rules, etc., will be mailed by the Recorder upon request.

EDWARD EBERLE, *Recorder*,
902 Main st., Hartford, Conn.

MICHIGAN BOARD OF EXAMINERS.

The next regular meeting of the Michigan State Board of Dental Examiners will be held at the Dental College, Ann Arbor, commencing Monday, November 10th, and continuing through the 15th. For full particulars and application blanks address

F. E. Sharp, *Sec'y*, Port Huron, Mich.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending August 15, 1913:

Harry M. Deiber, act.d.s., August 11th, left Fort Thomas, Ky., *en route* to Fort Logan H. Roots, Ark., for temporary duty.

L. B. Wright, act.d.s., August 11th, reports at Fort Ontario, N. Y., for temporary duty.

First Lieut. J. R. Ames returned to status of leave from treatment at Walter Reed General Hospital.

First Lieut. F. L. K. LaFlamme arrived at Fort Hancock, N. J., August 13th, for temporary duty.

First Lieut. R. H. Rhoades left Fort Apache, August 6th, for temporary duty at Fort Bliss.

For the week ending August 22d:

J. W. Smith, act.d.s., arrived at Fort Sam Houston, August 14th.

First Lieut. J. R. Ames granted fifteen days' leave of absence on expiration of leave already granted him.

For the week ending August 29th:

First Lieut. H. G. Voorhies will proceed to Hot Springs, Ark., and report at the Army and Navy General Hospital for observation and treatment.

First Lieut. E. P. Tignor granted leave of absence for one month about August 25th.

First Lieut. F. P. Stone, August 25th, reports for temporary duty at Fort Williams, Me.

First Lieut. S. D. Boak, August 27th, returned to West Point, N. Y., from leave of absence.

For the week ending September 5th—(No changes).

ORIGINAL COMMUNICATIONS.

THE RESPONSIBILITY OF THE DENTIST IN ORAL MALIGNANCY.

By ARTHUR B. CRANE, D.D.S., Washington, D. C.

(Read before the union meeting of the Maryland Dental Association and the District of Columbia Dental Society, Washington, D. C., June 12 to 14, 1913.)

A GROWING knowledge of the importance of pathological conditions in the mouth in their relation to the general health and mortality of the human race is permeating the medical profession, and awakening a respect for dental surgery, hitherto somewhat dormant, notwithstanding the wonderful and artistic mechanical restorations of which our profession has been so proud. The coincidence of Riggs' disease with pernicious anemia, alveolar abscess with infective arthritis, irregularity of the teeth with respiratory diseases, unclean mouths with alimentary infection, and decayed teeth with low vitality, offer a field for study and research which may well occupy the minds of the medical and dental professions jointly. It is now recognized that in many conditions the dentist holds the keys to life and health, and upon the degree of intelligence with which he locks or unlocks the doors rests the future standing and recognition of dentistry. The obvious truth of this circumstance is the reason for the attempt of the writer to present the subject of malignant oral neoplasms.

IMPORTANCE OF EARLY DIAGNOSIS OF MALIGNANT NEOPLASMS.

There is no condition encountered by the dentist which is of more unfavorable prognosis, or which to any degree approaches the mortality attendant upon malignant tumors of the mouth; and yet, through mistaken diagnosis or lack of discernment, many of these dangerous growths progress, under the very eyes of ignorant or careless dentists, to such an alarming extent that by the time they reach the oral surgeon, all hope of successful operation is passed, and the unfortunate patient is doomed to a slow and horrible death.

OBSCURE ETIOLOGY OF NEOPLASMS.

The etiology of neoplasms is obscure, and while many possible theories as to their cause have been advanced, and though men of great scientific attainment, backed by the wealth of multi-millionaires, are daily striving to establish definitely their origin and a more successful method of treatment, at present the surest hope lies in early diagnosis and immediate surgical removal. It will be comprehended, then, how necessary it is that the dentist, who may often discover an oral tumor before even the patient is aware of its existence, and to whom, in any case, it is usually first presented, should be able to recognize the early manifestations of malignancy.

GENERAL CLASSIFICATION AND CHARACTERISTICS OF TUMORS.

A knowledge of the general classification and characteristics of tumors is prerequisite to intelligent diagnosis, and at the risk of being somewhat elemental, a brief outline is presented. Tumors are broadly differentiated, according to Coplin (Brown), as neoplasms and cysts. Cysts of the mouth are always benign, and only indirectly concern the subject under consideration. Neoplasms are newgrowths composed of tissue cells more or less retarded in development; they persist or increase in size at the expense of the organism, and have no physiological function. Neoplasms are classified according to their histology, as epithelial, or those arising from the epiblast or hypoblast; connective tissue, or those arising from the mesoblast, and mixed. Clinically they are classified as benign, malignant, and uncertain.

Newgrowths of the mouth are comparatively uncommon, and certain forms of tumors are rarely found there. Papillomata and adenomata are the benign representatives of the oral epithelial group, and carcinomata the malignant. Of the connective tissue group chondromata, osteomata, fibromata, and angeiomata represent the benign type, and sarcomata the malignant. The mixed group comprises a class of tumors usually referred to as teratomata or monstrosities, and are not found in the mouth, unless compound dermoids and the so-called "mixed tumor of the palate," both of which are benign, may be considered in this class. Although only two species of tumors are classed as malignant, it should never be overlooked that any of the benign forms may undergo malignant change; consequently any new-growth in the mouth which is not the result of inflammation or hyperplasia should be looked upon with suspicion, and either be immediately removed or kept under careful observation.

PROGRESS IN MALIGNANT TUMORS.

The prognosis of malignant disease is favorable in proportion to its duration prior to diagnosis. When early recognition is followed by prompt operation, sarcomata and carcinomata in favorable positions are often curable, but in the later stages they become not only incurable but inoperable. Unfortunately, the ease of diagnosis is in inverse ratio to the progress of the growth. While a well-developed malignancy of the mouth is not difficult of recognition, the early stages present many obscure and confusing symptoms, and the conscientious dentist who endeavors to expedite the diagnosis must expect to meet often with failure and ridicule—for even the most experienced diagnosticians are prone to be mistaken in their suspicions. Where life may be lost through procrastination, however, no personal feeling of timidity should be permitted to embarrass a complete study of the condition, and if, in a lifetime of practice, a dentist succeeds in demonstrating even one malignant tumor in its operable state, this is reward enough for many mistaken apprehensions.

DIFFERENTIAL DIAGNOSIS.

When an oral tumor presents, the possibility of inflammation or hyperplasia should first be considered. Alveolar or pericemental abscess, necrosis, pyorrhea alveolaris, empyema of the antrum, hypertrophy of the gums or tooth pulp, impacted teeth, and encapsulated roots are seldom difficult of diagnosis, although at times each may present symptoms suggesting a new-growth. The infective granulomata are more vague. Of these, actinomycosis, which is a rarity in man, may be known by the presence of the sulfur-like granules in the pus, which is early thrown off. Gumma and primary tubercular infections may usually be identified by the history or coexistence of other symptoms. Pyogenic granulomata are generally preceded by acute inflammation. While the granulomata, in some ways, resemble sarcoma, equal care is necessary in dealing with chancre and lupus, which simulate carcinoma. Enlargement of the lymph nodes from syphilis, tuberculosis, or other infection should be carefully isolated from a like condition resulting from carcinoma.

IMPORTANCE OF EXPLORATORY PUNCTURE IN OBSCURE TUMORS. CYSTS VERSUS TUMORS.

Some uncertainty may arise in distinguishing the cyst from the neoplasm, but careful palpation will usually disclose the characteristic parchment-like crepitation of the wall of the bone-cyst or the free mobility and fluctuation of the glandular variety. An exploratory puncture will indicate the fluid-filled cavity of the cyst, or the more or less solid consistence of the neoplasm. Too much emphasis cannot be given to the necessity for the exploratory puncture in the progress of diagnosis of all obscure tumors; cases of needlessly brutal operations from lack of this simple precaution are often noted. This step should not be carelessly undertaken, and should be omitted unless necessary, as malignant tumors resent such interference. The flexible silver probe should be discarded in exploring, and a stiff but delicate steel probe substituted. When the sense of touch has been highly developed, the use of such an instrument will not only impart an appreciation of the difference between a cystic cavity and a solid tumor, but will indicate the presence of enamel, bone, necrotic bone, or cartilage within the growth. When the cyst is within the bone, the radiograph is a positive aid to final identity. As a rule, cysts are slow-growing tumors, and are painless unless infected.

DIFFERENTIATION OF BENIGN FROM MALIGNANT NEOPLASMS.

When a true neoplasm has been recognized, it will present evidences leading to its identification as benign or malignant. In making this distinction, the history of the tumor is of primary importance. A newgrowth slowly increasing in size during a period of years is probably not malignant, unless stages of rapid growth have been noticed. It should then be classed as uncertain. A neoplasm increasing very actively without interruption and destroying all tissue which interferes with its progress is most frequently malignant. A malignant tumor is not often encapsulated or circumscribed, hence is practically fixed, while a benign tumor is usually encapsulated and circumscribed, hence mobile. The mobility is further influenced by the fact that the benign growths are not deeply adherent unless they become the seat of bacterial invasion, while the malignant types are always infitrating and therefore adherent. In the absence of infection, ulceration is unusual in benign neoplasms, but the malignant generally ulcerate upon reaching a free surface. A benign tumor in the mouth is ordinarily covered with normal mucous membrance; a malignant tumor soon breaks through the mucous membrane. Benign tumors are common to all ages; malignant tumors, with certain exceptions, are rare in early life. A blood-test for leucocytosis will often clear a doubtful diagnosis. In benign cases this is absent; in malignant cases it is often marked. Metastases, or transportation to distant points, forming secondary tumors, are wanting in newgrowths of a benign type, though all too common in malignant types. The tendency to recur after apparently complete extirpation is strongly indicative of malignancy. Cachexia, a condition of defective nutrition marked by rapid emaciation, anemia, and loss of strength, is an invariable though sometimes retarded characteristic of the malignant growths, and when present contra-indicates operation. The previous history of the tissue involved, as well

Papilloma superimposed on dentigerous cyst. Growth four years. Mistaken diagnosis of mixed sarcoma rectified before operation, by radiograph.

as the situation, formation, and color of the tumor and lymphatic involvement, all have important bearing in diagnosis, as will be pointed out later. All tumors of the mouth should be suspected as malignant until positively proved to be benign. A benign tumor may contain malignant areas.

DIFFERENTIAL DIAGNOSIS BETWEEN CARCINOMA AND SARCOMA.

It is often important to make a differential diagnosis between carcinoma and sarcoma prior to operation. Age is an important factor in this, carcinoma being rarely seen before middle life. About 40 per cent. of carcinomata begin around the age of sixty. When occurring in the young they are exceedingly malignant. Sarcoma may appear at any age, being most frequent between ten and forty-five. Under thirty a malignant growth is probably sarcoma. Repeated mild trauma in certain situations, such as the irritation of the lower lip from pipe-smoking, of the tongue or cheek from a jagged tooth, or of the alveolar process or floor of the mouth from dentures that do not fit, often precedes carcinoma. The history of an isolated, somewhat severe trauma should suggest sarcoma. Murphy (Brown) states that a trauma severe to the degree of laceration or fracture never causes malignancy, while Coley, who has a record of 225 cases of sarcoma following trauma, does not even exclude severe trauma (Scudder). Sarcoma following injury usually begins within one month, but the possibility of a late effect should be carefully taken into account.

Carcinoma springs from the epithelium and is primarily a surface tumor. In the mouth it is, therefore, exposed from its inception, except when it arises from the mucous membrane lining the antrum or within a salivary gland. Sarcoma begins its growth in connective tissue and may be discovered by palpation early, if starting from the periosteum, but is seldom discovered in its incipience when central in the bone or in the antrum. When arising from the periosteum, at first there is a pseudo-encapsulation, which makes it difficult to distinguish from certain benign growths, but carcinoma is always frankly adherent. A malignancy of the tongue, mucous membrane of the cheek, floor of the mouth or lip, or within a salivary gland, is probably carcinoma, while on the body, angle, or ramus of the mandible or the body of the maxilla, it is probably sarcoma. Sarcoma and carcinoma may each arise from a tooth socket. Sarcoma often grows more rapidly than carcinoma, but may grow intermittently, while the latter is continuous.

The shape of the tumor is indicative. The sarcoma, being smooth and globular, causes a rounded enlargement of the overlying tissues; the carcinoma is diffuse, cauliflower-like in appearance, and is preceded in its growth by an area of induration. Carcinoma ulcerates early and gives off a very offensive discharge that contaminates the saliva, which flows involuntarily out of the mouth. Sarcoma is more cleanly, and ulceration takes place late, if at all, and then usually from bacterial infection of a lacerated area.

The presence in the tumor of cartilage, bone, lime salts, pigment, or a cyst, points to sarcoma. A tumor free from bacterial invasion, which causes enlargement of the cervical lymphatics, is probably carcinoma. Carcinoma is more painful than sarcoma, although in the early stages pain is slight and is not a constant factor of either. Sarcoma is more tender than carcinoma. Edema and enlarged superficial veins are often encountered in both types of malignancy, and may suggest inflammation, confusing the diagnosis.

TUMOR IN THE MAXILLARY ANTRUM.

When a tumor is situated in the antrum, early manifestation is the exception, and a differential diagnosis is extremely difficult. A fleeting neuralgia or deep-seated pain in the region of the bicuspids or molars, without apparent cause, is frequently the first symptom, although pain is often absent. A sense of fulness or weight, symptoms of empyema, especially if the discharge is scanty and slightly tinged with blood, a slight edema of the infraorbital region, loosening of the adjacent teeth, disturbances of the eye, perhaps with slight exophthalmos, and bulging of the antral walls, are other suspicious signs. Later the alveolar and palatal processes bulge, the malar bone and nose are pushed aside, and, if the tumor is malignant, this is soon manifested by a breaking-down of the mucous membrane of the mouth or nose, or the skin of the cheek. A combination of several of the foregoing symptoms in a person past middle life, together with an enlargement of the adjacent lymphatics, would point to carcinoma, although recent investigations by Martens and Butlin (Scudder) seem to point to late involvement of the lymphatics from cancer of the antrum. In a patient under thirty, especially when accompanied by partial or complete stenosis of the lacrimal duct, such symptoms would suggest sarcoma. The extraction of a tooth in relation with the floor of the antrum sometimes gives the dentist an advantageous opportunity for seasonable diagnosis, provided the use of a probe in the tooth socket after extraction is a routine practice, for, even in the premature state, the probe will pass without obstruction into the antrum until it comes into contact with the mass of the tumor. Again, as the pain symptoms are usually first referred to the teeth, the patient may seek dental advice, even though no unsoundness of the teeth exists. In such cases, if clinical evidence strongly points to a tumor of the antrum, an exploratory puncture is justifiable. A perforation may be made between the roots of the first and second molars, or just posterior to the canine fossa, with a No. 5 spear-pointed drill under local anesthesia. Such openings readily heal, when suspicion is not confirmed. Transillumination and the radiograph are most helpful in demonstrating antral obstructions.

DENTAL SYMPTOMS OF MALIGNANT TUMOR.

In the course of daily practice, the dentist should be on guard against malignancy when teeth extracted from a supposed pyorrhetic area have glistening nodules of soft tissue adherent to the sides of the roots; when a tooth in relation with the floor of the antrum is extracted and the apex of the root is found to be apparently metamorphosed into soft, cartilaginous tissue; when the lower first molar is prematurely erupted and is not firmly held in the alveolus; when teeth with vital pulps are found to have the root apex eroded; when otherwise normal teeth suddenly become loose and change their position; when there is a rapid and decided unilateral change in the contour of the alveolar process or hard palate, without inflammation; when ulcers or fissures are increasing in size and will not respond to local treatment; when a patient with sound teeth or an edentulous ridge in approximation with the floor of the antrum has pronounced symptoms of empyema which do not yield to irrigation; when a tooth socket after extraction becomes filled with a bulging mass of tissue which one application of the actual cautery does not inhibit, and when epulis recurs after removal of the underlying periosteum.

MICROSCOPIC EXAMINATION IMPERATIVE.

All portions of soft tissue adherent to the roots of extracted teeth, which cannot be unmistakably identified as inflammatory or normal tissue, should be examined microscopically. In fact, in the ultimate analysis, the microscope offers the only unfailing means of determining the true nature of a tumor, and it is a general practice to excise small sections of the growth for this purpose. The necessity for this should be carefully weighed, however, as malignant neoplasms are often alarmingly accelerated in their growth by such interference, and, when all clinical signs point to malignancy, it is better to operate first and make tissue examinations subsequently. When sections *are* made prior to operation, the examination should proceed with as little delay as possible, as, in malignancy, safety is often a matter of days.

THE DENTIST'S ATTITUDE AFTER ESTABLISHING DIAGNOSIS.

When the dentist suspects a malignant neoplasm, an immediate consultation with a competent surgeon should be arranged, in order that the responsibility may be shared. The operations indicated are more extensive than the average dentist is experienced enough to perform, and his duty ends when a qualified surgeon has been retained to perform an operation, although he should prepare the mouth by as thorough a prophylactic treatment as circumstances permit, and he may perhaps assist at the operation by the extraction of teeth and so forth, if desired.

THE DENTIST'S SHARE IN AFTER-TREATMENT.

It is in the after-treatment of the successful cases that the dentist has a useful and almost undisputed field, for the deformities caused by the radical operations demanded for the sake of cure are often serious. The facial expression and the function of mastication must be restored as accurately as possible. While surgery is experimenting with bone-grafting and metal substitutes, the results as yet are far from gratifying, and some prosthetic appliance made by the dentist must perform this useful service. It is not the purpose of this paper to enter into an exposition of this subject, especially as each case presents its individual demands, but the suggestion of cast aluminum appliances, held in place where possible by Gilmore clips, may not be amiss. An excellent *résumé* of this class of work is given in Scudder's "Tumors of the Jaws." The prosthetic pieces therein depicted, however, seem to leave much to be desired from a dental point of view, and it is to be hoped that the reputed ingenuity of American prosthodontia will be vindicated in the near future by improvement in these devices.

In the preparation of this paper, the authoritative works on the subject have been reviewed and may have been unconsciously quoted. The writer has been guided by a somewhat extensive opportunity for clinical observation from the dental standpoint, as well as the advice of several friends of the medical profession.

NOTE ON POTASSIUM CHLORATE AND DENTAL CARIES.

By H. P. PICKERILL, M.D., Ch.B., M.D.S., L.D.S.Eng., Dunedin, N. Z.,
DIRECTOR OF THE DENTAL SCHOOL, UNIVERSITY OF OTAGO, N. Z.

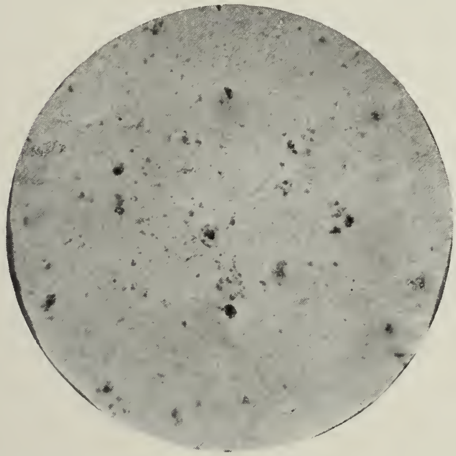
In a recent number of the Cosmos (*i.e.* May 1913, page 490) Dr. Nodine attempts to show bibliographically that potassium chlorate is in the way of being a panacea for all oral lesions of an infective nature. I am not concerned with his attack on Dr. Hermann Prinz' statements, but I wish to call attention to one or two points which concern me in connection with my work on the prevention of dental caries.

In his "Summary" (No. 10), Dr. Nodine states: "It is, by reason of its effects on alkaline salivary secretion, ... very efficient in preventing the multiplication of lactic acid bacteria, and in neutralizing the acids produced during the life activities of other bacteria and putrefaction processes" I fail to find what this is a "summary" of, since there is not in the substance of the article any mention, much less proof adduced, of the power of potassium chlorate to prevent the multiplication of lactic acid bacteria. Unsupported statements of this kind are, I think, to be especially deprecated in a critical and pseudo-scientific communication.

chlorate, and I discontinued them. I found that after the use of potassium chlorate, 5 grains three times a day, the average alkalinity of the saliva per minute was decreased from 1.73 (N/50 H_2SO_4) to 1.64, and the alkalinity per cc. from 1.5 to 0.94, methyl-orange being the indicator used).

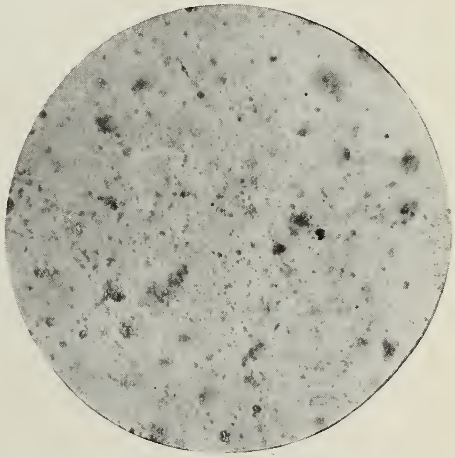
I also tested its possible action in reducing the amount of acid formed from various carbohydrates (chiefly

Fig. 1.



Photograph (by transmitted light) of the colonies of organisms developed from mouth-washings before using potassium chlorate. The growth throughout all the dishes was extremely uniform. (Leitz 1x obj., No. 3 eyepiece.)

Fig. 2.



Photograph of the colonies of organisms developed from mouth-washings *after* using potassium chlorate. The colonies were pink, by reason of the lactic acid formed from the glucose having acted on the neutral red.

Everyone is aware, I suppose, of the beneficial effect often produced by the exhibition of potassium chlorate in cases of infective and mercurial stomatitis; it is a matter of common clinical experience. It does not follow, however, that the drug will cure all cases and kinds of stomatitis, neither that it has any effect whatever in reducing the susceptibility to caries if used as a dentifrice. The jump, however, by the argument of analogy, is a small one. The same possibility occurred to me some two or three years ago, and I carried out some experiments to test its value in this direction. The experiments, so far as they went, were not favorable to the use of potassium

bread and glucose), and was unable to find that it had any definite action at all; the results were so variable as to lead to no definite conclusion. The average acid formed from the chlorated saliva and carbohydrate was, however, a little in excess of the control average.

The result of the following experiment is a direct negative to the statement that potassium chlorate prevents the multiplication of lactic acid bacteria:

The mouth was thoroughly irrigated with 10 cc. distilled water for one minute. A plate culture on neutral red glucose agar was then made from these washings, with of course full aseptic precautions. Six grains of potassium chlorate was then taken, sucked, crushed, and swallowed. One hour afterward another plate culture was taken in a similar manner to the above. Both plates were incubated for forty-eight hours. The number of colonies of lactic-acid-forming organisms developed was, if anything, slightly more in the culture after potassium chlorate than before it, as may be seen from the accompanying illustrations.

I do not contend that these experiments were sufficiently exhaustive to be conclusive, and so did not include them in my book on the "Prevention of Caries," but as far as they went they certainly are in opposition to Dr. Nodine's "Summary."

Potassium chlorate seems to require some active inflammatory focus to be present before it can exert its beneficial action, but this condition is certainly *not* fulfilled in the vast majority of cases where a dentifrice is indicated.

Dr. Nodine asks: "When has a therapeutic agent been condemned because of its transient taste?" May I draw his attention to the fact that my investigations have shown that the taste of a drug is probably far more important than its supposed therapeutic effect—at least from the point of view of the prevention of caries and oral sepsis generally?

There is no possible doubt that nearly all diseases of bacterial origin owe their inception to a favorable stagnation. Movement and circulation are in general terms opposed to bacterial action. Given a free and proper oral salivary circulation, there will be little chance of organisms lodging and proliferating sufficiently to cause a lesion. Now, the majority of drugs with disagreeable tastes act as salivary depressants, and will if habitually used undoubtedly do far more harm than good by producing a state of oral stagnation—and therefore, of bacterial proliferation.

That the glosso-pharyngeal and lingual nerves should be maintained in a condition of full excitability and conductivity is, I believe, essential to the preservation of natural immunity in the mouth. I would even suggest that caries of the teeth may be regarded as a symptom of failure of the nervous mechanism controlling salivary secretion to functionate normally.

CONFLICTING OPINIONS CONCERNING THE MANUFACTURE AND USE OF ALLOYS FOR DENTAL AMALGAMS.

By MARCUS L. WARD, D.D.Sc., Ann Arbor, Mich.

(Read before Section I of the National Dental Association, at its annual meeting, Kansas City, Mo., July 8, 1913.)

IN order to reach the part of the subject that should be of most interest to the profession at this time, it will be necessary to review so much of the literature that the title of the paper might well be called "The History of Dental Amalgams Since Dr. Black's Work." When the writer took up the work of teaching upon filling materials it became necessary, in order to get the requisite information to give much of a course, to do some work on the subjects involved. Practically nothing had been put in form for this purpose. The work of Dr. Black on alloys was in print in the DENTAL COSMOS in 1895–96, but was as he reported it, and not in good form for use by either practitioners or students of dentistry. A few other subjects were likewise in print, but of these the same might be said. It soon became apparent that the subjects least understood and demanding the most attention were those of alloys and cements and the other plastics.

PREVIOUS INVESTIGATIONS BY THE WRITER.

As a result of work in this field I have been called upon at different times to discuss the subject of alloys. One of my first papers appeared in COSMOS for December 1905, under the head of "Some Things About Alloys Not Generally Understood." I was prompted to write that article because I found, generally, that dentists did not understand the subject. The difference between the two classes of alloys that resulted from Dr. Black's work was not generally realized, nor the difference between those two classes and the alloys made previously. The same was true regarding the alloys that were high in silver and marked "Rapid setting," "Medium setting," "Slow setting." Various opinions were held regarding the cause of spheroided fillings. The use of more mercury to make a plastic mass than was to be left in the filling was quite generally held to be injurious, weighed proportions being considered the correct method of combining the alloy and mercury, and a change in formula the result of any other procedure. In the *Dental Review* for 1907 (vol. xxi, p 406) appeared another paper by the writer, entitled "Some Reasons for Instituting a Public Means of Protecting the Profession Against the Use of Poor Alloys." This article implied that one or two of those whom I supposed possessed information that would be helpful to me and the profession were not giving it out, or else did *not* know what they were given credit for; and that not only myself, but dental teachers generally, were not able to present the subject of alloys to students in a manner that would compare favorably with the presentation of similar subjects by teachers in engineering. It was pointed out that some alloys on the market appeared to be very poor and others very good, and that there was no reliable way for the dentist to find out the difference between the two; also that conscientious and capable manufacturers differed as to just what constituted a good alloy; also that the manufacturers who were making what appeared to be our best alloys were claiming to be following Dr. Black's plans, and that analyses of such products showed them to be composed of from 65 to 68 per cent. silver, 26 to 28 per cent. tin, 3 to 4½ per cent. copper, and 1 to 2½ per cent. zinc. Also, that while some of the claims made by the manufacturers regarding the use of different quantities of the different constituents had been recognized by some of those who did not follow such claims, the use of zinc was open to question, because some were attributing to it the property of facilitating long expansions after the filling had been inserted, and others were claiming it to be secondary to other materials in causing this phenomenon. An example of this difference in opinion regarding the use of zinc was mentioned and the amount of the difference given, though the names of the manufacturers were not given—for fear that an injustice might be done one of these two manufacturers, both of whom I had every reason to believe were conscientious in their claims, and because the difference between the two alloys mentioned was not great enough, in my opinion, to warrant taking the chance of injuring one of these manufacturers' trade. For reasons which will be obvious later, I will mention these names at this time. They were the Dental Protective Supply Co. and the N. K. Garhart Co., then of Indianapolis, now of Boston.

Along with the other things mentioned in the paper were reported some tests for strength of these alloys, which showed that those coarsely cut and containing the smaller quantity of zinc would be a longer time in reaching their maximum strength than those with more zinc and finer cut. The so-called plastic alloys were condemned as a class because of their low strength and long expansions, but to avoid condemning any one manufacturer's product I mentioned nine who were selling the same class of alloys, and mentioned, along with the plastic alloy that I was condemning, for each manufacturer a high silver alloy marketed by the same concern, thus enabling the dentist who desired to change from the plastic alloys to the high silver ones to do so without having to purchase a different manufacturer's products.

In Cosmos for 1908 (vol. l, p. 109) appears another article by the writer, entitled "The Effect of an Excess of Mercury upon Shrinkage, Expansion, Strength, Change in Composition, and Stability." In discussing this subject it seemed advisable to mention the names of some of the manufacturers' products to show the similarity in quantities of mercury required to make a plastic mass, so I mentioned eight of those mentioned in the previous article in 1907.

THE DENTAL PROFESSION'S CHANGED ATTITUDE TOWARD PLASTIC ALLOYS.

Not only up to this time, but subsequently, has the discussion of the subject by me been confined largely to the things that could be improved by the dentists. My reason for this was that I was satisfied that many of the leading manufacturers knew much more about the subject than did the profession, and were giving to the profession products as good as could be produced with our present knowledge, while on the other hand I saw many things that the profession could improve on. My aim had been to get the profession informed on the subject to such an extent that they could separate for themselves the reliable from the unreliable manufacturers; at the same time giving the manufacturers a chance to see the tendencies of the profession's demands and make improvements where possible. And, in fact, there has never been anything in my hands so effective in separating the good alloys from the poor ones in any community, as to give the dentists detailed information about alloys in general rather than to attempt to injure the manufacturer. At the time these papers were published it is clear that I regarded eight or nine of our manufacturers of alloys as capable of supplying products that were as good as our present knowledge of the subject would permit. I had mentioned the L. D. Caulk Co., the S. S. White Co., the Dental Protective Supply Co., the N. K. Garhart Co., Gideon Sibley Co., H. D. Justi & Son Co., and two or three others among those who were furnishing products that would give good results if the dentists would do their part in handling them. I feel certain that the manufacturers themselves will grant that this process of giving information to the profession has reduced their sales of the plastic alloys markedly, but made a corresponding increase in the sales of their high silver alloys. In fact, in many localities the representatives of the above-named houses will not try to offer to the profession one of the plastic alloys, because they know well that dentists have learned the difference between these and something better. The result is that the representative makes a sale of his high silver alloy. He must meet what the dentist demands or lose his trade; so we can see that the better informed the dentist is, the better informed must be the manufacturer and his representative. It seems, then, that we must not lose our confidence in a manufacturer because he supplies one of the plastic alloys to those who want it, so long as he is capable of furnishing one of the high silver alloys to those who want it. That does not make him to be distrusted; he is simply supplying what is demanded of him. For a year or two now I have had a great number of letters from all parts of the country asking what I had to say regarding the articles that have appeared mostly in the Cosmos, and Dr. Black's statements in his book on "Operative Dentistry," relative to the quality of the alloys that I had mentioned at various times as being the best we have. It is plainly to be seen that the channel by which these articles have reached the profession is such a prominent one that the articles have caused an unsettled condition regardless of the obscurity of one or two of the men themselves.

MC CAULEY'S ALLOY STUDIES, AND THEIR MISLEADING EFFECT.

For example, appearing in Cosmos, February 1912 and January 1913, and in the proceedings of this association, are articles by Dr. C. M. McCauley of Abilene, Texas. In discussing one of these papers Dr. J. A. Bliss of Ruthven, Iowa, says (Cosmos, January 1913, p. 58): "Dr. Black makes the statement that the only three elements that should enter into a perfectly good alloy are silver, tin, and copper. He emphasizes that any zinc introduced into an alloy is alarming, when we consider the fact it does not alloy uniformly with other metals, and consequently in one portion of one and the same ingot there may be a percentage of zinc above what is intended, and in another portion of that ingot there will be less zinc than was intended, and this necessarily results in an uneven alloy. Dr. Black, therefore, excludes zinc as being detrimental and undesirable, and *we are forced to the view* that any alloy that contains zinc should be excluded from our tests, which means all but two or three. This is alarming, when we consider the fact that of all the fillings made in the United States, at least seventy-five per cent. are made with amalgam." Dr. McCauley says, in the same article that Dr. Bliss was discussing: "I still maintain that the method of making and balancing alloys as discovered by Dr. Black is the only scientific and dependable method which has been introduced up to this time." We may note at this time that Dr. McCauley calls the method of Dr. Black's "scientific." In the same article Dr. McCauley says that "Silver, tin, and copper are the only metals that should be used in alloys." In the discussion of the same article Dr. McCauley gave some results of tests on the following alloys: Rego, Crandall's, Fellowship, Twentieth Century, True Dentalloy, and others. In these results it may be seen that Rego, Crandall's, and Fellowship are given a much better showing than are Twentieth Century and True Dentalloy. In fact, he reports three tests on Twentieth Century, all of which shrank, and four tests on True Dentalloy, two of which shrank. To those who do not follow the alloy question closely this may seem a very ordinary thing to happen, but to those of us who have followed the question in some detail it appears a strange coincidence that the three alloys to which Dr. McCauley gives first place should be made with little or no zinc, and that the Twentieth Century and True Dentalloy with more zinc should be given such a poor showing. This becomes more strange because of the great popularity of these two alloys, and, if these tests were representative of the true movement of these alloys, would tend to show that the dentists were not good clinical observers, or that a little shrinkage made no difference; and that the statements made by me at various times that there were several good alloys in the market, in which these two were included, were open to question. Another strange coincidence appears in the tests reported by Dr. McCauley in which he gives Garhart's Gold White an expansion of 342 points, when Mr. Garhart has been about the only manufacturer to say that he adhered to the given formula, and, like nearly all the rest, to the use of zinc—both of which Dr. Black does not now approve of.

Just what Dr. McCauley expected to gain by publishing a report of this nature is not clear. It would seem, however, that the principal thing that he did was to point out that he thought—what Dr. Bliss said in the discussion, viz—"That the condition is alarming, and that there are only two or three alloys in the market that were what they should be, and that these alloys are zincless alloys." Dr. Bliss in another part of the discussion makes a plea for assistance. He says, "I assure you that it is a great responsibility, and if you knew some of the persecutions endured by him (Dr. McCauley) since he began these investigations, you would be indignant. It is a shame that one man should bear the brunt of these attacks. In justice, therefore, to Dr. McCauley and his fellow investigators, these tests should be made under the supervision of the National Dental Association, or some state society, as a part of the society's work, thus relieving the investigators of any personal responsibility." These statements of Dr. Bliss just about represent the condition of affairs in the profession after the publication of results of the nature of the one published by Dr. McCauley, in which he places the largest, most reputable, and most competent manufacturers in the same class as those who could not be expected to furnish to the profession products of a high order, without taking the ordinary precautions of a scientist by giving some of the details of how the tests were made.

The publication of such results, which are damaging to reputable manufacturers and conflict with the opinions of others, must be carefully placed before the profession if the result is not to be generally bad instead of good. While Dr. McCauley makes the statement that "It is not intended that the practitioner should accept the above figures as conclusive, and select his alloy therefrom," the evil of his tests is not corrected. He has placed the good with the bad. He has gotten many of the dentists who have not looked into the matter to doubting; and when dentists begin to think that all are likely to be bad, the really bad stand about as good a chance as any.

THE ALLOY MANUFACTURERS' NOTABLE EFFORTS.

I have made the statement several times that some of the best manufacturers differ as to what constitutes the best alloy for all purposes, but that I believed these differences of opinion to be honest ones. I have also made the statement that as a rule the larger supply houses were best equipped for distributing uniform supplies because they were in the best position to secure the services of competent men. I have arrived at these opinions because I have known some of them willing to send men the entire length of the country to consult me regarding some comparatively minor things that would help them, and to build duplicates of my apparatus so that they could check me, and because I found them watching every piece of literature on any subject that had any bearing on the problems before them, including such publications as the Journals of the American Chemical Society, the Society of Mechanical Engineers, the Institute of Metals, and the Institute of Testing Materials, and watching the reports of the alloys research committee and purchasing about every work that came out on the subject of metallurgy.

These things have convinced me that we have no reason to become alarmed about many of the manufacturers not doing their part. There are some differences of opinion among them which we, as a profession, can help to settle clinically if no one presents any experimental data; and until these differences of opinion are settled, we can, in my opinion, rest assured that many of the manufacturers are even more anxious than we are that their products stand the tests that are demanded of them. One of these differences of opinion that has been the cause of two or three attacks upon the work of Dr. Black is that concerning the use of a plan of balancing instead of a given formula for making alloys. Some of the best qualified manufacturers we have, seem to take advantage of the statement of Dr. Black that a fixed formula is not good for general use in making alloys; while others who are good, reputable men present some good argument that this is nothing more than an acknowledgment that those who use a varying formula have not mastered the metallurgical part of the work. These statements, coming as they often do through our leading journals, and often in the proceedings of prominent societies, keep the practitioner somewhat busy trying to find whether it is simply advertising matter or whether it is a plan that has merit. Dr. Black says ("Operative Dentistry," vol. ii, p. 310), under the heading "Experiments with the Silver-Tin Alloys," "From this point another short course of alloys only ½ per cent. apart was necessary to find the exact balance which would produce an alloy that would absolutely lie still while hardening. When this was found, it was a good formula for that batch of metals, but not for another batch, for the purity might be different; and the formula for each new batch of metals had to be found. Therefore, no fixed formula could be good for general use. If it were possible to use chemically pure metals a fixed formula would be possible, but such metals would be too expensive for use in dentistry."

ATKINSON'S CRITICISM OF THE G. V. BLACK METHOD OF ALLOY-MAKING.

In the June 1913 issue of the Cosmos, at page 584, under the subheading, "The G. V. Black Method of Alloy-making, and Its Defects," W. W. Atkinson says:

Had Dr. Black left the utilization of his work to others, the luster of his achievement would now be undimmed; but unfortunately he followed his researches into a strange realm, that of metallurgy, and as a result threw the question of alloy-making into confusion. He developed an elaborate system of "balancing" which is entirely empirical, and the system itself is condemned by the facts. Summarized, it is as follows: First—As. in his opinion, all metals procured commercially for use in amalgam alloy-making are impure, and as impurities aggregating from 4/10 to ½ of 1 per cent. are fatal to the attainment of certain requirements in an amalgam made from their alloys; therefore test batches must be made from each new lot of metals, and, upon the basis of the results obtained on the micrometer and dynamometer a perfect "test" formula must be evolved from which the regular batches intended for use are to be made. Second—Alloys are not chemical compounds, but mere physical solutions of two or more metals within each other, the percentages of which may be varied at will. Third—No "formula" is needed when the manufacturer follows the G. V. Black method of "balancing."

Let us take up the first of these assumptions. Upon the authority of Mr. Jacob P. Eckfeldt, chief assayer, U. S. Mint, Philadelphia, bar silver of a fineness of 999.5 and from that point upward to 999.75, is commercially available at the U. S. Assay-office, New York City, N. Y., at current market rates. This silver the writer is able to purchase, regularly, from a Philadelphia broker of precious metals, who does not seem to regard its fineness as being espcially remarkable. Purified shot copper, electrolytic, has a guaranteed fineness of 999 plus, and analyses have shown that the odd one-thousandth of impurity is oxygen, due to dissolved oxids, an easily corrected deficiency. "Straits" tin, purified, has an average fineness of 999.5, often it is finer, and a recent analysis of commercial tin made for me by Booth, Garrett & Blair, showed a fineness of 999.61. Thus a "G. V. Black" alloy made from a formula approximating 68 per cent. Ag, 27 per cent. Sn, 5 per cent. Cu, made from metals of the purity noted, should be within 0.036 of 1 per cent. of 1000 fine, a negligible difference.

It might be argued that such metals were not to be secured at the time of Dr. Black's investigation, but that would not be correct, for pure metals were certainly then obtainable at an added retail cost to dental alloys not exceeding 20 per cent. With such metals available, a formula once established could be continuously reproduced, provided the work were done by a metallurgist having the knowledge and exercising the care needed in such operations.

Pursuing this, then, to its logical conclusion, it must have been assumed that the dental fraternity was unwilling to pay a price commensurate with an alloy of pure metals, which assumption seems untenable.

The second assumption, that the metals of an alloy may be varied in their percentages, which means that their chemical affinities may be disregarded, shows that Dr. Black either did not avail himself of the copious literature on the subject or entirely ignored it, and therefore merited to some extent the caustic criticism of Dr. Ad. Fenchel, who denominated Dr. Black's measurements as superficial and his metallurgical investigations as barren of a true comprehension of the internal structure and chemical constitution of alloys.

* * * * *

The third assumption, that no formula is needed for the making of an amalgam alloy when the manufacturer follows the G. V. Black system of "balancing," might at first thought be dismissed as the extravagant utterance of an overzealous enthusiast, were it not for the commercial advantage which may be taken of it, to the consequent detriment of efforts to secure uniformity in this most important material. It has given rise to a multiplicity of formulæ, afforded opportunities for advertising claims of wonderful and mysterious properties secured through the medium of awe-inspiring "tests" with micrometers and dynamometers—all with the glory of Dr. Black's prestige skilfully interwoven—and, through the relatively enormous expense which attaches to frequent analyses of such alloys, has blocked attempts to ascertain their constituents or to secure other details of importance excepting those of strength and volume change. This leaves the behavior of amalgam fillings made from these "tested alloys" to the "test of time," the very thing that Dr. Black most strongly and most justly condemns. The assumption that no formula is needed, however, falls of itself, for it is a well-known fact that, under the Black method of "balancing," a formula must be worked out before a melt is made, and this formula must be based upon a previously attained "tested" formula which has met the physical requirements noted.

N. K. GARHART'S VIEW.

Whether or not this argument stands the test, of course, depends upon the amount of corroborative evidence presented in the future. That I might find out more in detail how Mr. N. K. Garhart felt about the matter—knowing as I did that he was one of the manufacturers who did not believe in this plan of balancing, and that he, like Mr. Atkinson, had come in actual contact with the advantage that those had who were privileged to use this form of advertising, and that he actually believed that the use of such advertising and its acceptance by the profession and teachers of dentistry blocked the efforts that were made to secure uniformity—I recently took the matter up with him privately, and later secured his consent to use some of his letters. A part of one of them follows:

I am now taking you back to the early period of Dr. Black's writings, and in which he referred to filings giving better results than shavings. His explanation or theory as to the cause was a very weak one, and in my opinion not scientific. At the conclusion of his early writings in the COSMOS he contended that you could not make a satisfactory alloy from a "set" formula—and about which time a course in alloy-making was added to others of the Northwestern University. Caulk, Sibley, and the S. S. White Company sent their men there to take this course. These parties have consistently followed this argument in their advertising to the dental public. While I was in Indianapolis, I published a small booklet on the manufacture of alloys, the latter part of which contained some experiments on the "thickness of cut." These experiments showed that as a given formula was cut progressively thicker or heavier, the factors of efficiency were increased accordingly. I also stated that shaved alloys at that time were thin in cut while those of filings were much heavier; and so this was the real reason why Dr. Black found filings to be more efficient. In later years Dr. Black has verified this important factor, and states that a suitable alloy depends on the fineness of cut as well as other important details. Thus, later, my work on thickness of cut was confirmed by Dr. Black.

Dr. Black has been more or less silent concerning the subject of "set" formula since then. Now the point comes up, Did Dr. Black realize that the real secret of producing a uniform alloy depended on automatic processing?—that his statement "You cannot use a 'set' formula" was not scientific, or not in keeping with facts, was found to be an error? Did he realize so afterward? Yet this very statement has been the foundation for faking on the part of our large manufacturers. They were wise enough to take advantage of this claim and use it for their own ends. The main point was, Our formulas are secret; chemical analyses will not reveal their make-up. We have to change the formula before we can make a satisfactory alloy; therefore this constant variation in our formulas makes their percentage of composition inconstant. Thus these heaviest advertisers have been deluding the profession on this point all of these years.

"WHO IS WRONG?"

There can be little doubt about how these two manufacturers feel regarding this plan of balancing. Neither can there be much doubt in your minds about the effect of such caustic and contradictory statements in preventing the profession from arriving at a definite conclusion from the standpoint of knowledge of the subject, or the selection of products for use in the practice of dentistry. We may expect the question will be often asked: "Who is wrong?" as long as such differences of opinion exist, but as one of the principal objects of this paper is to restore, as far as possible, confidence in many of our manufacturers' ability, and to temper somewhat the widespread feeling that the question of amalgams is one of chaos, I want to emphasize the statement that I made in the last edition of the "American Text-book of Operative Dentistry," which is as follows:

> A review of Fenchel's recent work and the earlier work of Kirk and Burchard, each of whom have viewed more closely the chemical phases of alloys, would not suggest the plan offered by Dr. Black. The question "Why does a fixed formula not give a definite movement during the setting?" has been asked of the writer so many times by teachers and practitioners alike, that it would seem that the plan had not been understood nor accepted generally by the profession. All seem agreed, however, that the plan gives as good results and furnishes us with as good alloys as our present knowledge of the subject will permit. It is the manner of reaching the result about which there seems to be a difference of opinion.

I treated the question at that time considerately—First, because I did not want to stir the profession into a state of distrust when the evidence would not warrant it; and second, because some of the technique involved in the plan would be good to follow as a check against error even though a definite formula were determined upon and definite metallurgical methods arrived at in the manufacture of these products. It would seem, then, that the objections to the plan were—First, that it furnishes an excellent advantage in advertising to those who are privileged to use it; and second, that it implies indefinite methods of manufacture and difficulty in securing metals of a high degree of purity.

To one who has gone far with the study of metallurgy as a science and reached the place where he presents his results in the form that Dr. Fenchel and scores of others present theirs, or has any conception of the statement of Dr. Kirk in his editorial in the June COSMOS, that "It is the business and end of scientific research to ascertain the exact truth, which when ascertained and systematized into an organized grouping of data is what constitutes science," the statement of Dr. McCauley that "The plan of making and balancing alloys as discovered by Dr. Black is the *only* scientific and dependable method which has been introduced up to this time," not only appears like an utterance from one who not only had not done much work, but had ignored the literature on the subject except as to that portion presented by Dr. Black, the greater part of which was seventeen years ago.

W. W. ATKINSON'S VIEWS SCRUTINIZED.

Another phase of the problem has been placed before the profession within the last two or three years which because of the nearness of it to the principles of the chemistry with which the profession is most familiar, promises to upset for all time the plan of balancing which the profession has had for its consideration for the last seventeen or eighteen years. The work of Fenchel has already been referred to, also one of the articles of W. W. Atkinson. Another article by Mr. Atkinson appears in COSMOS for August 1912, which, like the one previously mentioned, has principally to deal with what he designates as a discovery. Whether it be a discovery, and whether the discovery, if it so prove, has merit, remains for the future to tell. One thing seems true at this time—that it is so near to it that, like the plan of balancing, which he condemns, it promises to give the product which he offers as an example of his discovery advertising which that product may not merit. He criticizes about every alloy made upon the ground that they are made "without respect to their atomic relationship, and therefore, within them, atomic compounds are formed which are surrounded by an unappropriated surplus, a eutectic perhaps, which makes physical balance impossible;" but he presents practically no chemical evidence that this compound exists, nor if it does exist, that he has produced it, nor if it does exist and he can produce it, that it possesses properties superior to those that are not made in atomic ratios. The profession should be grateful to anyone who will present the subject in question along chemical lines, because it gets all to thinking along lines of accuracy and truth, but if we are to condemn the mystery surrounding the marketing of the alloys we now have, and are to make real scientific progress, we must demand of Mr. Atkinson the evidence demanded by those who deal with these problems from no other standpoint than a scientific one—or else he, like the ones now using the Black plan of balancing, will be getting what he terms "commercial advantage." Mr. Atkinson points out that silver, copper, and tin are the only metals that should be used in making alloys for amalgams, and says: "Amalgams made from chemically balanced alloys do not discolor—although they do not and cannot contain zinc—for the electrical and chemical affinities are satisfied." Following this he says that "A surface discoloration occurs when a patient is taking the iodids medicinally, but zinc in this instance offers no protection." He gives analyses of five G. V. Black alloys made by Dr. S. P. Burns, and in commenting on them says:

The sum of the percentages divided by 5 —the number of alloys noted—gives the following averages: Ag 66.76, Sn 26.92, Cu 5.408, Zn 0.814, Au 0.056, and therein lies the significant fact that these empirical experiments were successful only when the formula approached the percentage nearest to the established chemical compound of tin and silver, Ag_3Sn—for Ag_3Sn = Ag 73.1 per cent. plus Sn 26.9 per cent., and the averages of the percentages of silver and tin show the following results when in mutual relationship:

Average of
66.76 parts silver = 71.264 per cent.
26.92 " tin = 28.736 " "

This undoubtedly results in the formation of Ag_3Sn + the excess of silver and tin which combines with copper and zinc to form mixed crystals, so that the mixture or alloy consists of Ag_3Sn + mixed crystals and eutectic of silver, tin, copper, zinc, and, in the case of Odontographic alloy, gold.

It is obvious that Mr. Atkinson attributes what success the alloys known as Black's have had to the silver and tin being in percentages close to the formula, Ag_3Sn, which he says is established. In his first paper he discusses the chemical theory of alloys, a part of which paper is as follows:

There are two theories regarding amalgam alloys, the physical and the chemical. The first holds that alloys are probably solid cold solutions of two or more metals within each other, and may be varied in percentages irrespectively of their atomic relation, and to be satisfactory must meet certain requirements in the matter of strength and volume change. According to this theory, an amalgam must expand 1/20,000 inch in setting, and should withstand all stress of mastication.

The other theory is that all alloys should be made in chemical equivalence; that is, that the combining ratio of the metals is their atomic ratio, and that balance is only possible in this way. Both theories are correct in some respects. The first states the correct physical requirements of an amalgam, and the other points out the scientific means of attaining them. Both schools are in error in other respects—for, on the one hand, given percentages of given metals in combination with mercury will produce certain desired results, while on the other hand, the mere fact of chemical crystallization does not necessarily meet the physical requirements, for the crystal may be too soft or its volume change may be toward condensation.

Under the subheading "A Discovery and a New Amalgam Alloy," he says:

In September 1911 I deduced an alloy formula, with the metals in atomic ratio. It is based on the theory that chemical balance, other things being equal, is physical balance, and that silver, tin, and copper, by reason of their observed properties, are the most trustworthy metals with which to compound an amalgam alloy. Experiments were made to test my conclusions, which were entirely confirmed. The alloy compounded is the amalgam alloy instanced in another part of this paper. Its formula is Ag_2SnCu.

In his second paper, under the subheading "The Chemical Theory of Alloys," he says:

> Chemistry has shown that certain alloys of metals undergo condensation in freezing, and that others undergo expansion; that the affinities of certain metals for each other must be considered before they can be perfectly combined into an alloy, and that the atomic law is the important factor in such combinations. Herein lies the significance of the failure of percentage alloys; they are not combined with respect to their atomic relationship, and therefore, within them, atomic compounds are formed which are surrounded by an unappropriated surplus, a eutectic perhaps, which makes *physical balance* impossible.
>
> Therefore, bearing in mind the precision of its data, and the fact that such data afford the means whereby the physical behavior of alloys of metals may be accurately forecast, I place supreme confidence in the chemical theory of alloys, and *know* that it offers the only solution to the amalgam alloy problem.

While Mr. Atkinson admits that "The mere fact of chemical crystallization does not necessarily meet the physical requirements, for the crystal may be too soft or its volume change may be toward condensation," he later says that his alloy of the formula Ag_2SnCu is based on the theory that chemical balance, other things being equal, is physical balance. This leaves the real significance of the term "physical balance" somewhat in doubt, and the chemical theory as he describes it open to question.

Since he says, however, that the percentage alloys fail because they are not combined with respect to their atomic relationship, and therefore, within them, atomic compounds are formed which are surrounded by an unappropriated surplus which makes physical balance impossible, there can be little doubt that he intends to imply that the alloys that are made in atomic ratios are superior, for dental purposes, to those made from percentage ratios. This seems to be quite a common error, and in looking over the alloys used for structural work one is impressed more thoroughly than before that seldom do alloys, made according to atomic ratios, meet the requirements which are demanded of them. The thing of most vital importance in the consideration of alloys for a given purpose seems to have escaped the observation of Mr. Atkinson—viz, that *alloys in their true sense are not chemical compounds.* When most metals are mixed there is not the total and complete alteration of properties which is the distinctive feature of chemical action between a metal and a non-metal. When the chemical compound does occur, then, we may expect the properties of the constituent metals to be more nearly lost than when the solid solution or mechanical mixture occurs. "Alloys" then, generally speaking, means the accumulation of properties of metals; and "chemical compounds" means, generally speaking, destruction of them.

That those who are interested in the subject may get a more clear conception of these questions, I quote the following from the introductory of "A. Humbolt Sexton," which leads up to the statements by him that "Definite chemical compounds in no case form alloys of any industrial importance," and later, that "None of the definite chemical compounds are of any use in the arts," as well as the statement by Hiorns that "Most often, alloys seem to be mixtures of definite compounds with an excess of one or other metal," and the statement of Fulton that "Most of the physical properties of alloys are dependent—First, upon the formation of mixed crystals; second, upon the formation of chemical compounds; and third, upon the formation of a conglomerate of the two substances (eutectics or eutectoids)," also the statement by E. F. Law in discussing some of the alloys formed by definite atomic ratios of their constituents, that "They are perfectly homogeneous, brittle alloys, breaking with a conchoidal fracture—properties which render them practically useless to the art-metal worker":

> When two or more metals are melted together they, as a rule, remain intimately mixed, showing little tendency to separate

according to their densities, or, as it may be otherwise expressed, they remain in solution one in the other while they are in the liquid condition. When the mass solidifies, this state of uniform distribution or mixture may continue, or it may be broken up. In the former case the solidified mass will contain the constituent metals in a condition of more or less uniform diffusion, and such a mass is called an alloy. In the latter case the metals will separate according to their specific gravities, the heavier metal going to the bottom and the lighter rising to the top, such separation being as a rule the more complete the slower the solidification. The separated metals in this case are rarely if ever pure, but each retains a small quantity of the other, and strictly speaking both are therefore alloys. In practice, however, the term alloy is restricted to those cases in which neither of the metals is present in very small proportion; the other cases being simply considered as metals containing an impurity.

An alloy is neither a mechanical mixture nor a chemical compound. An alloy is, then, an intimate mixture of two or more metals, and the term mixed metals has sometimes been used in place of alloys. This is, however, very misleading, as the alloys are much more than mere mixtures, and mixtures of metals may exist which are not alloys.

If lead and copper be melted together, and the mixture be slowly cooled, the metals will separate. If, however, the mixture be quickly cooled, separation cannot take place and the metals will remain mechanically mixed the one with the other, they not having had time to separate into distinct layers, but the mass will consist of intermixed particles of the two metals, and if it be heated up to the melting-point of lead this metal may be, to a large extent, melted out. This, then, would be a case of a mixture of metals, but not of an alloy. In an alloy, the mixture must be of such a character that the constituent metals lose their individuality, and become blended into a new substance which has properties, to some extent at least, unlike those of its constituents.

As a rule, substances which are not elements are divided into the two classes, chemical compounds and mechanical mixtures, but the metallic alloy cannot be made to fit exactly into either group.

In a mere mixture the particles, however small and however intimately they may be mixed, always retain their individuality, and the properties of the mixture are always a mean of those of its constituents. If the constituents be black and white the mixture will be gray, if red and white, a paler shade of red, and so on through all the other properties. This, as is well known, is not the case with alloys. Brass containing, say, 50 per cent. of copper and 50 per cent. of zinc, is yellow, and this yellow color is certainly not a mean between the red of the copper and the bluish white of the zinc; nor is the specific gravity, or indeed any other property of the brass, a mean between those of its constituents. The only point in which alloys always resemble their constituents is that they are distinctly metallic.

Alloys, therefore, are not mechanical mixtures.

A chemical compound contains the elements in fixed proportions, these being always simple multiples of the atomic weights, and some of the physical properties follow from the molecular weight of the compound. This is not the case with alloys. As a rule, the metals are not present in any simple atomic proportion, and further, the proportions can be varied often within wide limits without producing any great change in the properties of the alloy.

The metals do not show any strong chemical affinity one for another, but there is no doubt that in some cases definite chemical compounds of the metals do exist, but in no case do they form alloys of any industrial importance.

Solutions. There is still another form in which substances can exist which, while not a mere mechanical mixture, is something less than chemical combination. If salt or any other soluble substance be stirred up with water it disappears, or dissolves in the water, and the result is a solution of the salt. This solution has some of the properties of the salt; it has, for instance, a salt taste, yet its properties cannot be said to be a mean between those of water and salt. The salt dissolves without increasing the volume of the solution, so that the solution is denser than the mean between salt and water. The addition of the salt also lowers the freezing-point of the water, so that the freezing-point of the solution, instead of being a mean between that of water and salt, is lower than that of either, and by the addition of proper proportions of salt it may be reduced to about —22.5°C.

The essential character of a solution is that the constituents are so intimately blended that they cannot be separated or detected by mechanical means, whilst at the same time they have not entered into true chemical combination.

Solid solutions. As a rule, when a solution is frozen the constituents separate one from another to a larger or smaller extent, but this is not always the case. We can imagine a solution to become solid without any other change, and the result would be a solid solution in which the constituents would still be so intimately mixed that no mechanical separation would be possible, and in which the properties would not be a mean of those of its constituents, but in which these constituents would not be present in the definite proportions required for a chemical compound.

Alloys. True alloys are never mere mechanical mixtures of metals, and though in some cases the metals do combine, yielding definite chemical compounds which often retain their metallic properties, none of these are of any use in the arts. Alloys are very frequently solid solutions of one metal in another, or of a chemical compound of the metals in the metal which is in excess. Many consist of mixtures of such solutions with definite substances that have crystallized out during cooling, so that the actual composition and structure may vary very widely; and each alloy, or rather group of alloys, must be studied separately, as it is impossible to lay down any except the most general rules.

The alloys of copper and zinc probably form as large, interesting, and useful a class of alloys as any in the commercial world. At least three have been recognized as having the following formula:

	Per cent.		Per cent.	
$CuZn$	—49.3	copper,	50.7	zinc.
$CuZn_2$	—32.7	"	67.8	"
$CuZn_3$	—24.6	"	75.6	"

If we now compare the alloys of commercial value with these percentages we find, instead of following them, there is about everything we can imagine, ranging from 90 per cent. of copper and 10 per cent. of zinc, to 15 per cent. of copper and 85 per cent. of zinc. Brass for wire often has about 72 per cent. of copper and 28 per cent. of zinc; brass for the more common work, such as fittings, etc., often has about 66⅔ per cent. of copper and 33⅔ per cent. of zinc. Brass for bolts, butts, etc., known as "Muntz metal," has 60 per cent. of copper and 40 per cent. of zinc; while if greater strength is desired the copper is furnished reduced to 56 per cent. and the zinc increased to 42 per cent., forming what is known as "Delta metal."

Of the alloys of copper and tin we find four described, as follows:

	Per cent.		Per cent.	
$SnCu_4$	—68.1	copper,	31.9	tin.
$SnCu_3$	—61.6	"	38.6	"
$SnCu_2$	—51.7	"	48.3	"
$SnCu$	—34.8	"	65.2	"

And we find gun-metal, one of the most useful of alloys, to be composed of from 8 to 11 parts of copper and 1 of tin, 90 per cent. of copper and 10 per cent. of tin being most generally used—a percentage ratio and not an atomic ratio. These two metals are often used for what is known as bell-metal in the proportions of about 80 per cent. of copper and 20 per cent. of tin, and in this instance we find percentage ratios. With the alloys of copper known as German silver one has but to look over the thirty analyses presented by Hiorns to find that the manufacturers are not only varying widely in the same constituents, but are often using a fourth and fifth metal to get some particular property.

The alloys of gold and copper, gold and silver, gold and copper and silver, and gold and copper, silver, and zinc, as they appear in scores of combinations for use in dentistry and in making jewelry, show that the percentage ratios far outnumber any possible atomic ratios. The same is true with the low-fusing alloys composed of lead, tin, bismuth, and cadmium. In fact, we can follow the same condition through the remainder of the non-ferrous alloys and all through the ferrous ones, each forming more evidence that alloys made in atomic ratios do not necessarily mean alloys that are more desirable for dental or other purposes, *and when alloys in atomic ratios do occur, they are usually more desirable when modified by an excess of one or more of the constituent metals.* This is where the knowledge of chemistry and the use of the microscope applies, —not always in forming chemical compounds, but in determining whether they have formed, and the effects of excesses upon the physical properties. It is *these* methods that make the plan of balancing as suggested by Dr. Black appear empirical, and have made it possible for the trained metallurgist with his microscope to form quite accurate estimates of physical properties without having made the actual tests himself.

For us to accept the formula of Mr. Atkinson, Ag_2SnCu, as *being possible,* and that he can produce it, without some of this kind of evidence, means for us to ignore the doctrine of variable valency, and assume that the greatest of questions in metallurgy, solutions, is thoroughly understood by him. We have learned, when speaking of the valency of an element, that it is essential to mention with what other element that value takes effect. For example, iron is di- and tri-valent toward chlorin, but is tetravalent toward sulfur and hexavalent toward oxygen. We have also learned that many compounds remain as such only within certain ranges of temperature; and oftentimes the pressure exerted by the products of dissociation has a controlling influence on valency. Consequently, it is to be expected that the general affinity ratios of the elements are dependent upon external conditions, of which temperature seems to be the most important and pressure next in importance. An exhaustive examination of the dependence of valency upon the nature of the atoms with which it enters into combination, and the effect of external physical conditions, internal physical conditions, position in the periodic system, etc., makes the assumption of Mr. Atkinson that he is justified in substituting an atom of copper for one of silver in his tin compound, Ag_2SnCu, on the ground that silver and copper *form no compounds* and the valency of tin is constant, when there is at least one silver-copper compound known (Ag_3Cu_2), appear also open to question.

THE OPERATIVE AND POST-OPERATIVE TREATMENT OF PYORRHEA.

By THOMAS B. HARTZELL, M.D., D.M.D., Minneapolis, Minn.,
PROFESSOR OF ORAL SURGERY AND CLINICAL PATHOLOGY, DENTAL DEPARTMENT, UNIVERSITY OF MINNESOTA, MINN.

(Read before the Dental Society of the State of New York, at its annual meeting, Albany, May 8, 1913.)

THE operative treatment of pyorrhea is now so firmly established that discussion of its advisability is beside the question. Owing to the fact, however, that there has as yet been no crystallized method of practice in such treatment, it will be my effort on the present occasion to attempt to portray a method so crystallized as to make it possible for one who has not hitherto made use of it to put it into practice in an intelligent manner, and gain the desirable and beneficial results for his patients so much sought by every conscientious operator.

POLISHING OF ENAMEL SURFACE BY THE AID OF DISCLOSING SOLUTION.

The most essential thing in undertaking any particular operation in surgery is to have a clear conception of the underlying philosophy upon which such operation or treatment is based. Therefore a brief description of the tissues to be operated upon is essential. Pyorrhea treatment should begin on the surface of the tooth; this may seem a little odd, but a moment's consideration of that surface will make my point clear. Since the valuable studies of Pickerill have been presented to the dental public, we have been convinced that normal enamel is not smooth, but is a surface of minute furrows and ridges. As early as 1907, I urged, in a paper read before the National Dental Association,* that a ragged enamel surface is one of the fruitful causes of pyorrhea.

Pickerill's study of the enamel surface, together with the use of Skinner's disclosing stain, emphasizes this fact. The bacterial flora of the enamel surface at the gingival line and interproximal surfaces of the teeth bears a constant relation to inflammation of the gingivæ. A series of recent studies made by the author convinces him that the bacterial flora of these surfaces is rich not only in ferments, but in diplococci, staphylococci, and strepto-bacilli. The constant presence, therefore, of such a rich flora of micro-organisms is a most important feature in bringing on inflammation of the gingivæ and the underlying bone. Therefore the author has changed his method of treatment to the extent that he begins with the tooth surface first, provided that the case is still in the operable class.

If the case be operable, then the operator should begin his treatment by rendering the surfaces of such teeth absolutely smooth by the use of sharp planes, fine stones, disks, abrasives, and such polishing materials as will give the highest glaze and most brilliant sheen possible. This work should be undertaken before the pyorrhea pocket itself is disturbed, for the very simple reason that, if pumice or fine silex is used in polishing the teeth, this material will find its way into the pyorrhea pockets that have been opened up by instrumentation. The presence in the pockets of insoluble particles of silex or pumice causes additional irritation to those tissues; hence the advisability of doing the polishing of the enamel surfaces before operative procedure is commenced on the tissues of the root. The disclosing stain should be used both before and after the tooth surface is polished;—before, to guide the operator to the points which need polishing most; after, to check up the result, because the etched surfaces and bacterial growth on the tooth surface are so transparent and elusive that the operator, even after what may seem to him a very satisfactory polishing, may attain very poor results, because of the great difficulty in removing all traces of the bacterial coat.

* See DENTAL COSMOS for March 1908, vol. l. p. 240.

MINUTE ANATOMY OF THE ROOT OF A TOOTH.

After this phase of treatment has been completed and the mouth and gums have been thoroughly freed of the polishing material by flushing them with water, the operator should begin the treatment of the root surface, a study of which surface is exceedingly important as a prerequisite to successful treatment. We are accustomed to think of the roots of teeth as being composed of pulp, dentin, and cementum, the cementum being the outer covering of the dentin, affording attachment to the fibers of the peridental membrane, which forms the joint between the tooth-root and the alveolar process. A study of the cementum itself is well worth while, and to that I now call your attention.

The cementum is composed of atypical layers of bone, with thousands upon thousands of bone cells scattered through it. These bone cells are most numerous in the deeper portion of the cementum, and they gradually become fewer in number as the external surface of the cementum is approached, until a distance of about one-fiftieth of an inch from the external surface is reached, at which point very few bone cells are found. The small spaces which the bone cells occupy are called lacunæ, and the cells intercommunicate through channels known as canaliculi. On account of the necessity for a firm layer of attachment for the suspension of the tooth in its socket and the formation of the joint between the root surface and alveolar process, nature has built a denser portion of bone in which are very few lacunæ at most, and usually none at all. This denser portion of external surface, which, as I have said, is at most not over one-fiftieth of an inch thick, does not occur as a distinct layer clearly outlined as something that could be dissected up and stripped off, but is merely a denser layer of bone of exactly the same kind as that which composes the whole cemental structure. This denser portion varies in thickness in different parts of the root, but is a constant feature in the root structure wherever one may chance to examine it. External to the dense layer, the porous layer varies in depth and in porosity at different parts of the root, but it also is a constant feature of cemental structure.

SURGICAL TREATMENT OF THE ROOT SURFACE.

The aim of the operator in this type of root-surface surgery should be to cut away from the root all evidence of this outer rough coat, in which the suspensory ligament of the joint has its insertion, and he should attempt to do this in such a way as to leave a brilliant, gleaming, polished surface. When once he has uncovered that surface, he should stop instantly, lest he cut through the denser layer of the cementum, and expose to subsequent infection bone cells in the underlying spongy portion of the cementum. The enamel surface and the cemental surface of the tooth are the only two areas in the whole physical economy which lack the protective activity of the leucocytes. There being no leucocytes in the saliva, the enamel surface must be protected from bacterial growth in one of two ways: First, by mechanical means through mastication, or second, by polishing by the patient himself or by the dentist. The only other way in which the enamel surface can be protected is by establishing immunity to bacterial growth, and this is the great problem which now confronts dentists the world over. Is it possible by a known method of diet or therapy to produce such a condition of immunity as will inhibit the growth of bacteria on the oral surfaces?

THE PROBLEM OF IMMUNITY.

Our knowledge of immunity at the present time has not advanced to such a state of perfection as to crystallize any known method of bringing about immunity to bacterial growth in the mouth and alimentary tract. So we can dismiss that phase in the present discussion, and simply say in passing that that part of the problem must be studied with an ever-increasing interest by our profession, if we are to make real and lasting progress.

CAUSE FOR FAILURE OF MEDICINAL TREATMENT.

I said a moment ago that the leucocytes offered no protection to the root surface, and it is on this account that all kinds of medication directed toward the inhibition of infections in pyorrhea pockets must, in the end, fail. However much good such medicaments may do for the moment, the root surface is soon reinfected, because the leucocytes do not pass out of the tissue to do their best work, and the porous inequalities of the root surface offer an undisturbed culture-bed in which bacteria procreate in infinite numbers, ever supplied with food material from the blood-stream and saliva, but out of reach of the activity of the leucocytes. It is because of this fact that it is necessary actually to skin the root surface. The author thoroughly understands that the so-called scaling of the root surface has been advocated for generations, but this scaling is not enough. One must actually plane off the infected porous coat with the putrescent remains of the ligament of attachment, if he would prevent reinfection of the root surface, and he must do this skinning operation in such a way that he will not open up the still more porous substance of the deeper portion of the cementum.

TYPE OF INSTRUMENTS TO BE USED IN SURGICAL ROOT-SURFACE TREATMENT.

To accomplish this operation in the best manner without cutting too deeply, thus causing harm, one should have instruments so constructed as to render it impossible to take off more than a thin layer at any one stroke, and these instruments should be so sharp that they may be very lightly held in the fingers of the operator. Each one should be so constructed as to contribute steadiness and accuracy by its form, therefore all instruments for this work should be in effect straight instruments. First, they should have their cutting-edges exactly in line with the center of the handle, no matter what curvature of the shank may be necessary for reaching otherwise inaccessible positions on the root; second, each instrument should have two points of contact with the root surface, the cutting-edge and as broad a point of contact on the root surface mesial to the cutting-edge as it is possible to attain; third, the cutting-edge should be sharpened at nearly a right angle, to allow of push-and-pull movement, as advocated by Gartrell, James, and others. The observation of these three requirements make for accuracy and perfection of movement, and if these principles have been observed in the creation of the instruments for this work, the operator is able to gain more perfect results than he otherwise could gain by haphazard operation with instruments of haphazard construction.

THE IMPORTANCE OF A LIGHT GRASP OF AN INSTRUMENT.

The most difficult thing we have to overcome in teaching instrumentation in root-planing is the disposition of the operator to hold the instrument very tightly and strongly in his hand, and to bear down too hard on the cutting-edge. Blades should, as I have said, be sharpened at almost a right angle, so that bearing down cannot drive the cutting-edge into the tooth. Excessive bearing down robs the operator of delicacy of tactile perception, therefore he should hold the blade just as loosely in his fingers as he can and still make the planing movement. He should remember that the blade is intended to rest on two points, the cutting-edge and that portion of the shaft between the cutting-edge and the hand, which we might call the plane head. The instrument will not cut unless it rests on these two points. The fact that the instrument has two contacts makes for steadiness and accuracy in planing, and is an exceedingly important feature. Another reason for light grasp of the instrument is that one can distinguish between the different types of material with which the blade comes in contact. If the instrument is held very lightly in the hand, the shaving of tooth substance or of calculus differs in the sensation conveyed to the operator sufficiently to inform him what he is cutting—for it is to be remembered that too deep cutting means reinfection, which increases sensitiveness.

SENSATIONS TO BE GAINED DURING INSTRUMENTATION.

This is the practical reason for insistance on a light, delicate grasp of the instrument and a very discriminating sense of touch, because there are five distinct sensations which may be gained from the movement of the cutting-edge of the instrument on the tooth surface. First, there is the more or less jelly-like feeling which one gets when touching peridental membrane fibers without calculus; second, there is the rough, gritty feeling which calculus produces; third, there is the sensation—quite distinct from either of the first two—which the plane gives when cutting the porous root surface after peridental fiber and calculus are removed; fourth, there is the smooth, velvet-like feeling which the sharp plane affords when it has arrived on the hard layer of the cementum; fifth, there is the sensation noticed after one has been cutting on this hard surface for a few moments, a sensation due to the chattering of the blade in the spongy structure of the atypical bone of the body of the cementum. This is a sensation which the operator should never let occur, and which will not occur if he will stop when he meets the velvet-like smoothness in the hard layer which results from perfect operation. It follows as a matter of course that one needs instruments adapted to the surfaces; curved plane-heads for convex and concave surfaces, and blades of varying length and breadth —all systematically arranged to facilitate speed and to avoid confusion.

In choosing my instruments for my clinical work, I am guided by two considerations—by the fact that the root surface is to be regarded as a weight to be moved, and by the fact that the handle of the instrument is to be regarded as a lever.

TECHNIQUE OF OPERATING.

In regard to the operative work itself, one should take short strokes, always keeping the wrist in line with the forearm, beginning at the gum margin and directing the instrument root tipward and around the curvature of the root, going deeper at each succeeding movement, thus clearing a path for the instrument and making the operation painless, because of the small displacement of tissue. It should be the dentist's aim to polish the enamel margins so that they may easily be kept clean. Sensitiveness is due largely to the irritating effects of acids which result from fermentation and too deep cutting.

CLASSIFICATION OF INSTRUMENTS USED.

The instruments which I use in my clinic number one hundred and forty-four, and they are classified in four ways. They are first divided into eighteen groups of eight. This division is based on the position of the surfaces to be planed in relation to the finger-rest of the operator. Each one of the eight planes is made to fit one of the eight divisions of a circle, or, to be still more explicit, each plane is turned on its long axis 45° from its adjoining neighbors. This enables the operator to sit facing his patient and operate from eight different aspects of any given tooth from the same finger-rest, without changing his position in relation to his patient.

A second classification divides the instruments into three groups of forty-eight each. One group is intended for planing straight or flat surfaces, one for planing convex, and one for planing concave surfaces. This is to give the operator a selection which will fit any type of root surface, as it is impossible to plane a concave area with a flat or convex instrument.

A third classification divides the instruments into two great classes, one with a large offset or angle in the shaft, to reach far back into the mouth without stretching the corners of the mouth, and another to permit operation in the anterior portion of the mouth, in which case the curvature or bend of the shank more nearly approximates a straight line.

A fourth classification divides the instruments again into three groups of forty-eight—long, medium, and short, or large, medium, and small. These different classifications afford the operator instruments for every conceivable type of surface, except V-shaped angles, such as we find at the bifurcation of roots.

NECESSITY FOR SHARP INSTRUMENT EDGES.

Next in importance to the necessity for having an instrument at one's hand for every conceivable type of root surface and depth of pocket is the necessity for extremely sharp edges on the instrument. Such keen and sharp edges are speedily gained by the proper use of a sharpening device which makes the maintenance of a proper edge automatic.

REGENERATING LOST ALVEOLAR PROCESS.

Assuming for the moment that by our course of treatment we have cared for the enamel and the root surfaces, the problem which now presents itself is that of the loss of the alveolar process. The experience of the great majority of operators tends to create in their mind the idea that the alveolar process is not and cannot be restored when once lost. However, these conclusions are based on experience which has not taken into consideration the physiological requirements for the development of new bone, and on the hypothesis that bone is produced from periosteum, an erroneous belief. Since the wonderful laboratory experiments of Macewan of Glasgow, we have been taught that bone does not grow from periosteum, but rather from pre-existing bone cells; therefore the problem is to bring about the proper conditions for the reproduction of bone. The conditions are asepsis, freedom from pressure, and the freshening of the bony surfaces from which production must occur. This, I will admit, is a difficult combination of conditions to bring about in the mouth, but in just the proportion we can bring them about we can have deposit of new bone around the roots of the teeth upon which we have operated. The problem is, How can we best satisfy these conditions? The plan followed by the author in his attempt to provide the proper conditions for bony growth consists, on completion of the operation of skinning the root surface, in freshening the margins of the existing process by light curetment, which, of course, is followed by profuse bleeding. The next step is to seal the margin of the gum to the root by a suitable dressing material. If the blood-clot which flows up into the space formerly occupied by the ligament of suspension and alveolar process can be maintained in that triangular area for even a few hours, the bone will actively produce new bone cells during such period of time. If the period of time can be extended from days to weeks, the outpour of new bone will continue as long as freedom from pressure on the uplifting bone and asepsis obtain. The blood-clot is the best provisional filler of the space formerly occupied by bone and ligament of suspension. It has a certain anti-bacterial quality, and it exerts no opposition or resistance to the outpour of new bone cells from the process margin. The author is convinced by repeated experiment and observation that new bone can be and is produced about the roots of teeth to a considerable degree. It is probably true that we can never expect to have the original outlines of the process reproduced, but it is certainly true that enough outpour of new bone occurs about the roots of teeth which have lost a portion of their alveolar support to vastly increase their mobility and resistance to stress—an occurrence that would have been deemed impossible five years ago.

SEALING SOLUTIONS FOR GINGIVAL MARGIN.

The matter of a proper material with which to join the gingival margin to the root surface affords a field for experiment. At the present time, the writer is using two materials. One is sandarac varnish, which is applied to the tooth surface and gum after drying with the air-blast. This varnish will be retained for some time, thus closing the pocket to the fluids of the mouth. A still better material for closing the pocket is a combination of creasote and iodin, which is applied to the tooth surface and gum margin. This is allowed to dry-in for a moment, when it is followed by a coating of a saturated solution of tannic acid in glycerin, as advocated by Adair. This dressing will stay from twenty-four to forty-eight hours. The author has repeated the application at intervals of from two to four days, first thoroughly cleansing the necks of the teeth with hydrogen dioxid, lightly stirring the new granulation tissue piling up around the tooth root, just enough to cause bleeding, and then reapplying the sealing solutions. Under the conditions produced by this procedure, a surprising amount of new bone will be gained, and the teeth rendered much more solid in their sockets than by any other method of procedure known to the writer.

POST-OPERATIVE TREATMENT OF THE TEETH.

The post-operative treatment of this condition consists in gaining and maintaining, as nearly as possible, freedom from bacterial flora on the tooth surfaces. This end may be attained through the regular use of the revealing stain, which enables the patient to see where the bacterial coat is accumulating, and, subsequent to the operative treatment, to remove from the root surfaces, by proper use of the tooth-brush, wood points in a holder, and floss silk, any bacterial coat which the revealing stain may show to be present.

The next thought in post-operative treatment is apt to arise from the fact that many of the teeth are hypersensitive to heat and cold after the root surfaces have been skinned. This can often be controlled by drying into them saturated solution of silver nitrate applied with wood points in the holder, rubbing this solution in as vigorously as possible and keeping the warm-air blast playing over the surface when the application is made. When the sensitiveness grows less from day to day nothing further need be done, but when the sensitiveness to heat and cold is cumulative, pulp removal and canal-filling must be resorted to, the work to be done under nitrous oxid anesthesia or interosseous anesthesia, as the operator may elect.

CARE OF THE SOFT TISSUES IN AFTER-TREATMENT.

The next problem which presents itself to the operator is the care of the soft tissues. Assuming that a sufficient length of time has elapsed since the beginning of the operation to permit the deposit of the maximum amount of bony material around the roots of the teeth, it is then advisable to attempt to improve the tonicity of the mucous membrane of the gingivæ. This is best accomplished by massage. In this connection the author has used a variety of medicaments. Among the earlier drugs used for this purpose was that recommended by Dr. Smith of Philadelphia, a proprietary preparation, but a very useful one. Sulfo-carbolate, in a 10 per cent. aqueous solution, was experimented with, and is still used with great benefit in certain types of cases. The tannin, alcohol, and glycerin compound, a proprietary remedy made under the name of Azone* has been by far the most useful of any of these remedies. A two per cent. salt solution in hot water followed by 70 per cent. alcohol in water is excellent. Whatever solution is used should be massaged into the gums with a cotton roll held in a hemostat, or Kuroris. The whole purpose of these measures is to stimulate the development of a dense gum membrane, and to cause the gingivæ to shrink tightly to the necks of the teeth; and for this very reason, this method of treatment should not be adopted until all possibility of bony uplift is passed, for shrinkage of the overlying tissues checks the outpour of new bone. When the labial or buccal and lingual levels of the process are high, and the process between the roots of teeth has been destroyed, it is possible to bring about, by such perfect operative procedure, a condition of asepsis which will permit nature to fill entirely the crevices between the roots, which crevices may be as deep as a quarter of an inch. The leucocytes poured out into these spaces are the provisional filler thereof, and subsequently organize into connective tissue. Moreover, the labial and lingual mucous membrane will bridge across such masses of granulation tissue, and cover and protect these areas which otherwise would remain open for the ingress of food materials and infection.

In a future paper I hope to deal with the following problems. First—

DANGER OF BREAKING DOWN TOO FAST THE GRANULATION TISSUES AROUND INFECTED TEETH.

An important thought in the operative treatment of pyorrhea is one which has been impressed upon the author by repeated misfortune, viz, that it is unwise to disturb more than two or three teeth at a sitting, on account of the fact that the wall of granulation tissue which hedges in pyorrheal infections is broken down through the effort to free the root surface of its infection. When the wall of granulation is thus broken down, large numbers of bacteria are introduced directly into the circulation. If only two or three teeth are disturbed, the individual can absorb and destroy the dose.

* Azone = alcohol, glycerin, decoction of red oak-bark, equal parts.

If, however, through the anxiety of the patient to have his work rapidly completed, a large area involving six or eight teeth is disturbed, the patient is liable to have a pneumonia supervene, or an active joint infection, or an acute nephritis, or he may have a sharp chill and considerable temperature for two or three days. Having noticed examples of each of these four types of post-operative disturbance described, the author limits the area treated in any one mouth to two or three teeth at one sitting.

In line with the thought just discussed is another bearing on the same question. The writer also forbears attempting to stamp out a mouth infection immediately preceding a grave surgical operation in other parts of the body. He prefers to have the mouth operated on from ten days to two weeks before subsequent surgical interference is necessary; for the patient is more liable to harm on account of the breaking-down of the wall of granulation tissue, which has existed for perhaps years, and which is the one factor which has prevented a pneumonia, a joint infection, or a septicemia, any one of which serious disturbances may follow after this protective wall of leucocytes is broken down. During the skinning of the root surface the patient may have absorbed a sufficient amount of bacteria to so weaken his resistance as to react very poorly under the added stress of a grave surgical operation; whereas, if sufficient length of time elapses for healing to have occurred before subsequent operation takes place, the patient is in a very much better condition to resist a serious operation in other parts of the body. The importance of splinting teeth which have lost so much bone that there is not enough left to hold them rigidly after infection is stamped out should be considered.

The second problem is—

AFTER-TREATMENT OF LOOSE TEETH, AND WHY TEETH LOOSEN.

Teeth loosen from two causes, the swelling of the ligament of suspension heaving them up in their sockets, and the actual loss of the process. Teeth often are very loose although they have ample bone to hold them. After the operation of root-skinning is successfully accomplished, this type of tooth regains its rigidity in a marked degree in from twenty-four to forty-eight hours. If, however, much bone has been lost, no matter how successful the operation of root-skinning may be in stamping out infection, the tooth remains loose. It then becomes a matter of judgment as to whether these loose teeth shall be retained for any further service. If they can be supplied with some artificial means of support which will prevent lateral movement in their sockets, they will, as a rule, bear all of the weight of mastication without complaint. Therefore the construction of suitable splints or bridges of a removable character, which will afford mutual support to these teeth and prevent lateral movement, is a most successful form of treatment.

Diet is of the greatest importance. Alcohol, tobacco, and heavy meats should be eliminated. Citrous fruits and vegetables should be used, and starches should never be mixed; one starch is enough at a meal. The patient should eat generously of few elements and gain variety by different menus, rather than by many foods at a single meal, and should consume at least two quarts of pure water in every twenty-four hours. The patient should also sleep out of doors, or in a well-ventilated room, and take reasonable exercise.

The third problem is that of—

VACCINE THERAPY.

Vaccines are needed only when recurrence occurs in a clean mouth or when the patient's resistance is extremely low, and then only when such tonics as pepto-mangan fortified by strychnia and iron (Blaud's pills), or phosphorus have failed, or when a joint-infection will not yield after the initial focus in the mouth has been eliminated, at which juncture an autogenous vaccine is indicated. Viable lactic acid bacilli, also, are of great service in this connection.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

INFECTIONS RESULTING FROM LOWERED VITALITY, CAUSED BY UNHYGIENIC MOUTHS.

By CLARENCE J. GRIEVES, D.D.S., Baltimore, Md.

(Read before the union meeting of the Maryland Dental Association and District of Columbia Dental Society, June 13, 1913.)

THE foregoing title assigned by the committee promoting this symposium on Oral Hygiene assumes that vitality—meaning, no doubt, the general cell resistance of the body to disease—is lowered by an unhygienic mouth; and that infections—meaning, according to Gould, "The communication of disease germs or virus by any means, direct or indirect"—arise from that lowered vitality. In a word, the title presumes too much and too little;—too much, for it is a bare statement that unhygienic mouths (implying, in the usual use of the term, uncleanliness) lower the vitality, without real substantiation in fact; too little, for if this hypothesis be correct, not only infections in the local sense of the word, but many well-defined and serious systemic diseases, are bound to result. It is thus immediately apparent that the writer is expected to discuss all of the as yet unsettled predisposing causes of oral and of much special pathology in thirty minutes, the time allotted this paper; he hastens to admit his limitations, for the reading of the most meager bibliography alone, bearing on the subject, would consume twice that period.

DEFINITION OF THE UNHYGIENIC MOUTH.

The first and most difficult question to dispose of, that this matter may be discussed sanely, is the definition of an "unhygienic mouth." This is not so easy as it would appear, for in this instance the usual definitions, "unsound" and "unhealthy," do not define. All mouths, in this sense, are unsound, hence unhygienic without the continual help of the dentist. The normal, the obverse of the unhygienic, is ideal only, and so rarely realized as to be a negligible quantity; so in any attempt at mouth classification, the "near normal" must be accepted. It allows a small percentage of malocclusion and caries of the first stage in childhood and adolescence, recurring deposits in the usual areas of salivary calculus through adult life, and abrasion, possibly erosion, and clean gingival recession in after life. Indeed, it may be said, if these defects are carefully corrected by the dentist, the mouth is normal and can be so maintained. Dental caries neglected (through damage to the interdental spaces and gingivæ ending in gingivitis and pyorrhea, if the diathesis exist; through malocclusion in the sense of missing and tipping teeth, or the loss of all the teeth; by infection, through the root-canal, and lesions of the mucosa and tongue from lacerating carious enamel edges) will most certainly cause unhygienic conditions of the soft tissues, resulting in the invasion of these tissues by pathogenic organisms and the presence of pus and tissue exudate, and producing a condition of real disease or infection, the dangers of which will be defined later. In this manner, caries is a predisposing cause to unhygienic and unhealthy mouths; but the line must be sharply drawn, with the knowledge in hand to date, between these lesions and the consequent systemic damage, and the existence in the mouth of progressive caries without such lesions of the soft tissues. For it has only been presumed, and never proved, that the ingestion of wasting carious tooth structure, the contents of carious cavities, and general filth from decomposing food lying therein, is obnoxious, except that the denture is rendered unfit occlusally, the food is bolted instead of masticated, often resulting in intestinal putrefaction, and the mouth is offensive owing to the lack of toilet.

THE QUESTION OF THE ETIOLOGY OF DENTAL CARIES.

Dental caries in itself is not a septic process. There is no evidence yet adduced, in the first place, to prove that pathogenic organisms are active in producing caries. Though some of these are acid-producing, they exist in carious cavities only as casual visitors. In the second place, granted great growth of such organisms in many carious cavities, it is not reasonable to suppose that the ingestion of them would produce lesions in the faraway gastro-intestinal tract until pyogenic conditions were produced locally in the mouth, membranes, gingivæ, and alveolus. It is safe to presume that the gastro-intestinal tract is well guarded until the chemotactic power of saliva and other local protective powers break down, allowing local lesions, and caries *per se* can only predispose to gastro-intestinal infection. "No reference can be found in the literature relative to gastro-intestinal disturbance, or record of lesions therein, arising from the ingestion of common mouth flora and their products, which induce dental caries."(2) Of such Howe(1) says: "In other portions of the digestive tract, as the stomach and intestines, these organisms take an active part in the digestive processes. The fermentation processes that take place in the oral cavity, to the destruction of tooth tissues, have in the intestinal tract an inhibitory effect upon the microbic destruction of proteids."

Nor has it ever been shown that dental caries is an infection or infective locally, any more than it has been proved that caries is primarily a filth disease; in fact, "The local causes assigned for the initial lesions of caries, the decalcification of enamel, are numerous and not clearly elucidated. It is said to be due to fermenting particles of carbohydrate food retained about the teeth; to a definite film of bacteria covering all vulnerable surfaces and cavities; to oral mucus and its decomposition, etc. All agree that there is no specific organism ascribing caries to the usual, not the unusual, mouth organisms; that there must exist an agglutinated gelatinous plaque, protecting the bacteria and their acid products from the dilutions of saliva; and many state that a general acidity of the saliva does not produce dental caries."(2)

Finally, Kirk(3) affirms that dental caries is not a filth disease nor necessarily caused by fermenting particles of carbohydrate food lodging about the teeth, but that the initial lesion is due to a fermentable carbohydrate, possibly glycogen, excreted through the salivary glands, the ideal medium for the acid-forming organisms—and Black agrees with him; further, that the salivary secretion is an expression of nutrition, and that in turn is dependent on the food habit.

THE "LOCALISTS" VS. THE "CONSTITUTIONALISTS."

So the matter still stands undecided between these two theories—the "localists," headed by Miller and his followers, who maintain that caries is produced locally by the fermentation of carbohydrate food lying about the teeth; and the "constitutionalists," headed by Kirk, Michaels, and others, who believe that, while it is produced locally, the fermentable element is furnished by some constitutional defect or fault in metabolism, producing an excessive amount of glycogen in the saliva, which is agglutinated in a fermentable film on the teeth. The same division occurs in the etiology of that other great dental disease, pyorrhea alveolaris. Here, again, the "localists" claim that all pyorrhea is produced locally by trauma of the gingiva, principally from malocclusion and cervical calcific deposits, directly infected by fermenting and putrefying food particles as a pabulum for pathogenic organisms.

The "constitutionalists," on the other hand, are equally sure that it is but a local expression of some defective diathesis, or lowered vitality if you please, such as arthritism, disturbed metabolism, etc.

"UNCLEANLINESS" NOT THE PRIME CAUSATIVE FACTOR IN MANY MOUTH LESIONS.

So, in the light of assured facts, it will not do to glibly assert that caries and pyorrhea, the two greatest of all oral diseases, are due to filth and produced by unhygienic mouths, in the sense of unclean mouths. The term "unclean" is too often thus confounded with "unhygienic" in our minds, and while, from the standpoint of treatment, cleanliness is not only "next to," but becomes real "godliness" in all surgery, and cleanliness will always be the *vade mecum* of the dental surgeon, the fact that cleanliness is practiced and taught in the treatment after the onset of caries or after pyorrhea pockets have occurred does not necessarily indicate that uncleanliness is the real cause of these diseases any more than that it is a contributory cause to the onset of any disease. We must not befog our still doubtful etiology by our treatment, which is as often as not empirical. There is a long list of oral diseases calling for surgery or medication, always general as well as local, in which the teeth play little or no part. Aside from the lesions of syphilis, tuberculosis, and gonorrhea, there may be mentioned stomatitis, phlegmonous, ulcerative and catarrhal, cancrum oris or noma, nearly always fatal; marginal gingivitis, unassociated with calculus; Ludwig's and Vincent's angina, etc., and the neoplasms and blastomas; also the diseases antedating or coincident with the eruption of teeth, as aphthous stomatitis, particularly thrush, which is a stomatitis of nursing infants, produced by the *oïdium albicans*. G. V. I. Brown([4]) gives uncleanliness of the mouth and feeding apparatus as the local cause, particularly in bottle-fed babies; but he emphasizes the constitutional state as the real cause, saying, "It is rarely seen except in ill-nourished and debilitated children." This is true of every oral lesion; we will find the constitutional element, lowered vitality, malnutrition—be it a dyscrasia, diathesis, or real disease—to be the prime factor to be reckoned with, whether teeth and the filth collecting about them exist or do not exist in the mouth as local foci. It is probable that we may have "the cart before the horse" in the etiology of many mouth lesions, and that, after all, lowered vitality from malnutritional or other causes may be the real reason for the oral infections which seem entirely local.

"CLEANLINESS" NOT THE PANACEA FOR ORAL DISEASES.

This would appear to be confirmed by the treatment, or the failure of the treatment, in every instance. First, because, while it might be possible to keep the mouth free from food débris or "dirt," which has been defined as "matter out of place," the organisms—and it is said that over one hundred and thirty have been cultivated—which are the normal flora of the mouth, are matter not *out of* but decidedly *in* place, and hence not dirty. Cleanliness, as a treatment *per se,* fails before the fact that it is impossible to get a mouth surgically clean. Second, mere cleanliness, as far as it is possible to carry it out, will only assist but never induce a cure without the building-up of the general cell resistance. For instance, can an oral syphilitic lesion be treated by cleanliness alone? This is the main defect in our treatment of caries today—it is all local, not based on a clear etiology; and this explains why we are never through treating recurrent caries in the same mouth, until an immunity is established by body processes, and not the operator's processes. And this is why, after failure of local treatment in pyorrhea, vaccines are being exploited.

CLASSIFICATION OF ORAL SEPSIS.

The type of unhygienic mouth, then, which is really associated clinically with lowered vitality is thus shown to be not necessarily the mouth reeking with caries, but the mouth where caries, or any other contributing cause, induces local lesions of the soft tissues; and this condition, for want of a better term, is called "oral sepsis." It covers a multitude of mouth sins, and is ably explained by D. F. Colyer(5) when he says:

> The term "oral sepsis" is used not to denote a specific disease, but collectively to include all chronic inflammatory diseases about the mouth;—there occurs an increase in number and variety of organisms commonly found in the mouth, especially those of the pyogenic class. Under altered environment many of these organisms may undergo change in virulence in the direction of exaltation or attenuation—some of those which were non-pathogenic may become pathogenic. The catarrhal and suppurative products which result from bacterial activity undergo putrefactive change, and in this condition are constantly passing into the gastro-intestinal tract with enormous numbers of bacteria.

It is apparent that the term covers all inflammatory mouth processes, and it is to just this lack of definition that we object; if the term pyorrhea alveolaris stands for confusion in pathology, then oral sepsis is "confusion worse confounded."

We can now classify oral sepsis as follows(2):

(A) Tissue exudate and pus freely evacuated into the mouth from pyorrhea, fistulous dento-alveolar abscess, or from any freely draining surface; ingestion and absorption of pyogenic products via the gastro-intestinal tract.

(B) Tissue exudate and pus retained in the alveolus from chronic "blind" dento-alveolar abscess and peridental abscess; pressure absorption via the blood stream by metastasis.

(C) A combination of the foregoing in advanced pyorrhea and dento-alveolar abscess, or deep necrotic surgical areas, which only drain occasionally; pus retention below the level of drainage. Damage results by methods in A and B.

LOCAL EFFECTS OF ORAL SEPSIS.

In looking into the local effects resulting from oral sepsis and the infections arising therefrom, it is obvious that these will occur at any point in the soft tissue where local cell resistance is lowered, either from traumatism or constitutional causes. The gingivæ, peridental membrane, and alveolus are histologically the most vulnerable tissues exposed, being transitory structures subject to trophic change, hence are those most frequently involved. Other local expressions of infection are empyema of the antrum, to which, however, Worthington allows but 2 per cent. to be caused by septic teeth; and the infections of the pharyngeal ring, pharyngeal and faucial tonsils, which occur so frequently in oral sepsis as to be more than coincidental. Pickerill(6) also names Ludwig's angina or cellulitis of the floor of the mouth, arising around the lower third molars; parotitis, from ascending infection through the duct; and from dento-alveolar abscess, periosteitis, and necrosis of the jaws, but rarely osteomyelitis, and, the most common of all, lymphadenitis, through the circle of Waldeyer, in which the submaxillary and post-cervical glands are most frequently involved.

SYSTEMIC EFFECTS OF SWALLOWED PUS.

It is worthy of note in nearly all of these conditions that the common pathogenic organisms recovered from the pus are the staphylococcus albus and aureus, streptococcus, and pneumococcus. The influenza bacillus evidently plays an important rôle, principally by hematogenous infection, and Hartzell(7) reports fatal cases of alveolar infection, in which an anaerobe was recovered from the blood. A most serious and frequent question in dealing with the mouth of the average child, quite as important systemically and locally as diseases of the tonsils and adenoids, relates to the persistent fistulous dento-alveolar abscesses on the roots of temporary molars. It is next to impossible to really cure these cases, and the operator is confronted by an open infected inoperable root-apex on the one hand, and, on the other, the knowledge that the early loss of these premolars will produce malocclusion in the permanent teeth.

With sweeping pus areas often entirely surrounding the erupting bicuspids, it is surprising how little local damage is done, and appreciable systemic disturbance is so rare, except in the case of the ill-nourished, that it would appear that the ordinarily healthy child is almost immune to pus absorption. The reverse, however, is equally true, for, when the cell resistance, local or general, is lowered, the tissue areas involved are large and rapid, and systemic disturbance is profound and lasting.

As to the general systemic effects of these infections causing oral sepsis, the field is so large as to be difficult to condense intelligibly. Under the classification previously given, class A, in which the pus is freely flowing in the mouth owing to pyorrhea, in which, if the whole denture is affected, the suppurating area is said to be four square inches, and in fistulous alveolar abscess, serious systemic effects arise, according to Pickerill(9)—as secondary infections of the gastric and particularly the intestinal tracts from the ingestion and absorption of organisms and toxins, pus, and tissue exudate—and frequently result in septic gastritis and enteritis, colitis, appendicitis, etc.—from the absorption of pus by the intestinal walls into the blood stream, producing, according to Hunter(10), "pleurisy, nephritis, endocarditis, cholecystitis, and various toxic effects in the blood, as septic and pernicious anemia, chronic toxemia, septicemia. Sometimes the toxins are selective, as when exerting their influence on the nervous system, producing severe mental and degenerative effects; or on the organs of excretion, as the kidney, producing nephritis; on the skin, producing rashes; on the joints, producing so-called rheumatic swelling." A long list of authorities might be here named, principal among whom stand Hunter(10), Goadby(11), Mayo(12), Pickerill(9), Colyer(5), Billings(13), and Hartzell(7). In class B, where the pus, micro-organisms, and toxins are retained, as in "blind" dento-alveolar abscess and peridental abscess, pressure absorption occurs directly into the blood stream by hematogenesis. These cases are quite as dangerous, if less apparent, than the freely flowing pus cases, producing infectious and rheumatoid arthritis, arthritis deformans, endocarditis, and amylaceous lesions of the kidney and liver. The recent invetigations on this subject by Baer(14), Gilmer(15), Rosenow(16), Rhein(17), and the writer(18), will explain the etiology of these lesions more fully.

ORAL SEPSIS AS AFFECTED BY CERTAIN SYSTEMIC DISEASES.

The foregoing are but a few of the systemic diseases attributed to oral sepsis, and it yet remains to speak of the effect of certain systemic diseases, aside from those already mentioned, upon the oral cavity, producing a condition of oral sepsis and predisposing to local oral infections. It is to be noted that oral sepsis is classed as both cause and effect. Ulcerative stomatitis and gingivitis and general catarrhal conditions have long been associated with continued contact, as in the workers in brass, lead, nickel, antimony, and bismuth, and the effects of phosphorus are fully recognized. That the continued administration of mercury is productive of mercurial stomatitis and interstitial gingivitis, finally resulting in the loss of the teeth and alveoli, our forefathers very well knew. Scarlet fever, measles, and diphtheria, acting locally on the mucosa, and pneumonia, typhoid fever, and all other diseases in which the vitality is continuously lowered, induce an unhygienic mouth and a condition of oral sepsis.

THE VICIOUS CYCLE AND SYSTEMIC RESISTANCE.

So the status of the whole question appears equivocal, and we seem to reason in a circle, as in many other phases of the great and unsolved question of vitality. It has been here postulated that lowered vitality, or generally weakened cell resistance, is the basal cause of nearly all oral diseases, as it is of general disease; and the septic mouth conditions established through this agency, the oral sepsis prevailing against the local and constitutional defenses, will in turn as surely induce some of the various diseases previously named. And it is just as certain, if the oral sepsis preexist, that it will add to the gravity of the prognosis in any disease. This is known as the vicious cycle, and no consideration of the subject is complete which ignores its early recognition and the seriousness of the part it plays.

The possibility of general malnutrition and disease lowering the resistance of the local tissues, when some lesion, ordinarily simple, becomes a chronic pus focus—the local absorption of pus, micro-organisms, and toxins by hematogenesis, or the more usual ingestion of these products, finally affecting areas of the digestive tract and again lowering vitality and weakening the resisting powers of the local cells engaged in protecting the primary portal of entry;—this is the significance of the vicious cycle, and it is so grave as to make each of us wonder how we ever have survived thus far, and to be devoutly thankful for the wonderful alchemy of the human body and its immunizing powers, which are becoming better understood in the hourly fight against disease.

MODERATION AND RESEARCH URGED.

The field we have been considering is comparatively new, and, like all new fields in the healing art, most seductive. The etiology of a disease is hardly dry in print, the research only fairly in hand, before the operating begins. So it was with infection of the appendix, until the recoil has now assigned to the appendicitis operation its important and proper place. So it is with infection of the tonsils; after wholesale amygdalectomy, a sane understanding is gradually prevailing as to the relation of diseased tonsils to general health.

It is to be hoped that the dental profession will keep its balance, and not be carried away by this terribly new hypothesis—that every disease under the pathological sun is caused by an unclean mouth. This can be done only by the most assiduous research into oral pathology in its proper relation to general pathology. This we can and must do, and do quickly, if we are to deserve that high encomium paid our profession by Sir William Osler when he said to the dentists generally, "You are the keepers of the gate."

SYNTHETIC PORCELAIN, USING MALLET FORCE FOR INTRODUCTION.

By CLYDE DAVIS, M.D., D.D.S., Lincoln, Nebr.

(Read before the National Dental Association, in general session, at its annual meeting at Kansas City, Mo., July 8, 1913.)

THE term "synthetic porcelain" is one which should be applied to all processes in which an attempt is made to manufacture porcelain. Synthesis is the opposite of analysis, and means the uniting of elements to form a compound. We have synthetic rubber—also synthetic eggs—and, correctly speaking, dentists manufacture synthetic gypsum when they make a plaster-of-Paris model.

In all the attempts made to manufacture a dental filling of the silicates, the powder is composed largely of the same ingredients as fusible porcelain—that is, silex, kaolin, feldspar, water, and pigments.

PROPORTION IN THE INGREDIENTS.

In all synthetic processes the final result may be chemically quite like the original; yet in most instances there is a considerable difference in the physical properties of the product, as well as in the several different attempts at manufacture. In all of the synthetic processes the best results are obtained by having the ingredients as nearly as possible of the same proportions as found in the materials produced by natural processes. To illustrate: We have a plaster-of-Paris model more nearly resembling the gypsum rock when the mix is made as thick as possible and yet constituting a homogeneous mass (*i.e.* 21 per cent. of water and 79 per cent. of calcium sulfate). Or, in other words, there must be an abundance of the basal ingredients. This rule is true of the production of synthetic porcelain. In order to obtain the best results, the mass must be heavy with these basal ingredients, much thicker than is produced when following the instructions of the manufacturers of the various silicates.

SECURING HOMOGENEITY.

It is absolutely essential in all synthetic processes that the mass be homogeneous. Before the process of setting begins we have a mixture of fine sand and a fluid, which is like a mixture of fine sand and water—and it is practically impossible to produce a very thick mixture of sand and water by the process of spatulation and have that mixture homogeneous. In endeavoring to overcome this difficulty I have developed a method which has proved entirely successful, and which has produced a filling that is uniform as to time occupied in setting as well as uniform in texture, is stress-resisting, and seems to be far superior to the fillings which are produced by the advertised method.

This method is as follows: Put a small quantity of fluid on the slab, adding powder from time to time in a hurried manner, spatulating until there is produced a mixture as solid as very thick putty, even to the point where it has lost practically all adhesive property. The mass should be quickly worked into a compact form and then patted or paddled with a clean part of the agate spatula. I term this plan of mixing, the puddling process. With this process, viewing the mass under the magnifying glass the effect is seen to be quite similar to that in the manipulation of moist sand. You have all illustrated the process by patting the sand on the beach with the foot, when bathing.

We attain this same result when preparing a homogeneous mass in making a fused inlay. This is done by jarring the mixture as it is held in the matrix, the most common method being to draw a file across the pliers holding the matrix. Those who are familiar with porcelain work will notice the similarity of results when patting this otherwise dry and unworkable mass of synthetic porcelain.

The puddling process requires only a few light blows with your spatula, when the proper shade will immediately show up and the surface will gloss. The material is then ready for the cavity. The conditions as to the use of the matrix and as to the surface exposed should be the same as for introducing an amalgam filling, using the mallet force.

APPLICATION OF THE PORCELAIN TO THE CAVITY.

In approximal cavities in anterior teeth, the matrix should be used to supply the missing lingual and approximal walls. In approximal cavities in molars and bicuspids, the missing axial wall is restored with the matrix. The porcelain is carried to the cavity with a small agate instrument; take from the mix a quantity sufficient to about half fill the cavity. Wipe this hurriedly against all walls and into all angles, being sure the margin next to the matrix is covered.

The second portion taken should be sufficient to more than fill the cavity. This is applied hurriedly and the approximate contour secured. Immediately apply the plugger point which I will describe later. This should be dipped in melted cocoa butter, all excess being wiped off. This precaution is to prevent the material from partially adhering to the flat face of the plugger point. Apply mallet force to the plugger, using a very light blow with a light mallet. I will describe the mallet later.

If this process be viewed under a magnifying glass, it will be seen that the porcelain again develops the normal color, and the surface looks glossy and wet just as it did on the slab.

The blows at first should be light, and the plugger point should be held back so as not to distort the contour. As the setting process begins there will be noticed a resistance which feels as though one were malleting a piece of rubber. Before this condition arrives, the effect is to produce a homogeneous mass. As the setting process begins, a slight condensation takes place as the particles of sand are driven into closer adaptation, removing many little spaces which exist, and which is analogous to bridging in building a good filling. Fifteen or twenty blows will probably constitute the entire process. Just before the last four or five blows the plugger point should be dipped in cocoa butter and carried to the filling so that the entire surface is flooded. If the process of malleting be carried on too long the filling will begin to take on a lighter shade, which is the result of breaking up the process of crystallization, and irreparable damage is done.

ADVANTAGES OF THIS FILLING. THE SPECIAL PLUGGER POINT AND MALLET.

Fillings so produced will all set in practically the same time, which is at least twice as soon as by the method published by manufacturers; the maximum edge strength is always obtained, and the filling will be entirely uniform and superior in every desired respect.

As to the plugger point referred to, I have made it out of platinized gold. I pass it around for your inspection. This plugger point could be made of any material which it would be possible to keep clean and having a surface sufficiently hard to always remain intact. The form shown seems to be the best for most cases.

I also pass around the mallet, which you will notice is very light and has a soft surface. The reason for this kind of mallet is quite apparent. If you will revert to the sand-and-water mixture mentioned, you will readily agree with me that the light blow is the one to be desired.

To illustrate: Make a very thick mixture of sand and water. You can easily puddle this with a light paddle, whereas if you strike the mass with an iron hammer and a heavy blow, you will make a very dry mixture at the point of contact, driving the water to the periphery. Is not this the principal reason for so many fillings having poor edge strength? We have been taught to crowd them into the cavity with a spatula and then draw a matrix tightly over the mass while setting. If such manipulation be indulged in before the setting process begins, it will certainly tend to crowd the fluid out of the central mass and spread it about the margins of the filling. In this case one will not only have a mass that is not homogeneous, but one that is altogether too fluid in the region of the margins. If the spatulation or crowding of the matrix be done after the process of setting has begun, cracking of the mass will certainly result in destroying the texture of the filling.

FINISHING THE FILLING.

Manufacturers have cautioned us not to use steel instruments in finishing these fillings. No instrument coated with an oxid should be used in placing the material before the setting process begins, as particles are liable to be dislodged and incorporated in the body of the material as a mechanical mixture; this later affects the color of the filling by further chemical dissolution or combination.

After the filling, however, has been condensed and properly surfaced, particularly if it has been coated with cocoa butter, any clean instrument or a steel file may be used with impunity without involving any discoloration. I make it a practice to trim the fillings with a clean, keen-edged chisel and fine finishing files such as are used for finishing gold fillings. The margins do not break, nor do the fillings discolor, and I have as yet to see a single filling injured thereby.

If the mallet force has been employed in introducing the filling it will be necessary to do all finishing within a few minutes after placing the filling, as when the setting is complete it will be so hard that a new gold-trimming file or plug-finishing knife will slip off of the surface as it would from that of glass. When a high polish is desired, a second sitting may be resorted to, and the polish secured by the use of disks and strips carrying a fine grit. It has been my experience, however, that the best shades are secured by finishing the filling at one sitting, which may be begun in four or five minutes after completing the malleting and the entire process finished fifteen minutes later.

REASON FOR USE OF COCOA BUTTER AND OF WAX.

In no case should the surface of the filling be allowed to become cleaned of the cocoa butter, as exposure to the air during the process of setting allows water evaporation and will destroy the color as well as the texture on the surface of the filling. The profession does not seem to be entirely clear as to the reason for using cocoa butter and wax, which is this: During the process of setting, the cocoa butter prevents the evaporation of moisture. As soon as the setting process is complete the filling will absorb moisture for some little time, entirely reversing the process. These two conditions are true of a plaster-of-Paris cast. For this reason we use a wax to coat the filling when complete, to remain in place for at least twenty-four hours. If the wax be not used, the filling absorbs the fluids of the mouth, which implies the carrying-in of organic substances that will later decompose and by a process of oxidation will produce discoloration.

The white wax which has recently been furnished with the porcelain is entirely worthless, as it seldom remains in position longer than a few minutes or hours. The form of sticky-wax which was first put out for this purpose in the little glass tubes, and is yellow, is ideal.

DURATION.

As to the length of time any of these synthetic porcelains will stand in a practically perfect condition, no one can say. We have had invariable success so far. There is no question that such a filling will last and preserve the teeth for a number of years. Some years from now the profession will be able to judge as to final results.

It is very difficult to get a correct and adequate contact point in approximal fillings. Synthetic porcelain requires time and experience in manipulation to be able to produce a correct contour when working as hurriedly as the manipulation of this material demands. One cannot be sure that correct contact point, even though it be secured, will be maintained. It is questionable whether or not it will resist interproximal wear; I predict that it will not. Dr. Black states that in a mouth forty years of age, where no cavity existed, the approximal wear in the length of the entire arch was equivalent to one-half the width of a bicuspid in that mouth. This was the result when the approximal surfaces were covered with normal enamel. The possibility of building a filling of synthetic porcelain so as to resist such wear is very questionable.

The profession should also be cautioned about using this material unsupported in angle restoration in the anterior teeth. At the incisal edge we have a cord-of-wood proposition to deal with in both labial and lingual enamel plates, as the stress is sidewise to the enamel rods. The incisal edge must be beveled to the axial when using any filling, or the enamel margin will not stand. It is possible to make a gold inlay protecting this incisal edge, leaving the labial face open to receive a porcelain filling after setting the inlay. We have found this method a temporary solution of this problem in class IV fillings.

Yet the synthetic porcelains, with all their faults, are being accepted as quite ideal in many cases, and should be taken up by every practitioner, in order that he may develop the maximum skill in their use. The manufacturers are spending large sums to assist us in this work. It is certainly up to us to do our part. However, those of us who are studying this new material have found that we cannot simply buy the package, secure a patient, and make a perfect operation. It takes much laboratory work, and a large number of attempts, to obtain ideal results. It takes a longer time to learn the correct use and manipulation of any of the porcelains than it does to make a good gold inlay. In fact, one has found in the teaching of students that it is next to cohesive gold in the time required to master its peculiarities.

A WORD ON CAVITY PREPARATION.

The length of this paper forbids a consideration of cavity preparation for synthetic porcelain, hence I will close with a general statement applicable to all cavities. Be sure to have the full cleavage of the enamel. Keep the margins as far as possible from excess stress. Avoid acute angles in filling material. Every cavity should have retentive form equal to that desired for amalgam. Vital pulps need fully as much protection as when using cohesive gold or amalgam. Be sure all decay is removed from the dentinal walls, as the acid of tooth decay seems to be absorbed by the filling after setting, affecting both color and texture.

Bear in mind that the material while setting gives off moisture, and that the dentin must not be desiccated, particularly in non-vital teeth, as it will absorb moisture from the material to the ruination of the filling. It is good practice to varnish the dentinal walls in all deep cavities.

Lastly, while this filling is as yet far from perfect, it deserves honest consideration by every practitioner.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE SALIVA.

By PERCY R. HOWE, A.B., D.D.S., Boston, Mass.

(Read before Section I of the National Dental Association, at its annual meeting, Kansas City, Mo., July 8, 1913.)

THE most important problem now before the dental profession is to determine what differences exist between the saliva of mouths in which microbic life extensively flourishes and the saliva of those in which it is inhibited.

This is not a simple task, but involves broad and complicated physiological and pathological questions. The search in the saliva for a specific agent for or against dental caries has not been successful. We must, then, examine critically the fundamental principles of growth, nutrition, and disease, which the vast work of physiological research is making more and more clear to us; and we must try to establish, bit by bit, the connection between these principles and the local action of tooth decay.

VARIATIONS IN SALIVARY REACTION.

Analysis shows that the saliva from a resting gland differs from that flowing under a stimulus. The saliva from the resting gland is frequently acid, that under a stimulus alkaline, the degree of alkalinity depending on the degree of stimulation. Pain causes a very alkaline reaction. Analysis also shows that under the same stimulation saliva differs in different persons. The saliva is, then, individual in character; and it is reasonable to infer that that which accompanies rapid and extensive decay differs in some respects from that which is not associated with that pathological condition.

This may be readily demonstrated by experimentation. Collect from the parotid gland of several subjects one or two cubic centimeters of saliva, using every precaution against contamination from extraneous material, using in each case the same stimulant to incite the flow. Prepare a solution of sugar or starch. Then by means of a pipet add 1 cc. of one of the salivas to 2 cc. of the sugar or starch solution, incubate, and test for the amount of acid formed as described below. It will be found that the amount of acid differs in each case. In one it is twice what it is in another; in still another it is three times as much. The bacteriologist would attribute such differences to the number and kind of bacteria present. These play an important part in such an action, but are not the complete explanation, for activity of growth and virulence must be taken into account fully as much. If we subject the salivas to analysis, it will be found that they show wide analytical differences, so that we may feel that this difference in bactericidal activity or virulence is to be thus accounted for.

EXPERIMENTS IN VARYING THE CHEMICAL ELEMENTS OF SALIVA.

In order to arrive at a conception of the possible character of a saliva favorable for the proliferation of bacteria of the type that we believe to be concerned with tooth decay, I have carried out a series of experiments in which certain elements of the saliva have been artificially increased, and the effect on bacterial growth compared with controls. The bacteriology of dental caries, as worked out by Dr. Miller now more than twenty years ago, has received no material change, and we still believe this process to be due to lactic acid-forming organisms. On this basis I have determined the comparative activity of these organisms by estimating the lactic acid formed. The estimation has been carried out in the usual manner by titrations with phenol-phthalein for an indicator and with N/100 NaOH. Although the exact composition of the saliva has not been so completely determined as to have an established formula (I have carried out some rather complete analyses and balances that I will report later), yet for the present purpose it is sufficient to mention as elements albumin and globulin, mucin, phosphates, carbonates, chlorids, and the bases calcium and magnesium, sodium and potassium. These elements I have added to cultures of maltose, lactose, dextrose, and levulose; and have determined the lactic acid formed in the different cultures under exactly the same conditions.

STIMULANTS AND DETERRENTS OF LACTIC ACID FORMATION.

These experiments, comprising some five hundred tests, show that in every case the phosphates of the alkali bases are decided stimulants of lactic acid formation. They act here as in alcoholic fermentation.(1) Here and there throughout physiological experimentation it has been remarked that sodium phosphate, both the mono- and the dibasic, excites bacterial cultures to growth, and that it promotes cell growth. This property is not confined to the sodium phosphates, but is common to the phosphates of the other alkali bases. The phosphates of the alkaline earths act in the same way, but, on account of the solubility difficulties, are not so markedly shown. An increase of albumin and mucin, each of which I have added to cultures of the type described, produced a marked increase in the lactic formation as compared with controls. Creatinin causes a similar increase.

If it be true that with the picric acid test no other substance forms the distinguishing color,(2) then creatinin is a constituent of the saliva. On account of the colloidal nature of the saliva it requires a little time for the color to appear. Weyl's test and Salkowski's also give a positive reaction. Creatinin, as is well known, is a product of muscular (endogenous) metabolism, and it may here be accounted a stimulating agent.

The carbonates, bicarbonates, and chlorids diminish lactic fermentation, according to these experiments.

PROBABLE EXPLANATION OF PHENOMENA.

When we consider all these elements of the saliva from the standpoint of furnishing bacterial life with its nutritional requirements, we have a very reasonable explanation of their respective actions in these experiments as excitants or depressants. The globulin, albumin, mucin, and creatinin are all able to furnish the nitrogen for the structural requirements of the bacteria. Bacteria are selective, and with utilizable sugar present, even pathological germs form simply lactic acid, yet they must have nitrogen for their own structural purposes. Dr. Kendall is authority for the statement that the typhoid bacillus grown in broth forms toxins, but, when utilizable sugar is added, it forms lactic acid. In the first instance the smallest amount injected into a guinea-pig produces toxic symptoms, but in the second almost any amount can be injected with no ill effects. The organisms that attack the teeth must find not only suitable carbohydrate material, but also some material from which to obtain the nitrogen upon which their very existence depends. Under the conditions provocative of tooth decay even pathogenic bacteria become lactic-forming, and indeed the very growth that in the mouth causes such damage is, farther on in the digestive tract, considered a very desirable thing. Metchnikoff has advocated the introduction of lactic-forming bacteria for the purpose of changing the toxic character of intestinal putrefaction.

Others to effect the same end have advocated furnishing the microbic flora with a suitable medium by feeding some utilizable sugar.

Certain bacteria cannot be grown *in vitro* unless they have amino-acids.(3) These acids furnish a nutritional requirement. They are of course obtained from albumins, either by the action of a ferment or by proteolytic bacteria. From this we may feel that when the albumin or the globulin of the parotid or the mucin of the submaxillary saliva becomes subjected to the action of the proteolytic bacteria (and these exist in quantity in the mouth),(4) the lactic bacteria would here find a very available source of nitrogen, and that it would stimulate these organisms to active growth. I have experimentally found this to be so; and by adding amino-acids to cultures have found the lactic acid production to be indeed increased.

PATHOLOGIC CONDITIONS AS FAVORING LACTIC ACID FORMATION.

Local infective processes of the gums, tonsils, sinuses, and nasal passages, adenoids and inflammations of the pillars of the fauces and of the uvula, or catarrhal conditions in which the colloids of the mouth show evidence of alteration or liquefaction by bacteria, are distinct aids to the lactic-forming organisms through affording an available source of nitrogen. I have shown this to be so *in vitro*. The albumin and the globulin are the better source of nitrogen as compared with the glycoproteid mucin, for mucin is comparatively poor in nitrogen. Viscidity of the saliva does not always signify a favorable medium for bacterial proliferation *per se;* viscidity of the parotid usually does. In cultures such as I have described the parotid saliva produces more acid than the submaxillary or the sublingual saliva. Compare the decay of the first molars with the decay of the lower front teeth.

Urea is frequently found in the saliva, and acts in the same way. Amino-acids are converted into it.

PHOSPHATES AND CARBONATES.

When we recall that bacteria of the kind associated with tooth decay are low forms of vegetable life, we know that phosphates meet nutritional requirements; and this may be considered a possible explanation of their stimulating action in lactic fermentation.

Although chlorids are essential to or are tolerated by certain kinds of bacteria, they here act in an inhibitory manner; and the same is true with the carbonates. Nor can we see, with our present knowledge of bacterial life, how they could be of service from a nutritional point of view. While I have termed the carbonates inhibiting substances, their action is to neutralize the lactic acid formed. Bacteria are able to form this acid in the presence of carbonates, as may be seen by a comparison of the degree of alkalinity in a control with that in a culture of some hours' incubation. Here the alkalinity will be found much lessened owing to some of it being used to satisfy the acid formed.

BALANCE OF ELEMENTS IN THE SECRETIONS.

Physiological chemistry has shown that under normal conditions the secretions of the body maintain a certain proportion or balance of many of those very elements which we have been discussing. The albumin and the globulin sustain a rather definite ratio to each other. The amount of sodium relative to the potassium, and of the calcium to the magnesium, are other ratios. Individual in character this balance may be, but under certain pathological conditions it is materially changed. The proportion of albumin to globulin, for example, in certain kidney disturbances is changed so that the globulin greatly exceeds the albumin(5); while in tubercular conditions the albumin much exceeds the globulin. In pneumonia is to be seen another example of this, for here the sodium-potassium relation is reversed from what it normally is,(6) and the calcium-magnesium relation undergoes great alteration. The sodium, chlorin, and calcium are here retained, whereas the potassium and the magnesium are excreted in excess. (7) It has been shown, too, that in the intestinal disturbances of infantilism similar irregularities occur. (7) Calcium is here not taken up by the tissues. (7) In one case reported, a normal urine contained a calcium-magnesium proportion of 244:100, when in the abnormal case the ratio was 27:100. In intestinal crises 60 per cent. more calcium is excreted than is taken in by food. These few cases serve to illustrate the fact that these very salivary constituents suffer disarrangement under certain systemic metabolic conditions, so that one element unnaturally predominates over the other. The saliva is no exception to the other secretions in the feature of having a balance of elements, as is known to every investigator of the subject. The chlorid-retention of fevers holds true in respect to the saliva. Under normal conditions the phosphates are increased by a heavy protein diet. Excess of the earthy phosphates in the urine is indicative of a heavy phosphate content in the saliva.

The chlorids remain usually constant, (8) but show increase by introduction through food supply. There is, however, a heavy demand for sodium chlorid in the system, for it is supposed to furnish the sodium base for all sodium salts in the body. It appears in the blood in connection with potassium phosphate, and a certain portion of it is taken up in a double decomposition forming sodium phosphate and potassium chlorid. On account of the large amounts of potassium salts present in vegetables, the individuals living on such a diet need more chlorids. The deficiency of chlorids in the saliva allows the mucin of the submaxillary saliva to become precipitated by the organic acids of the mouth. (9) Drinking a large amount of water will cause an increase in the chlorids in the saliva. (11) From many analyses I believe that in mouths where extensive caries is progressing it will be found that the chlorid content of the saliva is low. The administration of diuretics lessens the chlorid content. The chlorids under normal conditions maintain an isotonic relation in the tissues and in the bodily fluids.

Carbonates represent the ingestion and ultimate oxidation of carbohydrate material. Fatty acids given in the form of salts of sodium cause large quantities of carbonates in the urine: Schotten. (10)

A FIELD FOR INVESTIGATION WORK: LATER CONTRIBUTIONS—PICKERILL'S WORK.

These few facts serve to show some of the possible ways in which these elements of the saliva are disturbed in their arrangement, and in what way we may expect to increase or to diminish them. This clearly shows, as well, the immense amount of investigation work that needs to be done in order to clear up the connection between dental caries and the various systemic phases that effect such alterations in the habitat of the micro-organisms as to cause them to take on an active growth.

This manner of consideration of the subject of tooth decay is based on the supposition that an abundance of utilizable carbohydrate is always available from the food supply.

A thick, viscid saliva can be thinned out and the chlorid content raised by drinking a liter of water with the meals according to the experiments of Mathill and Hawk, (11) and as I have ascertained by actual measurement, using a viscosimeter described by me in the Cosmos for April 1912 (page 431).

With respect to the effects of stimulation of the salivary glands, Dr. Pickerill's interesting and instructive work shows that acid and sapid foods produce the greatest flow and cause the greatest degree of alkalinity. (12) He advocates the use of such sapid substances for this purpose, and for the same reason he recommends acid mouth-washes and the incorporation of potassium bitartrate into powders. He attributes (and rightly) the greater degree of alkalinity to the larger amount of alkaline salts present, believing that the activity of bacteria is in no wise interfered with, and that they still have every facility for the formation of lactic acid, but that the presence of these alkaline salts in the salivary fluids will satisfy this acid, and that they will be chosen rather than the salts of the teeth. This idea of alkaline salts to neutralize acidity has been our usual treatment. Dr. Pickerill obtains a more constant presence of these salts. In respect to phosphates, he believes them to be protective agents for the reason that they may satisfy an acid. My experiments have convinced me that they are a nutritional stimulant to these organisms. Dr. Pickerill feels that mucin is a protective agent because it gives an alkaline reaction when it decomposes. I believe that it is a protective agent from a physical standpoint, but that its decomposition encourages a vigorous growth of lactic-forming bacteria by affording the necessary nitrogen, and that it is then converted into an augmenting factor. This I have substantiated by experiment. It is undoubtedly true that organic acids have their place in our armamentarium, yet I feel that the neutral and alkaline salts also have theirs.

The increased alkalinity arising from stimulation is of course due to the increased flow of blood that ensues upon the activity of the gland. The reaction of a resting gland may be acid, but when the gland is activated the reaction becomes alkaline. The degree as given by indicators is only relative. Dr. Pickerill has used methyl-orange, but it is not considered a very sensitive indicator—indeed Sutton says it is unfit for organic work. I have used methyl-red, which was recommended to me by the Industrial Institute of Chemical Research at Washington. This indicator can be used cold, in the presence of carbonates, and is very sensitive. It reduces the alkalinity as given by Dr. Pickerill. Phenol-phthalein, with the addition of a bit of potassium oxalate to take care of the calcium salts, and boiling, adding by tenths N/100 HCl and boiling again, repeating until boiling no longer causes it to redden, gives very accurate results.

Dr. Pickerill deals for the most part with the saliva under stimulation, but not wholly, for he advocates a protracted diet of acid foods, thereby producing a more alkaline saliva. It seems to me that it is during the longer intervals between meals, when mechanical friction has passed, and when stasis can best occur, that the bacteria find the opportunity for the largest production of acid. It is the character of this slowly exuding saliva that has the more prolonged effect upon caries, rather than the flow that follows the stimulation of eating, and persists only for a few minutes after. In either case the saliva depends for its individuality on many systemic phases, some of which have been indicated. The saliva may contain foreign or morbid products, as I have shown in different articles. It is capable of alteration, but demands familiarity with physiological principles, together with a knowledge of chemistry sufficient to guide any attempts at treatment.

SUMMARY AND PRACTICAL SUGGESTION.

One aim of this article has been to emphasize the fact that many systemic conditions are directly reflected in the saliva and act to promote decay.

Another idea is to show that the condition of the surrounding parts, by furnishing proteolytic bacterial substances, encourage tooth decay. It is desired to suggest the consideration of the saliva as a medium furnishing acid-forming bacteria with necessary nutritional requirements, and not simply as a neutralizing agent for acid already formed.

We recommend, then, as general suggestions, coarse foods, and sapid and acid foods as salivary stimulants. We recommend also dietetic consideration on account of the nature of the metabolites, attention to intestinal conditions on account of the toxemias that result,([13]) and fully as much attention to the state of the kidneys for very similar reasons(14); and finally, seeing that the adjacent anatomy is free from inflammatory and catarrhal states.

ORTHODONTIA AND ITS RELATION TO DENTISTRY.

By ROSCOE A. DAY, D.D.S., San Francisco, Cal.

(Read before the National Dental Association, in general session—being transferred from Section I—at its annual meeting, Kansas City, Mo., July 9, 1913.)

THE relationship of Orthodontia to general dentistry is such that it demands hearty co-operation upon the part of both the orthodontist and the general practitioner, and is of pronounced assistance to both in accomplishing the results desired. The orthodontist is in the same relation to dentistry as the rhinologist, aurist, and oculist is to medicine. Not that the orthodontist feels himself greater in his art, but simply that the time has arrived, in this advanced and progressive age, when the laity demand individual attention to themselves and families, especially in the proper care of the children from every point of vantage looking toward normal development of the human body.

IMPORTANCE OF ATTENTION TO OCCLUSAL CONDITIONS.

I believe I am not presuming too much in saying that there is not a person present here today, who follows his general practice closely and has his patients' welfare at heart, who feels that he can afford to give time to a case of malocclusion, or any character of malformation, without neglect of some other department in his practice. Thus is shown one of the reasons why the science of dentistry is being divided into its many departments, called "specialties." Another very important reason is that the laity are becoming educated to the facts, and are demanding that they receive the benefit of that "special education" that is necessary in order to fit the competent man to practice successfully his specialty and get results.

The position of the general practitioner of dentistry demands that he should be very familiar with orthodontia from its many standpoints. The family physician first takes the responsibility of the child from its conception, through the prenatal and postnatal period, up to the time of the presence of the full complement of the deciduous teeth. Then the family dentist comes in, and as a rule he is the first to come in contact with the patient who is in need of the services of the orthodontist. His advice is always asked regarding the development of the dental arches, the condition of the teeth, and especially the dental occlusion. It is of great importance that he be thoroughly familiar with normal occlusion and its relations—with the influences it exerts upon the development of the facial bones and proper muscular functions—so as to enable him to diagnose the condition at once and offer the best judgment in regard to cases that come under his observation.

"NORMAL OCCLUSION" DEFINED.

It may seem rather superfluous to present to you the definition of "normal occlusion," given by Dr. Edward H. Angle, but I cannot resist doing so at this time, inasmuch as it covers so thoroughly the cases that come under the care of the dentist. It will assist materially in enabling him to diagnose those cases, while it implies as well the probable prognosis if they are not given proper attention.

He defines—"The line of occlusion as being the line in which, in form and position, according to type, the teeth must be in harmony if in normal occlusion."

There can be, then, but one line of occlusion, and it must be the same as the architectural line on which the dental apparatus was constructed. This ideal line was intended to govern not only the length, breadth, and peculiar curve of the dental arches, but the size and position of each tooth, cusp, and inclined plane composing these arches; and more than this, that as the dental apparatus is only a part of the great structure of the human body, each part and organ of which was fashioned according to lines of design, it must have been intended that the line of occlusion should be in harmony in form and position with, and in proper relation to, all other parts of the great structure, according to the inherited type of the individual.

Anyone giving this definition sufficient thought and study may apply it to cases that come within his observation, and can readily appreciate its broadness, and see how completely it covers the individual case at hand.

ETIOLOGY TO BE STUDIED.

An important factor in the majority of cases relates to the etiology, or causation, of malocclusion and abnormal development. The etiology of each case presented demands the most careful and thoughtful consideration, in order that the operator may be able to remove the cause, if possible, and prevent further abnormal development along the line of perverted normal occlusion.

The causes are numerous, and each one has its own individual characteristics in that regard. Those most commonly associated with malformations are nasal stenosis, brought about by adenoids, polypus, infected tonsils, some form of deviated septum, or irregularity of the turbinate bones, resulting in an underdeveloped nasal passage, lacking capacity for normal breathing. The natural result is the necessity, in the case of a patient so afflicted, of using the oral cavity for breathing purposes in conjunction with its other normal functions, and in the greater majority of cases creating an habitual mouth-breather, whose habit greatly retards the normal physical and mental development.

We know that the osseous development is greatly influenced by mechanical stimuli, whether of muscular function or otherwise. In the case of a mouth-breather, the abnormal functioning becomes greatly pronounced by the mouth being constantly held open in breathing, which creates abnormal muscular pressure against the lateral halves of the upper arch and a backward pull on the mandible, with lack of the normal function of the tongue in assisting, as it does when in its normal position, in forming the arches.

Mal-locking of the cusps of the teeth as they erupt in their respective positions, and continual pounding of the mandible into the upper arch when the teeth are in malocclusion, also altered conditions of atmospheric pressure in the inspiration and expiration of air, are pronounced factors in the abnormal development of the bones of the face and accessory sinuses. Nature fully intended the nasal fossa to be used for breathing, and in so doing made provision for the air to be properly prepared and treated for its reception into the lungs; and when the oral cavity instead has to perform that function, the absence of the preparation of the inspired air results in the lack of full distribution throughout the lung cells; a continuation of such conditions greatly hinders the distribution of sufficient oxygen to the system, which tends to entail lack of development in the region of the chest and a general anemic condition of the patient as a whole.

MALNUTRITION AS A FACTOR IN ETIOLOGY.

Another mode of causation that presents itself very frequently is malnutrition, which may be traced as far back as the prenatal stage, namely, to the anemic or faulty assimilation of the mother.

In early infancy the child, in some cases, cannot be fed by natural means—the mother's milk—which necessitates artificial feeding; and many times the physician is not able to prescribe a formula that takes the place of the natural food—all of which necessarily retards the early development of the child. In some instances a too highly organized food is given—food lacking the proper ingredients for bone-building.

The eruption of both the deciduous and the permanent teeth is at a period when the greatest growth of the body is in progress, and if malnutrition or any other abnormal factor is present during this period, it is quite natural that it should seriously affect the normal development of the dental arches and interfere to a great extent with normal eruption of the teeth into the respective positions.

HABITS AND ENVIRONMENT.

Diseases acquired in early childhood and improper environment are influences which tend to deflect from normal development—as oral habits of various characters acquired in early childhood and not overcome before having become the cause of some pronounced abnormal functioning. The habit of mouth-breathing, acquired owing to some obstruction of the naso-pharynx, when it has been of long duration, is in many instances the one that is hardest to overcome. Thus, many times, after the rhinologist has removed the cause of the nasal stenosis, and the orthodontist has restored normal muscular function and normal occlusion of the dental arches, the patient, through lack of effort and long association with the habit, continues to breathe improperly—especially when fully relaxed, as in his sleep. This is not a common condition, but one due to a chronic condition of long-standing malformation, and must be overcome by mechanical assistance in closing the mouth while in repose.

Higher civilization is another great factor in causation, associated with disuse of the oral cavity, in lack of sufficient amount of natural exercise in mastication, owing to the fact that our food of today is so prepared that it is to a greater extent predigested before being served for consumption. It is proved, therefore, that the great factor behind these maldevelopments, in many instances, is perverted nutrition and the rearing of the child in a hothouse existence, as it were, with a lack of the proper amount of natural environment, in not being associated closely with nature as the Creator intended.

IMPORTANCE OF CARE OF THE DECIDUOUS TEETH.

One of the most material points, one that is frequently of the greatest significance for the future welfare of the patient in the matter of oral development, is the thorough and conscientious care of the deciduous teeth. This is of the utmost importance in its bearing on the normal development of the dental arches. Through the efforts of the dentist the parents are becoming more enlightened in that regard, and are much more appreciative of the necessity for the proper care of the deciduous teeth until their successors erupt; they are being educated to understand the very important part that the deciduous set play in assisting nature to insure a normal growth of the dental arches, and it is one of the essential duties of the dentist at all times to thoroughly impress this fact upon the parents.

FACTORS IN THE CAUSATION OF ABNORMALITY.

A causal factor that appears in some instances is a congenital anatomical deficiency, such as cleft or non-union of the suture of the superior maxillary bones, malformed or misshaped cusps and crowns of teeth, non-formation of the permanent tooth-germ to succeed its predecessor, the deciduous tooth. These causations, fortunately, are not common, but, when they occur, present a serious difficulty to overcome. Again, in some instances the phenomena of deficiency may be reversed, even to the extent of supernumerary teeth erupting inside the upper dental arch, disarranging the teeth as they erupt, and so bringing about a malocclusion.

The causes mentioned are general, and there are many instances, perhaps, where we may be able to trace the etiology to some other origin; and this emphasizes the necessity laid upon the dentist that he be so equipped with knowledge in relation to orthodontia as to enable him to diagnose the cases that present themselves. It is of the utmost importance that these abnormalities be recognized at or as near the beginning as possible—not waiting until they have developed to the chronic stage, so to speak, but taking them into consideration at once and giving relief through proper orthodontic procedure.

OBJECT OF ORTHODONTIA TO SECURE NATURE'S IDEAL.

The relationship and object of orthodontia in dentistry is purely to assist nature toward the normal functions of the oral cavity, normal development of the facial bones and dental arches, normal muscular functions and normal occlusion of the teeth—which, when established, maintains a balance of function that was originally intended by nature, and in consonance with the inherited type of the individual.

You are all fully aware of the results of a dental impaction of long standing, and the difficulty in trying to overcome a malformation that has gotten to such an extent of development that every function is practically abnormal; also the fact that many of the more pronounced cases of delayed development of children are influenced by dental impactions. This is a factor recognized by the science of medicine—especially by the man in that profession who is devoting himself to the care of children—and by the rhinologist as well. Nature's original intention is harmony of development and function in all parts of the human body as to its inherited type of the individual. She creates the size and form of the teeth in harmony with the bones of the face, and they are so constructed and arranged that they properly resist the natural forces when the teeth are in normal occlusion. Each bone of the skull bears a relationship to the others as to size, and the failure of one or more to gain its full size naturally affects the growth of the other bones that articulate with it; and when this change of bone-development takes place to such an extent that the erupting teeth are forced to take a position in occlusion other than normal, the perversion of bone-development immediately becomes further assisted by the exertion of the mechanical forces of occlusion, besides the creation of a perverted muscular function, upsetting the balance of expression of the facial features.

Other anatomical deformities of the human body, such as come under the care of the orthopedic surgeon, are given attention, as we know, at the earliest possible age, in order to place nature at her best advantage for a more perfect development of the parts afflicted. We, as dentists, have the same responsibility in regard to oral deformities and malformations, and beg to suggest for your consideration whether it be not more logical and practical that the dentist should recognize these abnormalities at the earliest age possible and assist nature toward realizing her original intention of development in the case of each individual.

You cannot but agree that it is of the utmost satisfaction to the dentist, and as well to the patient, to realize at maturity a normal development and balance of function of the oral cavity and its affiliations. It is, as well, of great assistance to the dentist in the future upkeep of the organs of mastication. The creation of and the skill in the adaptation of appliances for use in the cases at hand are essential, and need to be thoroughly understood, but, even so, these become of no material value to the operator unless, further, he be able to proceed on a scientific orthodontic basis from the beginning to the completion of each case treated, and be thoroughly familiar with the laws governing normal occlusion.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

Correspondence.

AN AMAZING CONTRAST: "RESEARCH" AND "RELIEF"— A SUCCESS AND A FAILURE.

To the Editor of the Dental Cosmos:

Sir,—The Research Committee of the National Dental Association is said to have a fund in hand of $16,000, and more in sight. For more than twenty years past, a Relief organization has been talked about; articles have occasionally appeared in dental journals advocating the cause, and telling of the great success and of the good work done by the British relief organization; a few years ago a committee was appointed by the National Dental Association to solicit money;—and apparently the unfortunate and the aged are still unthought-of and uncared-for! The donors to the research fund are seemingly unaware that research workers or scientific investigators are too often men who sadly need care and assistance, and they are forgetful, if they ever knew, of the number of deservedly prominent dentists who in the last thirty years have been wholly dependent on the charity of friends.

While most heartily congratulating the Research Committee on their success in getting money, the apparent failure of the Relief Committee is sadly disheartening. The warning note in the editorial in the Cosmos for December 1911 was not heeded. The object, movement, and work have been "allowed to lie dormant," and I feel sure that that splendid presentation and appeal to the profession was not generally seen or read.

The "recall and referendum," in dentistry, means a careful study of present conditions and grave thought as to the actual importance, value, and benefit dentists will gain by contributions to either or both the research or relief funds. The writer believes that dental colleges and universities all over the country, medical colleges, the Rockefeller and Carnegie Research institutions, and the grand Evans Memorial and Dental Department of the University of Pennsylvania have been giving and will continue to give all the scientific food that the dental, medical, and other professions can absorb and thoroughly digest for some time to come, and that the workers in these institutions will be glad to see energetic efforts made to raise money to care for the aged and unfortunate.

Money is wanted, and if the dentists will wake up and realize the grandeur of the relief movement, and work together, they can easily raise before Christmas $10,000 as a starter. In every town and city, I might say village, there are churches, asylums, and hospitals—beautiful object lessons that tell of the personal sacrifice of a poor but united people, whose money contributions were always small, rarely more than one dollar, but frequent, until finally the churches and charitable institutions were truly made in every sense homes for the unfortunate and aged. Let the same persistent spirit be manifested by the dentists of the country, and ideal homes, so lovingly pictured by Dr. J. B. Story of Texas, would soon be ready for guests.

It is estimated by enthusiasts that the National Dental Association this year will number over 12,000. A Relief Fund must be raised, and can be, if these members will give the fee received for one hour only of extra service each year to the fund. This will not be giving money. It means that they may miss a ball game, or an auto ride and incidental expenses, and allow the patient to do them an act of charity.

A few active men in city and state societies, making persistent personal appeals, with the kind co-operation of the dental journals, ought, and no doubt will, soon get good returns. Will the Cosmos please again publish the December 1911 editorial? It is so full of interesting information, suggestions, and good advice.

James McManus, D.D.S.

Hartford, Conn.

"DOES 'SECONDARY ENAMEL' OCCUR?"

To the Editor of the Dental Cosmos:

Sir,—My attention has been directed to a communication appearing in the September issue of your journal, calling attention to a statement made by me regarding the occurrence of "secondary enamel."

In reply to Mr. Tabak, I hasten to state that the quoted remark was not "meant as an indorsement of the now generally abandoned theory of Holtzmann and Boedecker, according to which physiological changes can, from time to time, take place in the enamel owing to the presence of a certain reticulum of organic, vital matter."

I have always considered enamel on an erupted tooth to be practically a finished product, and I continue to adhere to this belief.

Your correspondent evidently has failed to take into consideration the fact that the teeth referred to were unerupted, and were still confined in their follicles. This being the case, the enamel organs which were in contact with the partly calcified tooth-crowns made it possible for the defects, viz, enamel pits, to be partly or entirely repaired by a new or "secondary deposit of enamel," the so-called "brown spots" of hypoplastic teeth.

Sincerely yours,

I. N. Broomell, D.D.S.

Dean of Dept. of Dentistry, Medico-Chirurgical College of Philadelphia.

To the Editor of the Dental Cosmos:

Sir,—In the September issue of the Cosmos you published a communication from David Tabak, in which he asks the question: Does "secondary enamel" occur? In reply to this communication I will say, that in some cases it most certainly does occur.

I know a young negro girl, who was struck in the mouth with an ax some eight or ten years ago, the blow splitting the central incisor. There is a distinct scar in the tooth showing that secondary enamel certainly does occur. The tooth is in good condition, it has been giving service for all these years, and will probably continue to do so for many years to come.

Respectfully yours,

N. G. Slaughter, D.D.S.

Athens, Ga.

"NORMAL OCCLUSION," LINGUALLY, OF THE UPPER PREMOLARS.

To the Editor of the Dental Cosmos:

Sir,—In the communication "The Significance of Normal Occlusion," published in your issue for September, the author urges the importance of a knowledge of the minute details of the subject; and opinions in agreement with that standpoint have frequently been expressed in your columns. If then, on any significant point, it is found and reported that the relationship of teeth in normal occlusion differs from what is described as such in text-book and other published statements, those interested in the subject will be ready to criticize and re-examine for themselves, and as a result will either set aside the unorthodox findings, or accept them.

I found that the points of the lingual cusps of the two upper premolars do not normally occlude *between* the two lower premolars and between the lower premolar and molar, but in or at the distal groove or sulcus of the corresponding lower premolar. That was the relationship exhibited in all the finest dentures examined—in skulls, plaster casts, and in the living subject. It has since been independently verified by several observers of repute, and accepted by them as being the normal relationship. It was also noted that this occlusal arrangement is in at least one or two ways mechanically and physiologically superior to that hitherto described and accepted. And certain details in the normal morphology of each premolar come into clearer definition, and are in harmony with the observed normal occlusion.

The dentitions examined belonged mostly to European stocks, and of course a different normal occlusal relationship may in general obtain in America. After all that has been written about the importance of occlusion, the point should be worth inquiring into.

Yours faithfully,

D. M. Shaw.

Royal Dental Hospital,
London, September 13, 1913.

THE STORY OF "TIRADENTES."

To the Editor of the Dental Cosmos:

Sir,—Dentistry has its honored names of skilled workers, inventors, and worthy citizens; also of men who have had to do with great political movements, whose work is part of the world's progressive life. Of these latter, one had a life-story so unusual, and ending so tragically, that it is well worth while to repeat it.

This story is suggested to the memory by the name of the battleship (Minas Geraes) of the Brazilian navy which this summer brought Dr Lauro Müller, Brazilian minister for foreign affairs, to return the visit paid to that country, in 1906, by Secretary of State Elihu Root.

Minas Geraes (general mines) is the name of one of the largest provinces of Brazil, one full of mines, and among them the oldest gold mine in the country. With many villages and mining towns, the province had no large city. Through these villages, and over mountains and valleys, among miners and farmers and shepherds, Joachim José de Silva (*tiradentes,* or tooth-puller) worked for years as a dentist, and everywhere he preached freedom. With many others, he had been aroused by the American Revolution to wish for national life free from the corruption and despotic rule of Portugal.

The club of patriots to which he belonged worked eagerly and incessantly to awaken the people to demand independent national self-government. Roads hardly existed. The people were ignorant; discovery meant death. Plans were prepared for the expulsion of their Portuguese king and his adherents, and for the establishment of a republic. They were discovered, and forty of the leaders were arrested in Ouro Preto, the capital, and shut in damp and dark cells for months. All were condemned to death, but influence and bribery rescued all but "Tiradentes." He was made the scapegoat, and after nearly three years of imprisonment was executed, in April 1792, in the public square of Ouro Preto. His body was quartered, and the quarters sent to different cities and publicly exposed as a warning. All his property was confiscated. His house was burned and the ground salted, and his family was declared "infamous" even to the third generation.

But, today, his name is honored over all Brazil. Monuments stand in honor of him, and streets bear his name in many cities. In the principal plaza of Ouro Preto, on the spot where he was executed, stands a marble column bearing his statue. The pedestal of this monument is the stone on which he was exposed in a pillory and publicly scourged. The man died, but that for which he lived and died is triumphant.

PAUL EGBERT.

PASADENA, CAL.

Proceedings of Societies.

NATIONAL DENTAL ASSOCIATION.

Seventeenth Annual Meeting, held at Kansas City, Mo., July 8 to 11, 1913.

GENERAL SESSIONS.

TUESDAY—*First Session.*

THE first general session of the seventeenth annual meeting of the National Dental Association was called to order at 10 o'clock Tuesday morning, July 8, 1913, in the Century Theater, Kansas City, Mo., by the president, Dr. F. O. Hetrick, Ottawa, Kansas.

The President introduced the Rev. D. D. MUNROE, Kansas City, who invoked the divine blessing on the deliberations of the association.

The President next introduced Mr. HUNT C. MOORE, Kansas City, assistant city counselor, who, instead of Mayor Jost, welcomed the association on behalf of the city, as follows:

Address of Welcome.

Mr. President, ladies and gentlemen,—It is not often that I have the honor of representing the mayor on occasions like this—because he has a weakness, whenever there are ladies present, for abandoning all work at the City-hall and taking his automobile in hot pursuit. Today, however, he is detained at the City-hall with some city officials from Kansas City, Kansas. I understand he is giving them some pointers on city government and a lesson or two from the democratic code, and we don't object to that. Now, I am not going to make a political speech, Mr. President, but if I ever run for office I certainly would like to have this bunch of fellows back of me. [Laughter.]

The mayor wishes me to extend to you a most generous welcome. He wants you to feel at home and "be one of us." I am glad on this occasion that I can associate with you gentlemen without fear or trembling. Ordinarily, when the name of a dentist is mentioned in my presence I have a touch of "buck ague" and I imagine myself in a soft-seated chair, and every now and then jumping from one side of the room to the other. But, notwithstanding this, I realize that you are a lot of good fellows and never put a fellow entirely out of commission as do the surgeons and doctors sometimes. I am familiar with all of your instruments and just how you use them, and know which way a fellow is going to jump when the current is turned on.

To you dentists who have come here without your wives or sweethearts, I want to say while there are two police-courts in this city, that the city counselor can issue as many pardons as they can make convictions, and I want you to feel that the town is yours and that you are secure from molestation. [Applause.]

The bankers of our city do not have much to do with the lawyers of the town, but I have seen their advertisements in which they claim to have a surplus on hand. I want to say to you that if some of you visitors don't use a part of that surplus it is not my fault. We have a city with sixty miles or more of boulevards, and it is known as the greatest boulevard city in the world. We are justly proud of it and we want you people to see the city and take the inspiration you obtain back to your homes. Let me tell you another thing—confidentially—that all of your friends who are practicing dentistry here, while they may not admit it, are quite wealthy; they all have automobiles, so don't you let them "streetcar" you around while you are seeing Kansas City. [Applause.] Make them ride you in their automobiles and if they run away and will not do it, come down to the City-hall and I will see that your wants are supplied.

But seriously, my friends, we are proud to have this great convention in our city. We are proud of the splendid work that you are doing for humanitiy, and we congratulate you upon the progress you are making. Your organization is unlike many of the organizations of today, which combine solely for the purpose of raising prices and cornering the market. I know that your splendid organization will never encourage its individual members to raise the price for making an unfortunate a set of teeth! There is nothing but good to come from a meeting like this or from an organization like this. It is to the credit of you men, individually and collectively, that you are making the fight you are. I noticed in the press of yesterday that you are busying yourselves with proposed laws for the preservation of health, and among them the compulsory dental treatment of children. Nothing contributes so much to a strong and rugged body as good teeth, and, my friends, compulsory dental treatment for children is as important as compulsory education of children—which has been tried and found to be a good thing; and do not become discouraged—for this movement which you have inaugurated will bear fruit and eventually become the law of the land. It will be to your everlasting credit to realize that you and your associates were pioneers in this great work. In order for one to have a strong and vigorous mind it must be housed in a strong and healthful body, and every effort made toward protecting the body from the ills that come from diseased teeth should be encouraged by all right-thinking people. God speed the splendid work your great organization is doing along this line, and may it accomplish all of its worthy ends!

Finally, I want you all to feel at home. Be "one of us." Have a good time, and if there is anything you want and can't get, come down to the City-hall and I will see that you are properly cared for.

Again I extend a heartfelt welcome. [Applause.]

Response to Address of Welcome.

Dr. Geo. E. Hunt, Indianapolis, Ind., responded to the address of welcome on behalf of the association, as follows:

Mr. President, Mr. Moore, ladies and gentlemen,—It is a privilege and a pleasure for me to respond to this cordial welcoming address. I feel that we are going to have a most excellent meeting here this week, one replete with wisdom and overflowing with zeal. I feel that my little talk this morning should be in the nature of thanksgiving, in the nature of grace before meat—that I should say, "For what we are about to receive may we be truly thankful." And I trust not one here in this convention is as ignorant in regard to grace before meat as the little lad I shall tell you about. The Sunday-school teacher was trying to instil into the class the desirability of thankfulness for the good things of life, and turning to one little lad, said, "Tommie, what is it your father says when you sit down to the table and before you eat?" Tommie replied, "He says, 'Go easy with the butter, kids; it costs forty cents a pound.'" [Laughter.]

We come to you, Mr. Moore, from the four quarters of the earth. We come from the frozen North; we come from the sunny South; we come from the wild and woolly West, and from the effete and effulgent East. In the year since our last meeting we have had our troubles combating the perplexities of the high cost of living, but after the glorious Fourth had gone by and we were all safe and sane again, and the time had come for the annual reunion, we dismissed our cares, collected a few accounts, took our tooth-brush in one hand and our palm-leaf fan in the other, and hit the trail for the city on the Kaw.

The profession of dentistry is just coming into its own, and this week's meeting in your charming city will plant another milestone of progress on our way out of the wilderness in which all branches of the healing art have been groping in the past. We, in dentistry, have been harassed on one hand by the indifference and ignorance of the people regarding what we were able to do for them, and on the other by a lack of appreciation on the part of a large part of the profession itself regarding our duty to the public. Our troubles may be illustrated by the story of the two hunters who were once traversing a wild portion of the West, when an enraged buffalo bull attacked them. One of them promptly climbed the only tree within miles and the other dove headlong into a cave. After a moment or so the man in the cave came rushing out. The bull promptly charged him and he again precipitately entered the cave, only to as hastily make his exit from it. When this had been repeated several times, the man in the tree yelled to his partner, "Stay in the cave, you blamed fool!" And his partner replied irritably, "You go to thunder!—you don't know anything about this cave; there's a bear in the cave!"

But brighter days are coming to the profession and to humanity through the profession. Better health, better mentality, and greater efficiency is what we offer the world, and the world is preparing to accept it.

As I came through this great commonwealth of Missouri last Sunday and gazed through the car windows upon the acres after acres of ripened wheat, and mile after mile of growing corn, I said to myself, Surely this is the land of plenty, this is the Promised Land; and as I sat there looking over the fields and thinking of the bumper harvest that Missouri will experience in a few weeks, my imagination carried me forward a few months, and I could see the golden kernels, ripened as they will be then, part of them going to fill out the rotundity of the justly famous Missouri mule, and the other part being shipped to Peoria, Ill., to be turned into an also justly celebrated variety of corn-juice.

Mr. Moore, we appreciate your warm words of welcome, and we know we are going to like your town. We are prepared to like not only the town, but its citizens, and although, when we leave, the calves of our legs may be a little sore from climbing up and down your altitudinous streets, and although all our handkerchiefs may be in the laundry from mopping our brows, we hope that none of your citizens, after we leave, will feel it necessary to say it was the dentists of the National Dental Association who put the "can" on Kansas City. [Applause.]

The next order of business was the report of the Executive Council, by Dr. H. J. BURKHART, chairman, as follows: The Executive Council directs me first of all to report the resolution offered yesterday in the general meeting of the Executive Council, the Executive Committee, and those interested in formulating the new rules for this association, as follows:

RESOLVED, That in view of the apparent misunderstanding which exists relative to several matters in connection with the transition from the old to the new constitution, it is the sense of this meeting that the following action shall be taken:

1st. That the Officers and Executive Council elected at Washington shall conduct this meeting as under the old constitution, except that the Council will report to the House of Delegates, after it is organized, instead of to the general body.

2d. That the House of Delegates for this session shall consist of one delegate representing each state society which has voted to affiliate with this association, and that none of such delegates shall hold over for 1914, unless re-elected by their respective societies.

3d. That such house shall hold its first meeting on Wednesday, July 9th, at 2.30

P.M., in the "White room" at the Baltimore Hotel.

4th. That the House of Delegates shall select the place of meeting and elect the general officers for the ensuing year; also, a board of nine Trustees, all of whom shall serve for one year only, and shall transact all other business appertaining to the conduct of the affairs of this association, subsequent to this meeting.

5th. That the new Constitution and By-laws shall be in full force as applied to the 1914 meeting.

6th. That all former members, and new members who wish to be credited as members for the current year, shall pay five dollars dues, as per statements already sent out by the Treasurer, and that the payment of said dues shall cover membership up to January 1, 1914.

7th. That hereafter the fiscal year of this association shall agree with the calendar year, and dues of one dollar per member for the year 1914 shall be payable January 1, 1914.

8th. That all members of state societies which have voted to affiliate with this association, who are not already members, shall be extended all privileges of membership at this meeting, without payment of dues, but will not be entitled to receive the bound volume of the Transactions.

Dr. Burkhart moved the adoption of the resolution, which was duly seconded and was carried unanimously.

Dr. BURKHART. The Council suggests that all members present belonging to state societies which have not affiliated hold a meeting sometime during the day or evening, and select one person to represent them in the House of Delegates which will convene at 2.30 tomorrow, and certify the delegate that has been selected, to the secretary of this association before 9 o'clock tomorrow morning, so that the Council may make up a list of duly accredited delegates to the first House of Delegates to meet tomorrow.

The Executive Council will meet in Parlor D, Hotel Baltimore, at 3 o'clock this afternoon, and you are requested to bring all business matters before the Council at that time. There will be another meeting at the same place at 9 o'clock tomorrow morning, and the Council specially requests that those having any sort of business connected with the association will present it at one or the other of these sessions, so that we may clean up the business of the old association before the House of Delegates takes charge of the new.

Dr. Burkhart then announced the program for the day, and said that each day a daily program would be printed and distributed among the members outlining the entire program for the day.

Motion was made and carried that the report be adopted.

Dr. T. B. Hartzell, vice-president from the West, took the chair, while the president, Dr. F. O. HETRICK, Ottawa, Kans., read his annual address, as follows:

President's Address.

Members of the National Dental Association, ladies and gentlemen,—You have listened to the welcome from the high officials of our city—Kansas City belongs to Kansas, therefore we say our city—and I want to emphasize their welcome to you, my brethren, to our home. But once before has a dental convention of national proportions met in this section of the country, and that was when the American Dental Association met at Excelsior Springs, Mo., nearly thirty years ago.

We are highly honored by your presence among us again, and are delighted to say so. Let me say that we are glad—glad and proud—to welcome you here!

TIME OF MEETING.

This brings me to the first recommendation I have to submit for your consideration—viz, the time of meeting. The time of our meeting should be permanently changed to a more comfortable season of the year. We have reached a stage in the evolution of this organization when the convenience of the greater number should be taken into consideration. A change in the time of meeting might make a difference in the attendance at the first few annual sessions, but I firmly believe that, if tried for a reasonable time, the association could not be induced to again hold its meetings in the summer season. Compare the comfortableness of the going, coming, and time spent at the session held in Birmingham, Alabama, during the month of March, with any session held in recent years, and the evidence is all in favor of the Birmingham meeting. I have no recommendation as to the exact date, but I would suggest that the meeting be held not earlier than October nor later than March. Precedent and some argument is against such a change—but who wants to take a vacation and attend a dental convention at one and the same time?

THE NEW CONSTITUTION.

During this session of the National Dental Association we begin work under the new constitution. The revision of the constitution has been one of the storm centers for the past five years, and the past year has been no exception. We hope our differences will be amicably settled and that hereafter we may all work together in harmony and be factors in the upbuilding of our association upon a foundation that will be worth while and will endure. Too much of the time of this association in the past few years has been given to the settlement of personal differences and local difficulties, but with the larger house of delegates it is possible that this condition can be eliminated, and it should be, with no uncertain measures—the big stick if necessary. A house divided against itself cannot stand, and I would urge that every member take the broadest possible view of the questions that come before us and work for the upbuilding of the National Dental Association. There are plenty of aggressive movements upon which all our time and energy may well be expended, and which will bring greater results.

THE DENTAL JOURNAL.

There have been recently several movements inaugurated which are of vital importance to our profession, but to my mind the one demanding our first attention is the establishment and financing of our own dental journal. The machinery to accomplish this should be very definitely set in motion at this meeting, and our own journal should be established, and upon a solid foundation, not later than the year 1915. Several methods of financing this enterprise have been suggested, one of which is that five hundred life memberships at fifty dollars each be sold, thirty dollars of each membership to be set apart in an investment fund, the interest from which would pay the annual dues of the members who bought life memberships. This would give a fund of fifteen thousand dollars with which to establish our own journal. Whatever method may be employed, definite steps should be taken at this session, as it will take at least two years to accomplish our object.

THE SCIENTIFIC FOUNDATION FUND.

From this time the work of the Research Committee and the Scientific Foundation Fund Committee should be merged into one. You will hear the reports of these committees later, and I wish to call especial attention to them. One of the greatest movements started by this association was begun at our meeting last year. When you hear the report of the chairman of the Scientific Foundation Fund Committee, I am sure you will be gratified beyond your fondest hopes. What has been accomplished is but a slight forecast of the possibilities if the proper form of organization is adopted. The organization should be effected in such a way that it will be competent to handle large sums of money, and of such a character as to appeal to men of large affairs. It will be necessary to place upon this committee some men of national reputation who are already familiar with methods and means of organizations of this character, and who are already in touch with great problems. You will hear this more in detail from Dr. Weston A. Price in his report. Opportunity is knocking at our door; more institutions than we can use have thrown open the doors of their laboratories and have bidden us enter. Shall we heed the call? I feel that I cannot urge upon you too strongly that we should avail ourselves of these opportunities immediately. Compare the possibilities before us at present with the meager little sums that we have spent each year in the past upon research work.

Fifty years ago the dwellers on plains said there would never be a city of any importance built upon the bluff where Kansas City now stands; but there were men of splendid courage among those pioneers, and today you see the result of their convictions in that the hills have been cut down and filled into the low places, and this is yet but the beginning. Just so must we look and build for the future.

THE NATIONAL RELIEF FUND.

The work of the National Relief Fund Committee should have our most hearty support. This should come more particularly from the individual dentist himself for the relief of his unfortunate brothers.

THE CROCKER LAND EXPEDITION.

During the past year the Crocker Land Expedition, under the auspices of the American Museum of Natural History and the American Geographical Society, with the co-operation of the University of Illinois, has been fitting-out—an expedition whose object is the exploration of the last great land mass on the surface of the globe. The matter of the need of a dental equipment for this enterprise was brought to the attention of your president, and Dr. C. B. Warner of Urbana, Illinois, was appointed a committee of one to secure the necessary dental supplies for such an expedition. Permit me to quote from a letter from the leader and ethnologist of the expedition, Dr. Donald B. MacMillan. After extending his thanks for the "excellent supply of dental material and equipment," he says: "Our dental equipment is perhaps as complete as any we have, and I am sure every member of the expedition appreciates your gift. The physician has had special dental training, and will be able to give the members of the party temporary dental service other than extracting, and thus save their teeth until they return to civilization." Dr. Warner deserves special commendation for the active interest he has taken in securing the necessary dental supplies for the expedition.

DENTIST APPOINTED TO STATE BOARD OF HEALTH.

I am sure it is a source of gratification to you all to know that the Governor of Ohio, Hon. James M. Cox, has taken an advance step in appointing as one of the members of the State Board of Health a dentist and one of our members, Dr. Homer C. Brown, of Columbus, Ohio. I would suggest that a committee be appointed under authority of this body to draft suitable resolutions commending Governor Cox for this action, and that a copy of said resolutions be forwarded to him.

I wish in closing to express my deep appreciation of the honor you have conferred upon me by elevating me to this high office. For the future I bespeak the greatest harmony in our association, and hope that upon the two great problems confronting us, the journal and the Scientific Foundation Fund, we may present a solid, unbroken, aggressive front.

Dr. Hartzell appointed the following as the Committee on the President's Address: Dr. E. S. Gaylord, A. R. Melendy, and Burton Lee Thorpe.

The committee reported at a later session as follows:

Report of Committee on the President's Address.

Mr. President and members of the National Dental Association,—In review of the several recommendations in the President's address—

We approach the radical change in the date of our annual meeting with a degree of apprehension, as valid arguments present for and against such change. The subject is not new, having several times been considered by this body. We suggest this compromise: Adapt the time of our meeting to the locality, making the date sufficiently past the heated term to insure immunity. We recommend, however, that the 1914 meeting be held in the East about July 15, 1914, making it possible for the members so desiring to attend our meeting and the Sixth International Dental Congress in London, Eng., August 3 to 8, 1914.

We heartily commend the proposition to finance and establish the Journal as soon as possible. With the increased annual income under our plan of reorganization, it seems feasible to accomplish within the time indicated in the address, 1915.

In relation to the work of the Scientific Foundation Fund and Research Committees, we heartily concur with the address, and would emphasize the obligation created by the opportunity offered our profession in this great advance, to benefit humanity.

Allusion to the Relief Fund is also commended by your committee. The wisdom of making such provision for our unfortunate members is both wise and justified.

The appointment by Governor Cox of Ohio of Dr. Homer C. Brown as member of the State Board of Health is gratifying, and we believe we should work shoulder to shoulder with the medical profession upon these boards.

Respectfully submitted,

Burton Lee Thorpe,
A. R. Melendy,
Edward S. Gaylord,
Committee.

Dr Hetrick resumed the chair, and introduced Dr. Weston A. Price, Cleveland, Ohio, chairman of the Scientific Foundation Fund Committee, who reported for the committee as follows:

Report of Committee on Scientific Foundation Fund.

It is a great pleasure for me to be permitted to make the report for the Committee on Scientific Foundation Fund, and I wish to assure you that I am not going to bore you with a long statement of details, but will take only a few minutes to report some of the possibilities open to the dental profession.

I am sure that it is not necessary for me to remind you that a large percentage of the infections that enter the human body enter by way of the mouth, or that a great many septic conditions have their origin in the mouth. You have been listening to that during the last year through papers on oral hygiene; you are interested, however, in the larger question of our duty to humanity. The first part of the subject states clearly the need for this work; and, as I see it, the need of the hour is not that we shall approach the subject only from the standpoint of the pathologist, but that we should establish our position in line with all the great professions of the world. I am going to ask you to look with me at the march of civilization;—we shall see that all down through the thousands of years that have been passing, all of the great civilizations have had in their midst these great infections that have not only swept off the total population within every twenty-five years, but sometimes nearly the entire population of a district in a single year. There have been instances where the population was wiped out so completely that not one person was "left to tell the tale" of a previously large population, and I want to show to you a picture of such a civilization as that of Sweden, where one-twenty-fifth of the population died every year of one single infectious disease. That was twenty-five years ago; today we have only one in a million dying of that same disease. And when we think how the great sources of infections so common a few years ago are one by one being stamped out and no longer curse humanity, we are thrilled with joy. But this joy is soon mixed with pain—for there yet stands the great source of infection, the largest of them all, the one that has caused the largest amount of suffering and has afflicted the largest number of people, and we have done practically nothing to emancipate humanity from it—I speak of oral and dental infections, which are the most universal and the most serious of all that afflict mankind.

EMANCIPATION FROM FORMER SCOURGES.

I want you to see with me how the great emancipations from scourges have been accomplished. You only need to go into the study of any one particular disease. Let us look at the diphtheria scourge that a few years ago entered our homes and took from our families, in the United States alone, enough children every year to populate all the schools of Kansas City. These lives have been saved by the coming of the antitoxin for diphtheria. How and why did it come? Because the great medical profession realized its responsibility to humanity, and had men who were willing to go into laboratories and work for the love of humanity and the love of truth, and find a means for relieving their fellow men from this dreaded disease. When measured by the value of a few horses, the value of a few dollars put into laboratories, the value of a few hours' time for research work, no investment can compare in returns and desirability to having had five, ten, or a hundred dollars invested in that research work. Yet, while this great work has been done and is being done, we, the dental profession, have done practically nothing.

Let us look at another example: We know that a large percentage of all babies born have been afflicted with hemorrhage of the newborn, and if you have gone into the hospitals for babies you have seen, up to a few years ago, that these babies were condemned to die. But something happened. There has come to the world a great thing, the surgery of the bloodvessels, because a profession cared! It was necessary to add to the blood of these infants some blood that had the power of coagulation. One evening, just a few years ago, there happened in New York this picture: A physician the father of a first child was sitting by his newborn babe, whose life was slowly but surely going out as had been the case in all the past with these babies, and as the eyelids and lips were getting bluer and the child's paroxysms getting slower in its desperate struggle for relief, this anguished father telephoned Dr. Alex Carrel, one of the men connected with the Rockefeller Institute, and asked him if he could not do something for this baby. His answer was affirmative, and he came quickly to the house of the heartbroken father and mother, put the father on the bed by the side of his baby, and with his new technique for the surgery of the bloodvessels successfully united the father's artery with the vein of the child and put some of his blood into the child's body. Almost immediately they could see a pink flush in the face of the baby, very soon it was crying and hungry, and in a few minutes it was nursing with avidity at its mother's breast. There was no period of convalescence; the baby that was dying but a moment before was now well, for the fatal hemorrhage had ceased. It was saved!—and all through the coming years these babies can be saved. Why? Because somebody cared enough for these babies and for the truth to place laboratories at the disposal of men, and men who cared for the truth enough to give their lives in making this research. Surely there has been no power known to history so great as this power of truth, which is revolutionizing the whole of civilization in our generation.

Look at the yellow fever scourge in Panama, in Havana, and in Mexico, where half the population at times were taken off, and the complete stamping-out of that scourge, and see the spirit that made that relief possible. Scientists knew, or thought they knew, that it was the mosquito that carried the yellow fever germ, but there were four hundred varieties of mosquitos. They thought it was carried by the female of one of these varieties, but did not know; they thought this mosquito must take the poison from a person sick with yellow fever during the first three days of that person's sickness, and then must wait twelve days and bite a well man who would therefrom develop yellow fever. They could not experiment on animals by allowing the mosquito to bite them, because animals would not contract the disease; it was necessary that this experiment should be made on man. Men were not wanting, for Dr. Lozier and

Dr. Corell of Washington came and offered to bare their arms to the mosquito. These men had even been sleeping in the soiled clothes of men who had died from the disease, willing to get this disease even when they knew that it meant almost certain death to them. Few men have ever given service with so little realization of sacrifice and so great a sense of privilege as did these men. One of them when he knew that he was doomed to die, wrote a letter to his wife saying that he thanked God for the opportunity that had come to him by solving the problem, and thereby to give this relief to humanity. Was it worth while? It was!

THE PRESENT OPPORTUNITY—A GOOD START MADE.

But that spirit of sacrifice, measured by a life, is not what we are asking of you today. We offer you the privilege of helping to support some trained men to go into laboratories and do the research work necessary to bring to humanity and emancipation from the dental scourges. The laboratories are waiting and ready for this work. I also want you to know that this great dental profession is alive to this opportunity! You can scarcely appreciate the favorable conditions without having gone from place to place as I have gone and seen the response to this opportunity. Society after society to whom this matter has been presented, has, when the members have been told of this plan, supported the movement almost to a man; many times, every person present volunteered to give money in support of the work. In the city of Columbus, when this project was presented before the dental society, though with only forty-two present, every person contributed, to the amount of $1200. When it was presented in Cincinnati, $2700 was subscribed and the first year's payment entirely made, and they are enthusiastic to do more. The profession of Cleveland has subscribed $4010 toward this fund to help men to go into the laboratories and do the work, and other societies have taken up the work with enthusiasm and earnestness; and all are standing shoulder to shoulder with a solid front. A substantial start has been made toward the same result in Iowa, Missouri, Kentucky, Indiana, Maryland, District of Columbia, Pennsylvania, Minnesota, Colorado, Tennessee, and Texas, and Wisconsin joins this month. The reports are not complete from any of these states, and from many we have no report except the substantial subscription secured at the time the plan was presented. The total amount of these incomplete reports is $12,640; and we regret exceedingly that we could not have known how much has been secured in each city and state to date. Some of the incomplete reports are as follows: Cincinnati, $2767; Columbus, $1200; Cleveland, $4010; Toledo, $500; Washington, $700; Louisville, $500; Pennsylvania and components, $782; Iowa State University Dental Alumni, $500, with several smaller amounts. It is essential to remember that this is entirely a report of progress, for in many places the work has just started. Other states would have taken it up before this, had not conflicting engagements prevented the chairman of the committee from being present at their meetings.

GENEROUS TENDER OF LABORATORY FACILITIES.

Now I want to tell you something of the attitude of the public toward this movement. When this work became known to some of the great institutions of our country, they responded at once. One did not even wait for the committee to come, but sent for us and said we might have the use of their laboratories and they would give us every assistance. These free laboratories include privileges in the Cushing Laboratory for Pathological Research of the Western Reserve University, and the Case School of Applied Science Research Laboratory, both of Cleveland; Iowa State University Research Laboratories; Michigan State University Research Laboratories; Hygienic Department of the U. S. Department of Health of Washington; Bellevue Hospital Research Laboratory, New

York; Cincinnati Hospital Research Laboratory; Parke-Davis Research Laboratory, Detroit; University of Chicago, and several other competent institutions, including more very choice facilities than we can probably use for some time.

THE PROPOSED PLAN.

When I have said to men with money, "Can you help us?" the almost invariable reply has been: "We have means for such good causes, but there are so many demands that we have to have something of an indorsement. What are your indorsements? What has the dental profession done in financial support and service for such work?" And there was nothing that I could point to that indicated that we have made the sacrifices which our professional responsibility demands of us. Your committee has undertaken to get this indorsement in two ways: We want a fund for immediate use, and that fund shall be raised from the entire dental profession—it will be a guarantee of their indorsement, and will also pay for the bread and butter of the men who are going into these laboratories.

This money from these different societies that I have spoken of is for that fund, and we are asking that the dental profession of each state shall give each year for five years an amount equal to the number of men practicing dentistry in it—that is, about $40,000 a year for five years from the United States, or $200,000 in all. On this basis, Ohio would be expected to subscribe $12,000—and already Ohio has subscribed $9000 of that $12,000. Indiana will, I am sure, do the same. Illinois and Wisconsin will doubtless do the same. And as we have gone from one society to another we have found that same response, not always as fully as in Ohio, but as sure and certain; and my appeal in behalf of the Scientific Foundation Fund is that you help us to present a solid front, thereby showing that the dental profession is united in the support of this work.

With regard to opportunities for help, I have to say that we have been negotiating with competent research workers and find that a large number of men who are very competent and whose heart is already known to be in this work can be available for the service of the National Dental Association. If we as a great profession will support this work, by some such method as the committee has outlined, backed by the National Association and supported by the state societies and their component societies down to the very last man, then all the men back of this movement will have a strong bond of sympathy between them, for the profession will be united more closely than ever before—but, best of all, it will not be a despised profession! Never in my life have I been so proud of being a dentist as I am today, because of our opportunities, and I would not be anything else if I might for the asking, because the opportunities for us are greater, to my mind, than they are for any other calling or any vocation; hence I challenge you to join in this campaign for human emancipation from dental disease.

SHALL MEDICINE WIN THE REWARD?

If the dental profession does not do this, the medical profession will do it, and do it soon. I was told, just this morning, of another instance wherein one of the greatest institutions of the country, a body of medical men, were to be furnished to do this work that the dental profession has not done, simply because of the insistent need of it in the practice of medicine. As sure as the medical profession does it, they will have the credit, and they will deserve the credit. If we, the dental profession, are ever to deserve that credit, it will only be when we are willing to make real sacrifice. I wonder if there is one man in this room who would not feel unworthy of this great profession if he would not give at least half a day a year to help to rescue humanity from this scourge. While I was coming over on the train, a dentist said he wanted to give fifty dollars a year, and I think we shall find a large group of men who will be willing to do the same. In Cleveland we had a number of men give fifty dollars, and in Cincinnati the same, and some even one hundred dollars. Ours is the opportunity, and we can have exactly as much research work done as we are willing to plan a foundation for, and that foundation will be the moral and financial support and indorsement of the dental profession. Do you want insignificant, unsatisfactory work, done in a haphazard way in a few laboratories? No!—we all want a magnificent organization with a central institute, or with institutes in different parts of the country, where this work can be carried on by the best men, so that the entire world will look to the dental profession for help, and will acknowledge it as having wrought the greatest single service for the emancipation of humanity from its various afflictions.

The Executive Council has asked me to give to the members of this body the opportunity to say now whether or not they would like to have a part in this work. I do not present this as a plea; but as a privilege that is yours *now*.

RECOMMENDATION TO THE ASSOCIATION.

We will recommend to the association that the committee of three be changed to a commission of twenty-five, with an Executive Board of five to enlarge and carry on this work, and that technicians or assistants be engaged at once to enlarge the capacity and output of some of the men who are doing, gratuitously, the best private research at present.*

Respectfully submitted,
WESTON A. PRICE, *Chairman*.

The general session then adjourned until Wednesday noon.

WEDNESDAY—*Second General Session.*

The general session was called to order Wednesday, July 9th, at 12 o'clock, by the president, Dr. F. O. Hetrick.

The first order of business was the report of the Committee on Necrology (James McManus vice-chairman), and consisted of obituary notices of two members, viz, Dr. Wilbur F. Litch and Dr. Drury J. McMillen [brief sketches of the lives of both of whom have already been printed in the DENTAL COSMOS—see, respectively, issues for February, page 242; July, page 753].

The next order of business was the report of the Executive Council, made by Dr. Burkhart, chairman, which was the announcement of the programs of the general session and the various sections for the day.

The next item on the program for the general session was the reading of a paper by Dr. CLYDE DAVIS, Lincoln, Nebr., entitled "Synthetic Porcelain, Using Mallet Force for Introduction."

[This paper is printed in full at page 1108 of the present issue of the COSMOS.]

Discussion.

Dr. G. A. CRISE, Manhattan, Kans. "There is a tide in the affairs of men, Which, taken at the flood, leads on to fortune"—and there is a tide in the affairs of men as operators, which, if taken at the flood, leads on to perfection —and that is what we are after in this convention. We gather to discuss the different phases of dentistry and discover different ways of doing work because we desire to arrive at perfection in the thing we are most interested in.

I have read Dr. Davis' paper over thoroughly, and have tried to make the very best analysis of every phase of it. In the use of silicate cements I have spent about five years in research work and practice, and I believe that we are reaching the perfection point in the working of silicate cement fillings—that they are going to be a great boon to the dental profession in the way of esthetic work.

I do not agree with the essayist on some points that he mentions; in the first place, in the mix. I agree with him in the way he mixes silicate ce-

* The opportunity was given to those present to make a voluntary contribution, and about $2500 was contributed.

ments, but I do not agree that, when we insert the filling, it is absolutely necessary to use mallet force. I do not assert that he is not right; however, the opportunity comes for you and me to work out this problem in our own offices.

There is a different way of mixing each of the silicates on the market, and we have to use a different mix with every one. I take it for granted that Dr. Davis is referring in his paper to DeTrey's porcelain. This porcelain is peculiar to itself; the way in which the molecular parts come together is different from any other silicate on the market. The humidity of the dental office has a great deal to do with the silicate filling; an office kept at a temperature of about 65° would be about ideal for manipulation and mixing, but I do not agree that when the material is puddled on the slab and put in the cavity one would obtain a better filling by using mallet force to drive the material against the walls of the cavity than by inserting it in the way the manufacturers recommend.

I received the essayist's paper on the 25th of June, and had but little time to try his method in my office, but I did something in that direction. Of course I am a novice, but I have found already that the color and shade of the filling is the same upon the slab under the magnifying glass as it is in the mouth under the mallet. I do not believe that we get a better texture by mallet force than by the process laid down by the manufacturers. When we have the cavity prepared, the slab ice-cold and the spatula ice-cold, when all conditions are right, and the thermomeeter is at about 65° or 70°, the longest time the synthetic cement can be held at the exact point at which it must be inserted is about two minutes; after two minutes the point is passed at which the filling may be disturbed, else the action of the component parts in its setting qualities will be disturbed. After the filling is inserted it must immediately be coated with cocoa butter, and must be kept so for ten minutes, because synthetic cement has in it a component part of water, which must be retained in the filling for ten minutes; after ten minutes it has undergone a change, and we can finish the filling, which must then be coated with wax that is to be left only for two hours, this being the longest time advisable; I would rather have this wax stay one hour than two, about one hour and a half being better in a great many instances, depending a great deal on the conditions in the mouth. But that filling must have water then. Dr. Davis says that it must be twenty-four hours, but there I do not agree with him—because, like Portland cement, it must have water in order that it may assume the stone-like consistence of Portland cement, and we must have the same condition as in porcelain. Synthetic cement is made of different materials. All of the silicate fillings on the market have about the same ingredients, but DeTrey's synthetic is different from the silicate cements. By combining certain elements a preparation has been produced that, when inserted in the cavity, assumes a porcelain-like state, fulfils the same conditions as porcelain—and is, in fact, a porcelain.

After the filling is finished, or rather after it is inserted, I use chisels as Dr. Davis has suggested. I use the disk also as Dr. Davis suggested, and I use the wax that is sold with the cement, which is nothing but paraffin, and I instruct the patients, "In two hours from now, take that off the filling." I have demonstrated silicate cements for two years and I find that, if the wax is left on longer than twenty-four hours, the filling, when the saliva strikes it, assumes a different condition. I cannot explain this phenomenon, but, when the filling is examined under the magnifying glass, we see a difference. Anyone can make this experiment by observing one filling twenty-four hours after it has been coated with wax, and another two hours after it has been coated with wax. In the latter case a better result, more crystallization, a more healthy appearance in the filling will be noted. In that regard I do not agree with Dr. Davis, yet we are all striving for perfection. I hope to demonstrate these points in the clinic I shall give tomorrow, when it will be seen that a synthetic cement filling requires as careful or more careful technique than any other filling. I think it is really harder and requires more skill, more dexterity and more ability, to insert a good synthetic filling, that cannot be detected at a glance in the mouth, than any other filling, and if we are successful with synthetic cement fillings, then we have arrived at that ideal which we are all striving for.

Dr. L. L. Barber, Toledo, Ohio. I first want to say that in my belief the silicate cements are among the best filling materials we have for certain places. Next, that there is no silicate cement on the market with which I am familiar—and I believe I am familiar with all of them—I do not believe that there is one the manufacturers of which have not changed the directions for mixing from one to five times. When Aschers "artificial enamel" appeared first upon the market, I purchased a forty-dollar package. I took instructions for the mixing from their expert, and went home and used that forty-dollar package in my laboratory before I ever attempted to make a filling in the mouth. Then I thought I was equipped to do some wonderful things. I started in according to instructions, and made as many failures as many of you have made. I then began to make up the different silicate cements as they came along, and when I was in Germany I went with Dr. Ames to Dr. Schoenbeck's laboratory in Berlin, and we studied the whole process there and returned home with a goodly supply of Schoenbeck porcelain, which seemed as though it was going to be an excellent thing—and it was, in its way. In the same way we have taken up the different cements as they presented themselves, and have mixed them according to directions, but the next time we saw the demonstrators and pointed out the defects in their cements, they would immediately say, "You are not mixing it right." They would ask us to show them how we mixed the material, and then they would say we were all wrong, and would proceed to show us the improved way of mixing. You all know the whole mixing process, and how the manufacturers have changed their formulas, etc. Now comes Dr. Davis, with his method of malleting.

If it were possible, I allow, to follow out in the mouth Dr. Davis' technique in the insertion of cement fillings, I should find very little in his paper to discuss, because I have had my laboratorian, who is a good technical man, make many experiments along the line which Dr. Davis suggests, and I have come to the conclusion that silicate cement fillings, when we can get directly at them with the mallet as Dr. Davis suggests, are denser than those inserted in any other way. The central surface of the filling can be made as dense by putting a celluloid strip around the tooth and going over it with a steel burnisher, but the same result is not obtained in the edges. Instead of distributing the liquid evenly over the surfaces, as in Dr. Davis' method, most of the liquid is carried to the edges because of the fact that the celluloid strip forces it from the center to the edges. That has been my experience. If we could put our foot on this material, and pat it as we do the sand when we go in bathing, as Dr. Davis has said, it would be well and good, but there might be some objections to that method of procedure. My method has consisted in using agate and tantalum burnishers specially made for that purpose, and patting the surface of the filling in the same way with a mallet. This I find to give me the very best results. The same objection, however, prevails there as with Dr. Davis' method, because all surfaces cannot always be reached. Another way is to fill the cavity to excess and not attempt any finishing at all until after a given time.

I find by the aid of the magnifying glass that fillings made in holes drilled in metal—that is the way in which my laboratorian made the tests for density—are much denser if inserted by some sort of tapping or malleting, and the edges are very much better. In regard to the setting of the silicate cements, it has not been my experience that they set much more rapidly when inserted by tapping than by other methods.

Dr. Crise made a splendid point which Dr. Davis did not mention, namely, the temperature of the slab, spatula, room, etc. These are factors that retard or hasten the setting of the cement. Another thing that materially affects the filling is the rapidity with which we add the powder to the liquid. I can take any silicate cement and mix two masses of the same consistence, and have one take twice as long as the other to set, and I will not have spoiled the crystallization of either. Dr. Davis' remark about keeping the silicate cement filling coated with cocoa butter is a very essential point. It is a known fact that the moisture must not be allowed to evaporate from the filling until proper setting has taken place, and that the filling must not absorb the moisture of the mouth until complete crystallization has taken place. I have always thought that it is better to allow the wax to remain on the filling a longer time than two hours. I am not here to say that it is, but in my experience it is better to leave it on longer. A good way to get the wax covering off is to instruct the patient to brush the tooth vigorously at the expiration of whatever time the operator may consider best. Silicate cement fillings, of course, require as much judgment in the manner and selection of place of insertion as any other kind of filling. I believe that Dr. Davis' idea in regard to the removal of all unsupported enamel is good, but it can be carried out a little farther, probably, than he has suggested.

Dr. Davis (closing the discussion). Replying first to Dr. Crise, I would say that it was not my intention to drive the filling harder against the wall. The malleting is simply a convenient way of jolting the filling. I desire to strike it, as it were, with a stuffed club. I desire to affect the entire mass, and do not think of driving it against the walls. It is placed against the walls and in the undercuts with the spatula; the malleting is simply a means for agitating the mass and producing the effect of puddling while it is in the cavity. The same can be done with the mechanical mallet used in building a gold filling by striking the edge of the tooth, but the patient does not like the effect upon the teeth.

Some have criticized the length of time required in the use of this method. Any kind of cavity can be filled, I think, in as short a time by this method as by any other. I do not mean that one should mallet the filling until it turns white, as such a procedure would ruin it. As to a filling turning white on one side and not on the other, I cannot contribute anything to that observation. My method is to leave the wax on for twenty-four hours, and I have never had one discolor. If we fail to take the wax off, and the filling discolors, there is a reason that we should think about.

I respect Dr. Crise's opinion, because I think he has done fully as much in this line, and more, than I have. I would insist, however, that the points I have mentioned are valuable, and that you try them; if you have failures at first, try them again.

Dr. Barber speaks of making these fillings with burnishers instead of using the mallet with special plugger points. Burnishers will probably answer the same purpose, if they are properly designed for this work.

Dr. Barber also speaks of the varying time required for porcelain to set, and the controlling of the setting by the mix. I am convinced that by the method I have suggested one can obtain a more homogeneous mass and a stronger texture in the porcelain. The jolting process seems to have the effect of causing the porcelain to set in about the same length of time, and is always the same. It produces uniformly good results, and comes more nearly to perfection for some reason. My contention is that we get a homogeneous mass, and a better uniformity of action in the material.

Dr. Crise. When you mallet, do you not accomplish the same results as in making porcelain inlays—that is, draw the liquid to the surface and have not so dense a filling underneath?

Dr. Davis. No; my experience is that it makes a perfectly homogeneous mass.

One of the speakers criticized my remarks in regard to leaving unsupported enamel. You can leave some unsupported enamel the same as in any plastic filling, provided it is entirely removed from stress, as on the labial surface of a tooth.

The next order of business was the report of the Research Committee, by Dr. H. C. Ferris, New York, N. Y., chairman, as follows:

Report of the Committee on Scientific Research.

In the presentation of the report of the Committee on Scientific Research, your chairman is inclined to emphasize one or two salient points in the history of our efforts to advance our information on the physiological and pathological study of the organ of mastication. This study has been directed, as previously stated, to one field—vast enough in its scope to attract to it all the efforts of the gentlemen particularly interested, but with little means at our command.

STUDIES ON THE CAUSE OF DENTAL CARIES.

In this work, as in all other scientific fields, we find critics, who take what little truth has been established, and elaborate upon it, and draw conclusions from a few experiments; but we must appreciate that this problem of ours, the cause of caries of the human teeth, has been studied for centuries by the pathologists—that it is not a local disease, but a condition incident to bodily states the complexity of which has never been explained.

To be sure, we think we have in our specialty commenced to appreciate some of nature's workings, viewed from another angle, that have escaped the minds of the physiologists and pathologists—whose attention has been directed to processes more complex because of their difficulty to study and because they are more prominent in the painful conditions that are met in everyday medical practice; and even in this department of medicine the percentage of pathologists is lamentably small. It is not given to every man to have the patience to determine the etiology of disease, but some one man properly equipped with fundamental education will be found to carry on this work after we assure him a compensation.

TECHNIQUE FOR SALIVARY ANALYSIS.

We have established a technique for salivary analysis which we know is not without fault, but is sufficiently accurate to form a basis for research work. We are constantly trying to improve this technique so as to make it a standard for the investigation of the pathological field, as those who have been laboring in this direction have appreciated that a uniform technique is most necessary, if we are to reap the value of others' criticism. Writers will frequently introduce another reagent which carries with it its own problems, and disregard the requests of your committee to carry out their research work under a recognized method, and then parallel their findings with their new reagent!

THE PHENOL-PHTHALEIN INDICATOR.

It is not that we would recommend the narrowing of a man's procedure, but rather to multiply findings without too much technicality. For instance, considerable comment has been made in reference to the indicator, phenol-phthalein, in determining acid index—that it is unstable because it is sensitive to carbon dioxid. Even though it be proved to be sensitive to carbon dioxid, if the recommendations in the technique are carried out the specimen will be examined immediately in each instance, and the time of comparison will be a constant factor, and the CO_2 content will be estimated in the acid index. Acknowledging the necessity of correction, the report would add to our information, and will show, over long periods, modification beyond those caused by diet.

There is no objection to other indicators being used and more information acquired, but your committee cannot but urge adherence to a technique, even with its faults, if we are to make progress.

In pursuance of this line of thought,

we have been working upon the relation between the CO_2 content in the saliva, and its acidity to phenol-phthalein, and its alkalinity to methyl-orange, with three or four indicators.

The suggestions as indicated in Prof. H. Carlton Smith's report a year ago, to the effect that the acidity of the saliva was largely due to its CO_2 content, caused us to investigate after his method of procedure; and after numerous experiments we adopted a change in his technique, so as to be able to precipitate and centrifuge excess barium salts, instead of reading our findings with comparison of the turbidity. The change in the technique will read as follows:

CO_2 Determination.

The apparatus consists of a potash bulb to remove CO_2 from the air drawn in; a round-bottom flask in which the saliva is boiled; a test tube condenser and drip-cup, an Erlenmeyer flask which contains the $Ba(OH)_2$ to react with the CO_2 in the saliva, and a suction pump.

It is first tested for leaks by turning on the suction pump and watching the bubbles come through water in the Erlenmeyer flask, while the rubber connections between flasks are each closed in turn.

Then the apparatus is freed from CO_2, and at the same time a final test for air-leaks is made. This is done by putting 10 cc. N/40 $Ba(OH)_2$ into the Erlenmeyer flask, from a buret or pipet, and 50 cc. recently boiled water added to the round-bottomed flask through the separatory funnel. The suction pump is started and the gas flame under the round-bottomed flask adjusted so that almost 50 cc. will distil over into the drip-cup in one-half hour after boiling commences. It must be watched when the water begins to boil, to be sure that the vapor pressure of the water is less than the suction. Otherwise back pressure in the flask would shoot the water back through the potash bulb, and once started it would act like a siphon. After half an hour the suction pump is disconnected from the Erlenmeyer flask, at the same time that the air is admitted to the apparatus through the separatory funnel to avoid back pressure anywhere.

The $Ba(OH)_2$ in the Erlenmeyer flask is then titrated with N/40 H_2SO_4, using phenol-phthalein as an indicator. If the apparatus is free from CO_2 and air-leaks, it will require exactly 10 cc. H_2SO_4 to titrate the 10 cc. $Ba(OH)_2$ used.

Then the drip-cup is emptied, another Erlenmeyer flask containing 10 cc. $Ba(OH)_2$ is put in place, the suction turned on, and 10 cc. saliva and 50 cc. recently boiled water are added to the round-bottomed flask through the separatory funnel. The heating is continued for one-half hour after boiling commences, and then the Erlenmeyer is disconnected as before, and the excess $Ba(OH)_2$ is titrated.

The difference between this number of cc. of $Ba(OH)_2$ and H_2SO_4 equals the number of cc. of $Ba(OH)_2$ used up by the free CO_2 and the CO_2 from acid carbonates of 10 cc. saliva. This figure divided by 40 (N/40 $Ba(OH)_2$) is used, and, multiplied by 1000, it gives the parts CO_2 per thousand, which we call the CO_2 index.

Proceeding according to this technique, we examined numerous specimens for their free acid and combined acids with phenol-phthalein, then estimated accurately a quantity of carbon dioxid, reducing the figures to an index and subtracting the CO_2 index from the total acid. The findings of these investigations showed that there was a persistence of acidity after the carbon dioxid was accounted for.

Illustration of specimen three hours after breakfast from patient with no caries.

	Acid index.
Acidity to phenol-phthalein	5.5
" " aldehyd	2.0
Total	7.5
Carbon dioxid index	6.9
Acid index corrected	0.6
	Alkaline index.
Alkalinity to methyl-orange	13.0

Illustration of specimen three hours after breakfast from patient with extensive caries.

	Acid index.
Acidity to phenol-phthalein	12.
" " aldehyd	6.5
Total	18.5
Carbon dioxid index	6.75
Acid index corrected	11.75
	Alkaline index.
Alkalinity to methyl-orange	14.5

In a recent communication, Dr. H. Carlton Smith acknowledges that he has come to the same conclusion, viz, that the acidity exists in a large number of the specimens after the CO_2 correction. Examination of these specimens for alkalinity with methyl-orange as an indicator, and H_2SO_4 as a titrating medium, showed them to be alkaline in every instance, and we are shown by these differences that there are acid factors that are not accounted for by either of these indicators. The recording of these two findings, however, enables us to make a comparison which may have physiological value, and gives us some little idea of the metabolism of an individual system as regards its ability to produce carbon dioxid.

In all pathological examinations we have found an increased acid index both free and combined, with a lowered carbon dioxid content, and when the CO_2 content was not half of the acid finding, it would appear as a pathological specimen, indicating disturbed metabolism. If the CO_2 is higher than the free acids, it shows presence of acid carbonates. The number of investigations was not sufficient to establish this statement as a fact, as there are many other elements which may influence this finding; but we have at least satisfied ourselves that there are few salivary specimens that do not show acid findings, even after the CO_2 content has been quantitatively established.

To illustrate the point previously made in reference to the pathological conclusions, an examination was made of the specimen of a patient suffering with chronic Bright's disease of long standing, referred by Dr. G. R. Kuhn, chief of staff of St. Mary's Hospital, Brooklyn; and the following report on these properties shows the highest figures ever found in the laboratory:

Patient—Mr. J. G. M.

	Acid index.
Acidity to phenol-phthalein	41.
" " aldehyd	13.
Total	54.
Carbon dioxid index	8.1
Acid index corrected	43.9
Enzymic index	0.168
Proteolytic ferment	0.
Centrifuged sediment	32 per cent.
Overstanding fluid	Clear.
Mucin in sediment	14.3 per cent.
Overstanding fluid	Opalescent.

This is but one case, but if a thousand cases would show similar findings within physiological limits, we could then report a truth.

THE VISCOSIMETER.

Prof. H. Carlton Smith, Harvard Dental School, department of chemistry, has developed a viscosimeter, as reported a year ago, and has made a series of investigations with his instrument. His report is as follows:

In regard to the request which you make, I shall be very glad to give you the results of my work on saliva with reference to the viscidity and enzymes. In fact, it happens to be along just these lines that I am working at present.

I find that in the majority of cases the viscosity should be taken on saliva from which the solid particles have been allowed to settle naturally. In other words, the use of the sieve recommended in my text-book, which I presume you have, is not a desirable method, as the character of the mucin is liable to be so changed that the degree of viscidity is less than actually exists in the saliva before filtering. If the saliva is received at such an hour as to prevent a natural settling of the sediment and subsequent viscosity test on the same day, it may be necessary to clear the saliva in the centrifugal machine. I do not know yet just how the centrifuge affects the character of mucin, but feel that it is less than the sieve.

I also find that it is undesirable to have any volume of liquid whatever in the tube at any point below the restricted point in the condenser, as it apparently makes a difference with the amount of atmospheric pressure on the surface of the saliva. The temperature must be very accurately maintained within one degree C. of some selected point. I am using 20° C. at present.

In regard to the apparatus: The CO_2 apparatus I constructed from a very large test tube, a small Soxhlet flask and ordinary glass tubing which I bent myself. For the viscosimeter I took some Eimer & Amend 10 cc. graduated pipets, carried them to a local glassblower together with a 10-inch Liebig condenser, and explained from the cut what I wanted, telling him that the constriction of the pipet must be such that I could read 5 cc. within the condenser, and that the constriction must at least be an inch above the water inlet, and it must be of such character that it would take 5 cc. of distilled water at least one-half minute to run through it. This he did in a very satisfactory manner.

The viscosimeter that I am using now takes just 35 seconds to discharge 5 cc. of distilled water at 20° C. I use a stop-watch for time, and paper bands to facilitate accurate reading.

The viscosity tests are satisfactory and consistent, taken by the apparatus previously described. The enzymic index has caused us considerable trouble. I do not feel that the test with starch paste is satisfactory for general work, and have spent some little time in trying to work out a method based on a determination of the sugar produced in a given time, but as yet have nothing that I want to talk about.

We have examined over one hundred samples of saliva, finding about 16 per cent. of the samples showing acidity. Of these only 4 per cent. come from cases marked as having good teeth. Of the viscosity tests only 47 were from samples accompanied by a description of the condition of the teeth. Of these, two cases reported as from mouths with good teeth have high viscosity; fifteen cases showing decay have high viscosity. On the other hand, in ten cases of low viscosity the teeth are good; in nineteen cases of low viscosity the teeth show more or less decay.

These figures, as well as any I might give (and they all tell practically the same story), show that it is impossible to draw positive conclusions from any one factor determined by salivary analysis.

I feel that the lack of uniformity of methods must rather seriously retard the progress which is being made toward the positive interpretation of the results of salivary analysis.

(Prof.) H. Carlton Smith.

These findings seem to be conclusive on this subject, but I am sure I am voicing Dr. Smith's opinion when I state that he would prefer to have some other laboratory work through a similar series upon the same technique.

As chairman of the committee, I wish to officially thank Dr. H. Carlton Smith of Harvard University, and Dr. Russell W. Bunting of Michigan University, for the generous assistance which they have lent us in our undertakings; and if their example were followed by other universities of the country, our information would grow rapidly.

EFFECTS OF THIOCYANATES IN DISSOLVING GELATIN.

In order to determine the soluble effects of thiocyanates upon gelatin, a series of experiments was instituted by Constance E. Schradieck, pathologist, Brooklyn, N. Y., under a sterile technique, and established the fact that ammonia-sulfocyanates had no appreciable effect upon gelatins in solutions varying from 1:100 to 1:2000, which appears to be conclusive.

PRACTICAL APPLICATION OF THE TECHNIQUE ADVOCATED.

In order to practically illustrate the application of our technique in the study of pathological conditions, your chairman wishes to report a case from his own practice, observed for a period of three years, which resulted in a cure of chronic constipation:

Mr. C. P., twenty-four years of age, a college athlete and an electrical engineer, apparently was in good health until he became confined in office work, when he developed intestinal indigestion and a chronic constipation. He had been in the hands of several medical advisers, and Dr. T. P. Prout, pathologist, of New York City, had his case under observation during my treatment. All medication was eliminated. A quantitative analysis of his saliva was made which was as follows [exhibiting charts].

His urine and feces were examined by Dr. Felix Von Oefele, New York City, and were as follows [exhibiting charts].

An examination of his mouth showed a malocclusion, class I, mutilated by extraction, presenting 29 inclined planes in occlusion, representing 22 per cent. of normal.

After a year's orthodontic operation, returning the teeth to their normal inclination, Dr. Henry W. Gillett of New York City re-established the inclined planes with prosthetic pieces and gold inlays, developing 115 inclined planes in occlusion, which represented 85 per cent of normal, resulting in mechanical retention of the occlusion.

Examinations of the secretions and excretions were made at intervals, showing a gradual improvement, and comparisons were drawn June 23, 1912, which showed the functioning ability of his teeth improved 60 per cent.; ability to reduce starch to sugar in the mouth improved 66 per cent. The coefficient of non-utilized food in the feces showed an increase of 333 per cent., but was 3 points below normal owing to continued intestinal disturbance. The chronic constipation has entirely disappeared, and he has had no medication for a period of fifteen months.

The comparison of salivary analysis shows a marked difference in many properties and makes a very interesting study. The quantity in a given time increased. The consistence showed a more viscid condition, with the presence of mucin, while the original examination showed none. The ptyalin was markedly increased; the thiocyanates increased; the chlorin decreased. The total solids were decreased. All these properties showed improvement, but the percentage of Esbach's albumin, and the increased quantity of total acidity and urea, were unfavorable on the second examination, but were accounted for in feces analysis by a greatly increased auto-intoxication, which was attributed to a change of diet and the lack of use of the restored organism, with the adherence to the habit of selecting soft carbohydrate food, and the fact that liquids were taken with meals. Recommendation was made to eliminate these pernicious habits, and on June 30, 1913, a year later, another set of specimens was examined, which showed a constant improvement in all properties, and the following figures show the difference occurring between the original examination and the completed one: Ability to reduce starch increased 229 per cent.; non-utilized food in the feces showed one point below normal; the original auto-intoxication improved 12½ per cent.; coefficient of fat-splitting increased from 37 : 100 to 50.3 : 100, normal being 52 : 100.

An examination of salivary specimen showed total acidity 18, slight increase over original; amino-acids as ammonia greatly reduced; chlorin decreased; centrifuged sediment increased 7.4 per cent., thiocyanate remained the same.

He has enjoyed excellent health since the work was completed; his constipation entirely disappeared. His countenance has become more alert, and his eyes more brilliant; the photographic record (see Figs. 1, 2, and 3) will prove these assertions. He is more ambitious for work, and is doing well in business in New York City.

His record would not be complete without the following report from Dr. Henry W. Gillett from the prosthetic standpoint:

Report on the Case of Mr. C. P.

The slides illustrating this case make sufficiently plain the prosthetic steps, so that detailed description is superfluous. The gold restorations are cast, and are mostly of 2½ per cent. platinized gold, and the porcelains are hand-carved for the case. At all points thoughtful attention was given to the establishment of conditions that should conduce to the maintenance of cleanliness, that should eliminate mechanical irritation, and that should permit of efficient masticatory movements and at the same time promote retention of the orthodontic results.

In reporting this case from the viewpoint of the general practitioner, I desire to depart a little from the usual routine, and speak of the underlying principles involved, of the possibilities of our work, and of the responsibilities our position entails, using this particular case as an illustration.

I realize that but a small percentage of cases of this type can receive such treatment as has been possible in this case, but I desire to lay strong emphasis on the responsibility of our profession for keeping such patients informed of the grave effects upon nutritional functions of inefficiency of the masticating organ, and to urge that the train of functional disturbances and organic lesions which must follow such inefficiency be forcefully presented to our *clientèle* at all reasonable times and as cogently as lies in the power of the individual operator. We have no right to pass by the opportunity of calling attention to the facts—of emphasizing the certainty that

Fig. 1.

Fig. 2.

Fig. 3.

a material inefficiency of the initial nutritional organ is of as grave import as a similar inefficiency of any other single organ—be it heart, kidney, stomach, or liver—because it is likely to lay the foundation for disturbance in all these as well as other vital organs.

The portal of the digestive tract has been surrendered to our care, and in that portal the initial step of the complex nutritional function is performed. This fact loads us with a serious responsibility. This responsibility imposes upon us the need for a more careful consideration of the masticating organ as a whole than it usually receives. It is my belief that we are too prone to focus on the individual elements of the organ, and to lose sight of their relation to its other parts, and to its efficiency as a unit.

In this case the patient first presented with a message from his father to the effect that he wanted to know whether the dentistry in his son's mouth was adequate, and those of you who have thoughtfully studied the slides showing the original conditions will realize that a comprehensive and satisfactory answer was not entirely easy. I realized that what the father had in mind was the kind of fillings that had been done, and their condition. I also realized that if I confined my reply to the question as he meant it, and failed to take up the graver inefficiency of the masticating organ as a whole, I might in the future meet with severe criticism—because the father was himself an engineer of capacity, with a keen appreciation of the value of an efficient organ.

Fig. 4.

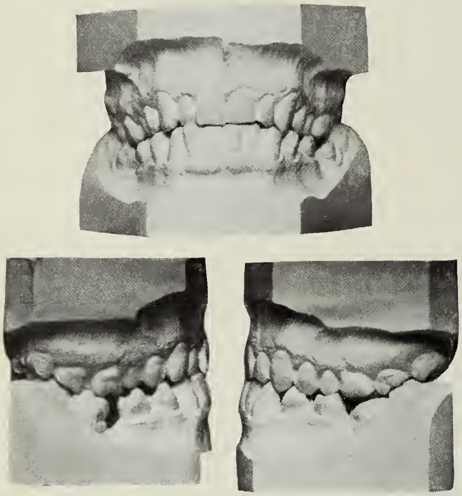

Fig. 6.

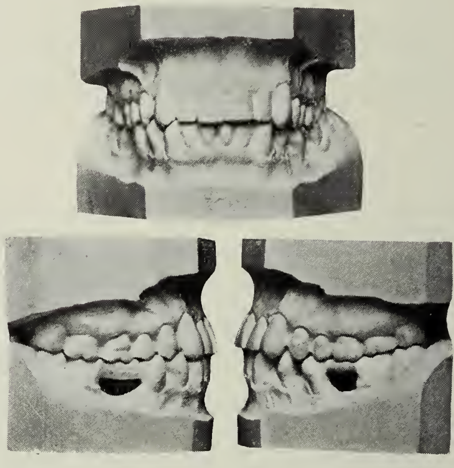

Fig. 5.

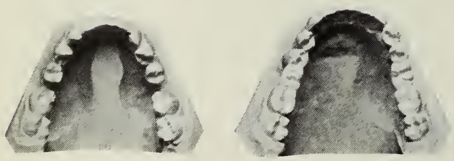

Fig. 7.

Therefore my reply contained the statement that if the young man carried out his intention of taking up active professional life in New York City, with its attendant pressure and complexity, it must necessarily follow that he would break down physically before reaching middle life, and that he must look forward to a lowered efficiency for much of the period in which he might succeed in pursuing his practice.

In preparing the reply to the further question, as to the right remedy, I consulted Dr. Henry C. Ferris, and asked him to first analyze the situation from the orthodontic and physiological side, and tell me what assistance I might expect from orthodontic procedure. After considering his report on these two elements, I stated to the father that by combined orthodontic and prosthodontic measures we might reasonably expect to raise the efficiency of the masticating organ from below 10 per cent. of normal, where Dr. Ferris conservatively estimated it to stand, to at least 80 per cent. of normal, and to retain it permanently at that point.

In work of this type I hold that it is necessary to adhere to two fundamental principles —namely, that anatomical restoration of individual teeth is of first importance, and that it is correct surgery to replace with substitutes any and all teeth or parts of teeth that cannot otherwise be brought into harmony with the lines insuring an anatomical occlusion and its permanence.

I believe a study of the slides illustrating this individual case will convince you that the life prospects for this subject have been profoundly modified by the procedures put in practice; that from an original certainty of continued struggle with hampering disabilities, his outlook has been changed to one warranting the expectation of high efficiency, and confidence that he will go far in his chosen field.

With this case as an illustration, I submit for your consideration the statement that, as a profession, we should give more attention than we do to the efficiency of the masticating organ as a whole, and that we need to make a broader study of the possibilities in all mutilated malocclusion cases than has been our habit.

HENRY W. GILLETT, D.M.D.

CONCLUSIONS.

(1) In drawing conclusions upon our past work, we must acknowledge that it is impossible to make a correct diagnosis from any one factor in analysis unless it be the percentage of the ptyalin in the specimen.

(2) We have also proved that we must look farther to account for the acids found in the saliva. Whether they are produced by the action of bacteria upon the muco-proteins is one of the problems for future solution.

(3) Gelatin is not more soluble in solutions of sodium thiocyanate than in water out of the mouth; but what effects this property has upon the muco-proteins in the mouth remains to be proved.

(4) We have shown that, by comparison of analyses of the secretions and excretions before and after an improvement in the functioning ability of mastication, we modify the whole organism, and thereby put our work on a scientific basis worthy of the consideration of the world.

In closing, we wish to say that while we have not been able to establish a great many truths, we have worked with a definite method of procedure, and our findings may be corrected or disputed— which means honest advance.

It is the sincere wish of your committee that this work continue under the new committee upon these broad lines, and not upon individual methods.

Respectfully submitted,
HENRY C. FERRIS, *Chairman.*

The general session then adjourned until Thursday noon.

THURSDAY—*Third General Session.*

The general session was called to order Thursday at 12 o'clock by Dr. T. B. Hartzell, vice-president.

The first order of business was the reading of a paper by Dr. ROSCOE A. DAY, San Francisco, California, entitled, "Orthodontia and Its Relation to Dentistry."

[This paper is printed in full at page 1117 of the present issue of the COSMOS.]

Discussion.

Dr. HORACE L. HOWE, Boston, Mass In discussing this most interesting paper, I will say that I heartily agree with the general sentiment expressed by Dr. Day. One succeeds best in those fields of work he likes best. The practice of dentistry today is so complicated that to follow all branches with equal enthusiasm is well-nigh impossible— therefore the development of the specialty of orthodontia.

To best serve the public it is necessary for us, who sometimes stand as advisers, to be thoroughly alive to the importance of normal functioning of the jaws and of the nose. The longer I study malocclusion, the stronger is my belief that most of its causes may be traced, directly and indirectly, to the too little use of the jaws and nose. The jaws were designed for USE. Recently a strong, handsome, splendidly developed Swedish gentleman came to my office for treatment. Every tooth was perfect. The jaws were large and well-developed.

FIG. 1.

Only four or five small fillings were present. I remarked that he must have used his teeth when young. In reply he told me that his people in Sweden considered bread unfit for food if less than three weeks old.

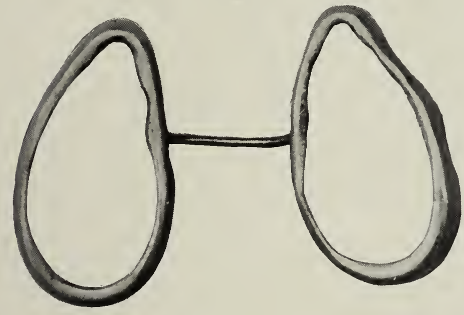
There is no doubt that the use of the jaws in vigorous mastication is the source of stimulation toward its development and the source of the preservation of the teeth after they erupt. The jaws will not develop without the blood supply, which is, in turn, dependent on the stimulation of exercise. One of the most pitiful objects I ever beheld was a boy of perhaps fifteen, whose lower jaw was of the size of that of a child of six. (Fig. 1.) What caused this condition? I *know* it was due to *lack of use.* Of this I am positive, because the boy had ankylosis of the jaw from childhood. His jaw lacked the stimulation of use.

Just a word regarding the importance of the nose: Dr. Day points out that in many cases of malocclusion where mouth-breathing is associated, even after the efforts of the rhinologist in removing the adenoids and polypi, and those of the orthodontist, the nose will still be unused. This, indeed, is the case. The nose, having remained unused perhaps for many years, lacks its proper development. The stream of air passing in and out of the nose under positive and negative pressure is an immense developing force. When we inhale vigorously through the nose, the whole internal head is ventilated, the accessory sinuses are cleared, the air is dragged from the frontal sinuses, the internal ears are ventilated through the Eustachian tubes. To demonstrate this fact one has only to breathe vigorously through the nose, especially in cold weather. Again, when the air is exhaled through the nose, a positive pressure is exerted, which sends the air forcibly through all these passages. Thus it goes back and forth, ventilating and clearing and developing the whole head.

Imagine the loss when the nose is not used. The stream of air when carried to the lungs through the mouth, besides losing the filtering and warming effect of the nose, does not become the developing and ventilating force I have described. Imagine what this loss means to a developing child! Is it any wonder that many cases persist in mouth-breathing even after our combined efforts? We need to take advantage of every possible factor for the establishing of the normal use of the nose. In many cases, the patient should wear the intermaxillary elastics for a long time after the correction of the malocclusion, simply to cause the closing of the jaws when the muscles are relaxed during sleep.

In connection with this subject, I wish to speak of a nasal dilator which I think will be an aid to establishing normal breathing. This is designed to be worn at night—when, as we all know, because of the increased blood pressure with the body in recumbent position, the passages of the nose are smaller than when the upright position is maintained. The dilator (see Fig. 2) holds the soft parts of the nose away from the turbinate bones and septum, allowing much freer passage of the stream of air. In many cases it is a physical impossi-

Fig. 2.



bility for a child to draw the proper amount of air through the nose. I hope this mechanical dilator will prove as useful as it promises to be.

In conclusion I would once more emphasize the importance of normal functioning of the jaws and the nose.

Dr. V. H. Jackson, New York. This is a very important paper, and I should like to have had time to read it carefully before taking part in the discussion.

Dr. Howe's introduction of this expander for the alæ of the nose is important. There is erectile tissue in the nose and in severe changes of weather this tissue becomes active and closes the nostrils, compelling the individual to breathe through the mouth. At night also, very often, this tissue becomes active, and it is of great benefit to the patient to have this apparatus hold the alæ of the nose in position while sleeping; it is very important for the growing child—in fact, for persons of any age. The nose does not develop normally unless functioning properly, and unless it is functioning properly the turbinates become overdeveloped.

Lack of development of the arches is due in many cases to constitutional conditions, and that brings us to heredity. I am a believer in heredity, but I think that some are not holding to that view as strongly as they should. It is very important that we should take these children in hand at the earliest possible opportunity and watch the development of the arches during the developmental stage. I have models of the mouths of children of four years of age in which I am expanding the arches, and every one shows a condition of distal occlusion, the lower arch being retruded and both arches developing according to these conditions.

The essayist's paper shows clearly the relationship between the practitioner and the orthodontist, and I was much pleased to hear him say that the general practitioner should be posted sufficiently in orthodontia matters to be able to advise parents in regard to their children. Every practitioner should be almost obliged to pass an examination on these matters, because, if we are going to be practitioners and advise mothers regarding their children, we need to understand all phases of the etiology of malocclusion and be able to advise the mother in the right way. I often tell patients, when they think me a little over-anxious to get these children under treatment, that they would not set a plant in a front yard and let it grow by itself, but would watch it and care for it and see that it was not strangled by weeds. We need to take charge of these children and direct the development of their arches and faces so that we may bring about what nature intended, by improving the groundwork or bony processes that will produce and support perfect arches and normal occlusion of the teeth.

The general practitioner is the man who must advise the parents as to whether a child shall go to an orthodontist, or whether he himself is to take care of it—and he should not interfere unless he can help the child by doing the best that can be done. That means that every practitioner should be thoroughly posted and be able to give the parents the best advice obtainable. Many practitioners are not following this method; often they attempt treatment of these cases although they do not understand the true requisites to bring about the proper shape of the arches.

I was pleased to hear the essayist's paper, which is calculated to bring out the best that is in us—and that is what we are working for.

Dr. F. C. Rodgers, St. Louis, Mo. I wish to compliment Dr. Day on his splendid paper. It has special importance at this time, when the subject of preventive treatment both in medicine and dentistry is rife throughout the country. Dr. Day has incorporated in his paper the basic principles of pathologic causes of malocclusion of the teeth, and has also pointed out the responsibility of the dentist in directing the development of the teeth and calling the attention of the parents to the necessity of having the malformations corrected at the earliest stage. If the interest of the general practitioner could be aroused to the point where all would work in harmony and with the object in view of preventing these distortions of the mouth and face that we see every day, and that are caused by maldevelopment of the teeth, there would be no need of the orthodontia specialist. These deformities are preventable in their early stages by very simple treatment; therefore the advice of the dentist is important. The general practitioner should guard against the development of malformation, and thus we should be doing a great service to humanity. Not only do irregularities of the teeth cause malformation of the jaws, but the relationship of the nose and the entire contour of the face is also affected.

This is a serious problem, and it should receive closer attention from the profession than, I believe it has been given in the past.

Dr. Howe. In connection with the essayist's paper, I want to speak of the work which Dr. Baker of Boston has been doing in showing the influence of mastication upon the skull. Dr. Baker took a group of young rabbits and removed the teeth from one side of the jaw to see what influence this would have upon the development of the rabbits. Perhaps some of you have seen the record of these experiments, and I mention them now simply to call your attention to them. After these rabbits had grown up, he compared their skulls with the skulls of rabbits that had developed normally, and the comparison was very marked. The median line was deviated toward the side which was used in mastication. The nasal fossa on the side used was larger than on the other side. The backbones of the rabbits were twisted, and the pharynges were also twisted. A German investigator connected with the University of Berlin also performed similar experiments with dogs, in order to show the influence on the development of that animal, and these experiments were even more marked in their results. I simply mention these experiments as being in line with Dr. Day's paper.

Dr. W. E. Grant, Louisville, Ky. I wish to say that I believe the greatest good the men who are working in the field of orthodontia can possibly do at this time is to inaugurate a campaign of education that will result in intelligent and enthusiastic work on the part of the general practitioner along the line of corrective measures. The general practitioner seems to have overlooked the fact that he has a professional duty to perform in this direction, and we all know that many good men are failing to do their professional duty in rendering service to young patients that come under their observation. This is true of practitioners in the larger cities, but especially of those in the smaller cities who do not have the opportunity to refer cases to the specialist; they do not think it is necessary for the patient to be under the care of a specialist at that time. In other words, the general practitioner in many cases believes in playing the waiting game; he believes that, after the child is twelve or fifteen years of age, there will be time enough

—when, as a matter of fact, corrective measures should be applied earlier in life. In my localities I have endeavored through clinics and papers to show the necessity of the general practitioner taking up this work and being able to give intelligent advice to parents in the care of such cases by the orthodontia specialist.

Dr. GRAFTON MUNROE, Springfield, Ill. It gives me much pleasure to voice my sentiments in regard to the excellence of this paper. Dr. Day has given us a paper worth the consideration of every orthodontist and practitioner of general dentistry. One of the most important developmental phenomena that engage my attention relates to the muscles of the child—of which, with reference to the mouth and nose, Dr. Howe has spoken. We know that the smallest children are actively engaging their muscles when obtaining their natural food. The child who is artificially nourished is not developing the muscles of the head, nose, throat, and cheeks as he should; when, however, the child is nursed by the mother, a more active development of the muscles takes place, and all the muscles of the head act, aiding the development of the bones of the head, consequently the nasal apparatus is better developed. As a general practitioner and not having engaged in the practice of orthodontia except in a limited way, I have found that a very important item to be considered is the appearance of approximal caries. As soon as approximal caries commences in the deciduous teeth, they will be noticed to fall out of their normal positions, and if the first permanent molar erupts against a carious or broken-down deciduous molar it will be tilted out of its normal position and occlusion. Of course, as orthodontists we all appreciate the fact that the first permanent molar is the keystone and guide of the whole arch, and if that is tilted out of position we shall have a disarrangement of the whole arch. Special attention should therefore be given to the appearance of approximal caries, and by taking care of the deciduous teeth we shall in a great degree prevent malocclusion.

Dr. J. V. BOSWELL, Springfield, Mo. After ten years of work in orthodontia I am convinced that we have only scratched the surface, and that, considered in several aspects, it is of more importance than we have often thought. Considered from the standpoint of the dietetist, it is almost impossible thoroughly to masticate or insalivate food without normal occlusion; while from the standpoint of the practitioner who is only filling teeth, we know that teeth in their proper alignment are less susceptible to caries, because there is a more normal contact and the interproximal spaces are more normal, thereby preventing food from lodging, fermenting, and causing caries. There can be no doubt that a great amount of irregularity is caused by lack of stimulation. We are living in a "spoon age," when people are accustomed to eat foods that can be eaten with a spoon and require no mastication. If I have studied correctly the investigations on the teeth of prehistoric peoples, I understand that by comparison the size of the crowns and roots differed from what it is today. Our teeth are set in the bones weakly; small roots and large crowns are the result of eating foods that require no great amount of mastication and promote no great amount of stimulation, whereas in past times the roots were larger as compared with the size of the crown.

One of the greatest troubles that the general practitioner has had in the past was that he did not seem to see these evils until they were fully developed. It was easy to see where teeth were missing, and where a bridge could be placed, or where teeth were decayed and needed filling; but apparently he did not see malpositions until they had made considerable progress. I had one dentist tell me, not a great while ago, that he never had a case for orthodontia presented to him. I believe it was because he was not a good diagnostician, and could not see the evil progressing. This feature should be considered carefully, for it is here that we owe our greatest duty to our patients.

Dr. H. A. ELMQUIST, Des Moines, Iowa. It seems that the early etiology of irregularities is the most important field of dentistry, and yet these irregularities date back farther than the time when the general practitioner of dentistry comes in touch with them. Here medical men and dentists should come closer together; the medical man is the one to see these conditions first, as we do not often see the patients until the damage has really been done. We often do not see children until they are eight, ten, or twelve years of age, when they have lost their deciduous teeth without having been taken to the dentist. Often the first permanent molar is already decayed to the point where it is giving trouble, and then the damage has been done by interference with the development of the jaw. The medical man, therefore, who comes in touch with these patients sooner than we do, is the one who should recognize these conditions, and he should send the patients to the dentist.

Dr. L. M. Waugh, Buffalo, N. Y. It is with a good deal of hesitancy that I rise to take part in this discussion, as I take it for granted that thus far the subject has been discussed only by men who are actively engaged in orthodontia, while those engaged in general practice have not yet voiced their sentiments in the matter. I have enjoyed this paper more, perhaps, than others which have been offered by orthodontists to the general practitioner for his enlightenment, because the essayist goes to the basic principles of his subject and does not obscure them with illustrations of failures which have resulted from the mistakes of the general practitioner. The points brought out leave in our minds a most vivid impression of the harm that comes when steps are not taken for the early establishment of normal occlusion. As a general practitioner who is paying a good deal of attention to prosthetic procedures, I believe that the prosthetist is recognizing more fully the necessity for observing the principles of normal occlusion than any other branch of dentistry excepting orthodontia. The sooner all the branches of dentistry, special or general, recognize the fact that normal occlusion is the ideal for every operative procedure, the better it will be for the profession. This principle is applicable from the time the deciduous teeth are erupted, all through life and in every part of our work, no matter what restorations are done, down to the senile stage when the teeth are replaced with artificial dentures. When we restore an occlusal surface with a filling, we should have the ideal of normal occlusion in our minds; when we make crowns, normal occlusion is the mark at which we should aim; when we make bridges or artificial dentures, normal occlusion is the standard toward which we must work. The orthodontist steps in to aid the practitioner in establishing normal occlusion when the general practitioner is unable, under the stress of the busy day, to give proper time to such work; and if normal occlusion is established, the patient retains the teeth and the face is developed normally. After the orthodontist has established the nearest possible approach to the ideal of normal occlusion, it is our duty to see that this normal occlusion is maintained in everything we do—in building contacts, in restoring occlusal surfaces, and in the making of crowns and bridges. The establishment and maintenance of normal occlusion, reinforced by oral prophylaxis, which is now being so extensively exploited, is the ideal toward which as general practitioners we should work.

Dr. Gustavus North, Cedar Rapids, Iowa. To me it is apparent that the greatest causes of irregularities of the teeth are mouth-breathing and thumb-sucking during childhood. Mouth-breathing is generally caused by nasal obstruction, and we as dentists ought always to advise that such children be taken to a specialist for treatment. Thumb-sucking is a habit in infancy, and this habit is often encouraged by the mother and the nurse.

Dr. G. R. Hodge, Kansas City, Mo. There is no doubt that the orthodontist is of great assistance to the general practitioner and his patient. We should be able to direct patients to the right place, either to the orthodontist or the rhinologist, if the case cannot be treated in general practice. The time has come when we should be able to educate the public along this line. These children can be benefited if rightly directed. Thousands of children are hard of hearing today on account of nasal troubles and enlarged tonsils. The education of the public along these lines would bring about grand results, and probably quicker results than can be obtained in any other way. Every day we see cases in which children would be benefited through life if their parents were properly instructed. In the case of my own child, who was a mouth-breather, I have seen the good results to be obtained from proper treatment. A few years ago I brought him to Kansas City and had adenoids removed from his throat, and in two weeks I saw a marked change. I think it is our duty to try to educate the public along this line by any means we can, and I am sure that it will prove of great benefit to the coming generations.

Dr. DAY (closing the discussion). I first want to thank you all for the kind criticism accorded my paper. It is really a pleasure to see how much you appreciate normal occlusion, and it is very flattering indeed to know that you have accepted the paper in the way that it was intended. I have tried to make it as broad as possible, and my object in reading it was to benefit all.

One or two points have been brought out that I wish to speak about. One was preventive dentistry; and here I may say that the one object of early treatment in orthodontia is prevention. In the locality where I established myself as a specialist I have had many headaches over the fact that I had predecessors whose practice it was to advise waiting until children were fifteen years and older before any treatment was begun. That, I think, is the greatest mistake we could make. The one thing to do is to be candid and recognize these conditions and advise corrective treatment early.

Last year I had the pleasure of going to a wild portion of Oregon where there is a settlement of Indians numbering some fifteen hundred, and while there I had the privilege of examining the teeth of many of these people and studying their habits. Among them I found some very intelligent men who—I want to emphasize this fact—believed in living the simple life, and lived upon coarse foods. The government gives them one hundred and sixty acres of land each, and food of the coarsest variety, and it was astounding to me that among these fifteen hundred people I did not see a case of malocclusion—not one!

As a matter of comparison I want to call your attention to another fact. Our state board of prison directors appointed a commmittee to examine the prisons in the state with a view to establishing a dental department to care for the teeth of the inmates. We have a state administration that is doing all in its power to assist the community at large, and they even continue their efforts after men are placed in prison. I went to the prison for the purpose of examining these men and making recommendations to the directors as to what would be necessary for the establishment of a dental chair in the prisons. It may sound narrow, but, after examining 1115 men, I was convinced that malformations and irregularities of the teeth had a great deal to do with the mental state of these people. One man had been condemned to die and had been reprieved a number of times, and just before I left I received two or three invitations to his hanging—which I hardly think will come off, because we are trying in California to do away with capital punishment. This man was sent to prison for life, and while there he killed three other prisoners; and he has a malocclusion of class III, the worst case I ever saw. His upper jaw is entirely inclosed within the mandible, with not one tooth in occlusion. Now, no one can convince me that this condition has not had its influence in the development of the man's brain and face. I saw many other cases of the worst types of malocclusion, and I am convinced that these conditions have their effect upon the mental development.

Someone spoke of the examination of children in the public schools. That is a great thing, but unfortunately the examiners' positions have gotten into politics, as in a certain city which I visited not a great while ago where I saw examiners at work who did not recognize irregularities of the teeth or malformations, but only saw cavities in the teeth. In the normal development of the mentality of the child these factors must be considered, because the mechanical forces of occlusion have everything to do with the facial bones and with cranial development.

Army Dental Corps.

Dr. Hartzell then introduced to the audience First Lieutenant ALDEN CARPENTER, official representative of the dental corps of the United States army, who addressed the association as follows:

Mr. President, members and friends of the National Dental Association,—It affords me great pleasure to receive this recognition; furthermore, let me say that the members of the dental corps of the United States army appreciate the consideration you have shown them in granting to them the right to representation in your organization.

I am sorry to state that I am not prepared to entertain you with an interesting paper—which is all due to the fact that our friend Dr. Dewey has been showing me what he has accomplished in research work, and also in orthodontia. This has so impressed me that I feel like giving up general practice and devoting all my time to orthodontia.

The climatic conditions this morning are such that a long-drawn-out paper had better be printed and distributed than read; so I have endeavored to prepare a short syncpsis of what constitutes our corps, and how the work is carried on in the army.

First, the act of Congress approved March 3, 1911, establishing the dental corps of the army:

> Hereafter there shall be attached to the medical department of the army a dental corps, which shall be composed of dental surgeons and acting dental surgeons, the total number of which shall not exceed the proportion of one to each thousand of actual enlisted strength of the army. The number of dental surgeons shall not exceed sixty, and the number of acting dental surgeons shall be such as may from time to time be authorized by law. Dental surgeons are commissioned with the rank of first lieutenant, and shall have rank in such corps according to the date of their commission. The pay and allowances of dental surgeons shall be those of first lieutenant, including the right to retirement on account of age or disability as in the case of other officers.
>
> Appointees as acting dental surgeons must be citizens of the United States between twenty-one and twenty-seven years of age, and graduates of standard dental colleges. They shall be required to pass the usual physical examination as required for appointment in the medical corps, and a professional examination which shall include tests of skill in practical dentistry and of proficiency in the usual subjects of a standard dental college course.

> Applications for examination should be made to the Surgeon-general of the army, and applicants who qualify at the examinations will be employed on a contract for a period of three years, receiving $150 per month, also traveling allowances in changes of station, quarters, heat and light, also medical treatment in case of sickness.
>
> After a period of three years, acting dental surgeons whose work and conduct give rise to no material and well-grounded criticism will be regarded as eligible for promotion to the grade of dental surgeon, subject to a physical and professional examination by a board duly constituted as prescribed by law. Members of the dental corps are not permanently assigned to any one station, regiment, or arm of the service, but are transferred from station to station as the needs of the service demand. All supplies, instruments, etc., are supplied by the government.

There are now twenty-eight dental surgeons and twenty-three acting dental surgeons in the service. Their field of operation necessitates their visiting all the military posts in the United States, Alaska, Hawaiian Islands, Philippine Islands, Porto Rico, China, and Panama. So you may see, gentlemen, that the young man of active mind who longs for a change of scenery and climate may realize his ambition.

Before closing, I wish to state that I know of no better field for the young professional man than in entering the United States army. He will there receive a training that will better fit him for his chosen field, and if he shows adaptability in any specialty pertaining to dentistry, his opportunities are many, with a commander ever ready to promote the art and science of dentistry.

The general session then adjourned until Friday at 12 o'clock.

FRIDAY—*Fourth General Session.*

The general session was called to order on Friday at 12 o'clock by the president, Dr. Hetrick.

Panama-Pacific Dental Congress.

Dr. Hetrick introduced Dr. T. SYDNEY SMITH, Palo Alto, Cal., who addressed the association as follows:

Mr. President, and members of the National Dental Association,—I have the honor to come before you in the interests of the Panama-Pacific Dental Congress, and to bring to you greetings from the officers of that congress and the host of willing workers in the Pacific coast states.

It is evident to all that the completion of the Panama Canal is one of the greatest achievements of modern times and marks a new era in the commerce and prosperity, not only of the two Americas, but also of the entire world. It is fitting that this new era of commerce should be celebrated and ushered in by a great International Exposition to bring together the nations of the world at some definite time and place. This Exposition, as you know, will be held in San Francisco, California, in 1915.

It is equally important that we should take advantage of this gathering of the nations to advance the interests of science in general, and that we should not neglect our especial branch, the science of dentistry. Realizing the significance of this, the dentists of the Pacific coast states took the initiative step and organized the Panama-Pacific Dental Congress. Having taken this decisive action, representatives were sent last year to Washington at the time of the National dental convention to secure the co-operation of this great organization. Our gratification can well be imagined when we obtained, not only the unanimous consent of this body to meet with us, but also secured the International Dental Federation. Having secured the co-operation of these two great bodies, it devolved upon us to work out ways and means whereby we could make this, if possible, the greatest congress which has been held in the history of dentistry.

To insure the success of this congress we found it necessary to elect permanent officers. The Committee of Organization, in regular session at San Francisco last June, elected the following officers:

Dr. FRANK L. PLATT, *President.*
Dr. CHAS. N. BENBROOK, *Vice-president.*
Dr. F. G. BAIRD, *Treasurer.*
Dr. ARTHUR M. FLOOD, *Secretary.*

The Executive Committee consists of the above-named officers, and eleven others who constituted the Committee of Organization. Executive committees, each consisting of a chairman and four others, have been appointed for about forty states and eighteen foreign countries, and the appointments of a number of others are pending. Negotiations are under way with manufacturers and dealers for the purchase of exhibiting space. Various means and methods for publicity have been put into execution and are awaiting development. Universal enthusiasm prevails throughout the coast states, and the most cheering and encouraging reports and letters are coming in from all over the world. The proposition grows larger with each day.

Subscriptions to our promotion fund have been generous and most satisfactory. So far the following organizations have subscribed:

The California State Association ...	$1500
San Francisco District Society	500
Alameda County Society	500
Southern California Association	1000
Additional private subscriptions to date (from Southern California) ..	1400
Oregon State Association	250
Portland District Society	300
Utah State Dental Society	150
Odontological Society, Salt Lake	50
Washington State Society	150
Seattle Dental Study Club	100

The total subscriptions to date are nearly $13,000.

It is desired by the committee that the members of the profession generally buy their memberships in the congress at their earliest convenience, so that the committee may, as early as possible, have some idea as to what the ultimate membership will be, as well as creating and establishing a personal interest in the Congress.

The Panama-Pacific Dental Congress will open on Monday Morning, August 30, 1915, and continue in session for ten days, not including Sunday. The congress will meet in the new million-dollar auditorium to be constructed by the Exposition Company as a part of the Civic Center of San Franciso, which will not be an integral part of the Exposition, and not within the grounds. In behalf of the officers of the Panama-Pacific Dental Congress, I most cordially invite you all to attend this great meeting, and to aid us in making it the largest and best ever held.

Motion was made and carried that the invitation to the National Dental Association from the Panama-Pacific Dental Congress presented by Dr. Smith be accepted with thanks.

Installation of Officers.

The next order of business as announced by the President was the installation of the newly elected officers. The following officers were then duly installed:

President—Dr. Homer C. Brown, Columbus, Ohio.

First Vice-president—Dr. Chas. Channing Allen, Kansas City, Mo.

Second Vice-president—Dr. M. L. Rhein, New York City.

Third Vice-president—Dr. H. H. Johnson, Macon, Ga.

Treasurer—Dr. H. B. McFadden, Philadelphia, Pa.

General Secretary—Dr. Otto U. King, Huntington, Ind.

Dr. Brown then introduced to the association Dr. W. S. Zeile, of Sydney, Australia, who addressed the association.

Dr. H. J. Burkhart moved that a rising vote of thanks be given to the retiring president, Dr. Hetrick, for his very efficient work in conducting the affairs of the association. [Motion carried.]

Dr. Burkhart also moved a vote of thanks to the Local Committee of Arrangements, and especially to Dr. Chas. C. Allen, for the splendid work done in making the arrangements for the meeting and for the very efficient manner in which they conducted everything placed in their hands. [Motion carried.]

Motion was then made and carried that the association adjourn until the next annual session—at Rochester, N. Y., July 14,* 1914.

* [As will be seen by reference to "Notes and Announcements," on a later page, the date above given has been *advanced* one week. Accordingly—*Read:* The National Dental Association will meet at Rochester, N. Y., July 7, 1914.—Ed. Cosmos.]

SECTION I: Prosthetic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

Chairman—Harry E. Kelsey, Baltimore, Md.
Vice-chairman—Frank T. Taylor, Boston, Mass.
Secretary—J. H. Wallace, Omaha, Nebr.

Wednesday—*First Session.*

The first meeting of Section I was called to order on Wednesday morning, July 9th, at 10 o'clock, by the chairman, Dr. Harry E. Kelsey, Baltimore, Md.

The first item on the program, as announced by the Chairman, was the reading of a paper by Dr. Percy R. Howe, Boston, Mass., entitled "The Saliva."

[This paper is printed in full at page 1112 of the present issue of the Cosmos.]

Discussion.

Dr. E. P. Brady, St. Louis, Mo. In reading the able paper which the essayist has presented it occurred to me that anyone who has not entered this field of study cannot appreciate the enormous difficulties that present themselves and seem to baffle every effort upon the part of the investigator.

A study of the saliva shows that that fluid is subject to many influences which tend to change its composition, as has been mentioned. The saliva secreted by a resting gland differs from that secreted by one that is under stimulation. The composition differs in different individuals also; it is individual in character. It is also found that, depending upon the variety of nervous stimulation, the character of the saliva secreted may be materially changed. To illustrate: The secretion from the submaxillary gland under a stimulus from the facial nerve is abundant, limpid, low in mucin, etc., while that produced under a stimulus from the sympathetic nerve is scanty, rich in mucin, and of rather high specific gravity. My reason for bringing this fact forward is that several cases have come under my observation in which grave pathological conditions of the dental organs have existed, and all of the patients were under treatment for nervous disorders. I am not prepared to draw the conclusion that a disturbance of the nervous system would also affect the nervous stimulation of the salivary glands to such an extent as to be the auxiliary cause of the pathological condition existing, however an abatement of the general disorder showed a corresponding improvement in the dental conditions. I am working in this field at the present time, and am not prepared to make a definite statement as yet.

I have not approached the study of the saliva from the same point of view as the essayist, and there are several points of consideration which he has failed to mention which appear to me of prime importance—as, for instance, in reference to the saliva from various persons in whom caries of the teeth does not prevail: How does it behave when it is incubated?—that is, Is lactic acid formed to an appreciable amount? How do the results from these tests compare with similar tests performed with saliva from mouths in which caries prevails? If the saliva in any of the above cases were alkaline to start with, of course the decrease in alkalinity would show that acid had been formed during the incubation. The point to be proved in the above would be: Is lactic acid formed in mouths free from caries?—and, if so, what is the combating element of the saliva? Would the alkalinity, if present, neutralize this acid?—or, conversely, Is the saliva of so-called immunes deficient in nutrient material?

It is understood in these experiments that the various carbohydrates be added to the salivas. In the classification of micro-organisms, the lactic acid bacillus is generally classified as one requiring the presence of nitrogen compounds to meet nutrient requirements. One authority claims that lactic fermentation occurs in the various carbohydrates, when animal nitrogenous matter is present. It is reasonable to believe that albumin, globulin, and mucin can meet these requirements. One or two investigators have experimented with the saliva, using various commercial enzymes with the hope of ascertaining if the lactic acid present in saliva be due to enzyme activity. No definite results were obtained; still the fact remains that an enzyme can be isolated from the lactic acid bacillus which produces the specific fermentation action of the mother organism. Also it has been shown that some substances in certain concentration kill the ferment and do not interfere with the action of the enzyme. This problem is rather complicated, and, as this field of investigation may be considered in its infancy, it is hardly in order to recall the various theories that have been offered as to the formation of lactic acid by the various enzymes. From what has been said, however, we may see that, although the saliva may be deficient in nutrient material, still lactic acid may be formed by the presence of a small quantity of enzyme acting upon carbohydrate material.

It is a well-known fact that constitutional disorders have a direct action on the nature of the saliva, and there is no need of any further elaboration upon this subject.

In regard to the use of the various indicators for determining the degree of alkalinity or acidity, it may be stated that Foa claims that the actual alkalinity is always considerably less than that found by titration, while the reaction as determined electrometrically is nearly neutral.

In the case of using $KHC_4H_4O_6$ as a mouth-wash, especially at night, it is only reasonable to believe that during this period, the mouth being at rest, even if the saliva be alkaline the interstitial spaces, the points that more readily succumb to caries, will not be penetrated by the saliva, and consequently the acid formed will not be hindered in its action; while on the other hand, if the treatment suggested by Dr. Miller be followed—*i.e.* if, in acidity of the saliva, milk of magnesia be used—the physical property of this mixture will keep it in contact with these points, and thus keep them alkaline.

The author suggests that the saliva be considered as a medium furnishing acid-forming bacteria with the necessary requirements, and not simply as a neutralizing agent for the acid already formed. In accordance with this suggestion it seems plausible that in those cases in which there is a prevalence of caries, the alkalinity of the saliva would in no way interfere with the activity of the micro-organism, but simply neutralize the effect of the acid formed; and in considering the nature of the mouth-washes used, necessary provision should be made not only to neutralize the acid, but also to inhibit the action of the lactic acid organism.

In conclusion, I wish to express my approval of the general suggestions offered by the essayist, as they all have a direct bearing upon the nature of the saliva and also the factors provocative of pathological conditions of the oral cavity.

Dr. Russell W. Bunting, Ann Arbor, Mich. There has never been a time in the history of dentistry when there was such a widespread interest in the cause and control of caries as is being manifested today. Everywhere we find men who have enough interest in the subject to spend considerable time and endeavor in the following out of some specific feature of the problem, and who are adding to the sum of acquired knowledge on the subject.

Since the trend of modern investigation seems to point out that the variable forces which determine the susceptibility and immunity of the teeth to caries lie outside of the teeth, the greater number of the investigations have been focused upon the saliva and its contents, seeking in that fluid the determining factor in the process. If, then, the saliva plays so important a part in the process, it is very necessary that close study be made of this secretion to ascertain its component parts, and their behavior with respect to caries. The paper to which we have just listened is a report of valuable work along this very line, and will be a distinct addition to the literature upon the subject.

The author has well stated his premise when in the opening paragraph he says that "The problem of caries is to determine the differences which exist between the saliva of the mouths in which microbic life extensively flourishes, and the saliva of those in which it is inhibited." Next, he has, by a long series of experiments, determined that phosphates, sugars, amino-acids, etc., stimulate fermentation in the saliva, and that carbonates and chlorids inhibit it. He has then gone into that very important and ultimate field toward which all investigators must gravitate—that of the dietetic control of the salivary secretion—and has suggested methods for decreasing the fermentations in the saliva.

All of this is very important, and is of especial interest to me, inasmuch as I have been engaged in studies of this subject from a somewhat different angle for the past two years. I have examined and incubated a large number of salivas, looking for some that would refuse to form acid. I have found that they all undergo acid fermentation in their natural state, some forming more acid than others in a given time, but those which showed marked differences were few in number and did not in any way coincide with the susceptibility or immunity to caries. In any case, the amount of acid formed in any saliva was inconsiderable as compared with that which would be formed in any of them upon the addition of one-half gram of bread.

The results of my experiments have led me to believe that the amount of fermentation in a given saliva is not so much dependent upon the particular bacterial flora present, or the presence or absence of some restraining influence, as it is upon the quantity and the character of the food which is available for fermentation. Carbohydrates must be present either in the salivary secretion itself, or come from ingested foods from which the acids may be formed. That the presence of amino-acids will accelerate the action of the acid-forming bacteria, as reported by Dr. Howe, is an interesting feature.

But interesting and important as is our discussion of the fermentations of the mouth and their relation to dental caries, it does not seem reasonable that we should emphasize this factor to the exclusion of all others, as the author seems to have done. For the process of caries, acid fermentation is indispensable, but it is also necessary to have an accessory factor—namely, protection to the acid-forming bacteria and to the acids which they have formed. The acids must be confined against the tooth, and some provision made to keep the saliva from diluting them and washing them away. We have all seen filthy mouths in which the fermentations were very high, and yet there was no caries. Acids certainly formed in these cases, and in no small amount, but they have not been able to affect the enamel of the tooth. It has been protected either by the filth itself, or by some form of plaque which was not conducive to caries. So that in the investigation of caries from the standpoint of the saliva we must, on the one hand, look to the acid fermentations of the foods, both salivary and ingested, and on the other, inquire into local conditions immediately about the teeth which make it favorable or unfavorable for the acids to attack those organs.

There is great need for further work to be done along these lines. Confined as we are to the saliva, we are under a great handicap, for we are dealing with a perverse and fickle fluid that seems to resist our every effort at investigation. By the nature of the secretion and by the variability of its constituents the most simple reactions are obscured and their veracity may be questioned. It is just such investigations as this, applied to every phase of the problem, that are needed. Careful and painstaking research must be carried on by a number of men who are well qualified to undertake the task, to get first a fuller understanding of the basic principles in the saliva, and then to study its relation to dental caries. It is a big work, and one of such importance as to be well worth our best endeavor. I wish to congratulate Dr. Howe upon the research he has made, and the association upon the presentation of his paper.

Dr. Howe (closing the discussion). The criticisms given are very interesting, and show, for one thing, the need of more extended study of oral pathological processes. They are, further, an evidence that creditable work has already been carried out upon these most important questions. In my paper I have endeavored to present some ideas respecting the constituents of the saliva that might act to stimulate or interfere with bacterial growth. In other words, I have presented a study of the saliva as a culture medium. The importance of the media to the bacterial growth may be further seen in the fermentation of sugars. It is the sugar in the souring milk that makes the lactic acid. Solutions of sugar exposed to the air are always converted into lactic acid solutions. So that we see that here it is the medium that controls the lactic acid fermentation, fully as much as the bacteria. A very great number of bacteria have been isolated that are concerned in this kind of fermentation—yet we must always have sugars or starches for them to act upon in the production of lactic acid. Other contributory factors have been considered in the paper which I have had the pleasure of presenting.

The next order of business was the reading of a paper by Dr. Marcus L. Ward, Ann Arbor, Mich., entitled "Conflicting Opinions Concerning the Manufacture and Use of Alloys for Dental Amalgams."

[This paper is printed in full at page 1082 of the present issue of the Cosmos.]

Discussion.

Dr. Clarence J. Grieves, Baltimore, Md. I wish to thank Dr. Ward for his valuable research in amalgam alloys. It seems that we have had a research meeting, and I do not know that we could find any greater argument for the necessity of dental research than these two papers by Dr. Howe and Dr. Ward.

It seems most unfortunate that when our profession decides that it really needs to investigate some phase of a subject, it finds that particular subject most difficult. It was thought that it would be easy to look over the saliva and by chemical analysis solve the whole question. The same can be said of amalgams, and you have seen this morning how easy it is!—for when we attack the proposition of alloys we find that an alloy is no simple thing, not a chemical compound nor a mechanical mixture—in fact, nobody appears to know just what it is; and right in this breach our help will come from such men as Dr. Howe and Dr. Ward.

I would like to speak for a moment from the standpoint of the general practitioner. We all admit that there is one thing of which we should be sure, and that is the exact nature of what we put into the human mouth, particularly as we put it there with the hope that it is going to stay. So in taking up the question of amalgam, a material that today is saving more teeth than any other one material in our hands, it is important for the dentists to know the metals that go to make it, and how they will behave in the mouth. When I read Mr. Atkinson's paper in the Dental Cosmos (issue for June 1913), while I am not a metallurgist, I thought that we had all been wrong, and that it had all been fixed for us—that the making of dental alloys was simply a chemical proposition; and here again we owe Dr. Ward a great vote of thanks. For if the manufacturers had gone into making amalgam on the laws of valence as suggested by Mr. Atkinson's article, we should have had very unreliable amalgams indeed. So the problem is not so simple as it looks. These alloys are curious things, the union of metals producing a result which apparently does not follow the laws of chemistry or physics, and we are not yet ready to depart from the rules laid down by Dr. Black. My particular part in the discussion has to do with the behavior of these metals in the mouth, and is based upon studies regarding the action of saliva on German silver, gold and platinous zinc alloys, which I reported some years ago. I recognized the value of zinc from the physical standpoint in small proportion as a good constituent in these alloys, and, if the proportion be small enough, I may agree with Dr. Ward, but I have an animus against the insertion of zinc in any percentage in the human mouth.

Allow me to quote from my former paper:*

> If it can be established that a vitiated saliva, or even a normal saliva and its mucous content, or the decomposition of food in the common retention centers, or a combination of all of these, affect the metals in use in operative and prosthetic dentistry in such a way as to bring about their corrosion, forming other retention centers to the minute but ultimate destruction of smooth surfaces, prophylaxis exacts of us that we correct the environment, if possible; close all retention centers against the lodgment of filth, or substitute some material impervious to such action.

* * * * *

* Cosmos, vol. li, p. 1041. September 1909.

The alloy German silver was found, by six assays of as many varieties manufactured, to consist of copper 6.1, zinc 2.1, nickel 1.7, and iron 0.2. . . . Plain German silver examined with low powers after exposure of a few weeks in the mouth, in child saliva, presented craters in the centers retaining food; on longer exposure these craters extended all over the appliances—an arch bar for instance—even to the parts kept clean by the lips and tongue; corrosion was more pronounced in fixed than in removable appliances, and distinctly more violent and rapid, even to perforation of the metal, when gold plating, which was always defective, occurred.

That the added layer of gold should greatly increase corrosion, even granting some damage to the alloy in plating, is significant when seen in the light of the table of Berzelius, gold and copper standing as highly electro-negative, as opposed to nickel, zinc, and iron, which are electro-positive.

It was found that the craters were cut in the food-retention centers just as the tooth was cut, but there the analogy ceased; for to conclude that this is an acid process *per se* is to admit either that the acid starting craters extends and is retained all over the appliance, even at the constantly cleansed spots, or to admit a general mouth acidity as high as the retention centers—a position entirely untenable, for all children wearing appliances do not have hyperacid mouths, while the corrosion of German silver is remarkably constant in all mouths.

Electrolysis is, then, the principal agent working toward the destruction of this alloy —with the acids of food decomposition first charging the battery, and with the saliva containing these as a general electrolyte. This may be further established by the following facts:

First: An alloy containing, approximately, gold 18, platinum 2, the remaining four parts of the 24 karats being made up of equal parts of silver, copper, and zinc, after short wear under like conditions presents corrosion almost as pronounced as with plain German silver.

Second: "Dutchmen" of German silver wire used to fill in bridge dummies surrounded by gold solder and exposed in finishing, present deep degeneration spots on otherwise smooth surfaces when placed in the mouth away from the abrasion of occlusion. . . .

Last, but by no means least, the study of a large number of 18-karat gold solder surfaces known to have been smooth when placed in the mouth by the writer, develops the interesting fact that whenever a food-retention center was created, as in saddle dummies where gum hypertrophy has produced a false margin, corrosion exists to a marked degree.

Gold solders, "18-karat," are really 16-karat gold, and nearly, if not all, contain approximately, gold 16, copper 5, zinc 3. It has thus been proved that German silver with 15 per cent. zinc, 18-karat gold solder with 12 per cent. zinc, and all below such percentage, and platinous gold alloy with 5 per cent. zinc, all corrode with the human saliva as electrolyte; while gold plates of a much lower proportion of gold, such as coin gold (gold 90, copper 10) and the lower dental plates alloyed with metals all of the same electro-negative class as gold, with copper, silver, and platinum, do not degenerate under the same conditions.

Zinc to the average extent of 5 per cent. is thus the disturbing element, and the following law may be safely deduced: *Metals violently electro-positive and negative to each other should not be used in alloy or apposition in the human mouth, with the saliva as electrolyte*—as, for instance, gold and zinc, copper and zinc, etc.

Corollary to this law stand the facts that it is absurd to spend time polishing surfaces which we are assured will shortly become pitted; that it is bad dental and general hygiene to have such pitted surfaces in the mouth that the degeneration waste metal is ingested continuously, producing possibly systemic detriment; and finally, that because metallic poisoning has not been generally noted, this does not in the least affirm that it has not occurred.

* * * * *

Tin, the principal ingredient of amalgam alloys, when associated with gold cervically as foil, under the influence of the saliva loses much of its physical character and becomes hard and brittle. Binary amalgam alloys (tin and silver) placed cervically as the base for gold foil operations are changed along these lines and to a greater degree. Tin, then, is the active factor, but who will say whether the force acting as to so modify metals is chemical or physical, for these phenomena do not occur outside of the mouth. The quaternary alloys, containing besides the usual proportion of tin and silver a small portion of copper, gold, or zinc, or any two of the latter, do not harden as do the binary alloys in apposition to gold in the mouth; those containing zinc 2 parts show, when placed as a cervical seat for gold foil fillings, corrosion just above the gingival margin. These spots have been found on well-finished fillings from the hands of careful operators, and have been produced experimentally in the mouth by the writer.

It may be noted that as far as these observations go, ternary alloys (respectively silver, tin, and a portion each of copper, gold or platinum), while covered with sulfids, do not show degeneration as do the cleaner-looking quaternary alloys having a small percentage of zinc, with gold or platinum (the writer does not take the latter any too seriously). This is of particular interest, first, because mercury, silver, copper, and tin, the metals common, in the order named, to amalgam alloys, occupy a central position in the series of electro-positive and negative substances, being almost equal in potential, while gold and platinum are as far away and opposed electro-negatively from this naturally combined central group as is zinc electro-positively; second, these four metals combined have long been known as producing the best practical results.

I am not at all clear as to the percentage of zinc Dr. Ward proposes, and I do not understand how it can exist independently in bulk in amalgam alloys without being dissolved out, when we know that German silver, which is a homogeneous zinc alloy—as proved by the fact that it is so often used as a resistance in reducing electric currents,—will degenerate in the mouth, as has been shown.

Dr. Hamilton. I wish to congratulate Dr. Ward on his paper, and I would like to ask how dentists who are not able to make these researches are to know what alloys to use. I have for the last twelve years used alloys made after the Black formula, but it seems that there is some question now as to their superiority. What alloy then should we use? To this question I would like to have some definite answer, if one can be given.

Dr. W. A. Price, Cleveland, Ohio. It is not safe to call upon me while talking of a subject that needs additional research, for I am liable to get my subscription blanks and try to collect more money to help Dr. Ward solve his problem.

I wish to emphasize that, after Dr. Black, Dr. Ward, Dr. Fenchel, or any of our great men, have made their most painstaking and careful researches, they are not in position to advise you to use such and such an alloy—as asked today—because immediately they would place themselves in the position of being partial to certain manufacturers, or are liable to be misunderstood. One of the greatest functions of the National Research Foundation Committee will be that we can bring about a co-operation of such men as Dr. Ward, Dr. Black, and others, and let them come to a conclusion and give us their finding, which we shall accept as final, and so give it to the profession. I have no doubt that before two more annual meetings come around we shall be able to accomplish this aim, if the members of the National Association will make it possible for us to furnish assistants to work under the guidance of these men. I cannot refrain from saying that we have the opportunity now for employing eight researchers if we had the means. I want to commend the work of Dr. Ward, and assure you that when his paper is printed, and we can study it more thoroughly, we will find that it has more of merit and usefulness for our everyday practice than we have suspected from this single reading.

Dr. Rich. I would like to ask Dr. Price to say a word regarding the electrolysis of zinc in the mouth.

Dr. Price. I would hardly like to enter into a discussion of that phase of the subject now, because it would require too much time to offer the premises from which to make my deductions. We should keep in mind the fact that zinc is positive to practically all other metals, and that when we undertake to mix in the mouth different metals of which zinc is one, we are establishing an electric battery. Zinc is always positive, and it has a potential of voltage in proportion to the electro-positive relation to other metals of the series. If we had zinc and platinum in the formula suggested, we would have a very strong battery; when we use zinc with tin, we have a weak battery. When we use a comparatively high percentage of zinc in one cavity, and gold in another, we have an ordinary battery with a potential of one two-hundredths of a volt, and an amperage capacity according to the size of the filling that will by measurement run as high as one-twentieth of an ampère. When we put that amount of current through vital tissue—as is the case when we have gold on one side and zinc on the other and they are in a united electrical circuit through the dentin of that tooth and through the tissues carrying blood—immediately there will be irritation of the pulp, which has many times to do with the deposit of secondary dentin and the ultimate destruction of the pulp, with a reflex irritation without a local irritation.

Dr. Daniels. I would like to ask if the saliva, after the filling is inserted, interferes with the union of the mercury and the metals?

Dr. Ward (closing the discussion). I will discuss the last question first. Generally, it is considered that moisture makes no difference, and I think that if the mass of amalgam is not chopped up badly, this is very nearly true. We cannot dispute the fact, however, that saliva between particles of alloy acts as a foreign body, and prevents the intimate contact necessary for the best strength. If, however, the saliva is simply allowed to come in contact with the surface of a filling after it is inserted, I believe that any possible action between salts in the saliva and the amalgam will be limited to the surface of the filling. I think it is quite likely that if there were any action between the substances in the saliva and the amalgam, it would be greater while the amalgam was setting than after it had quite fully set.

Dr. Grieves and Dr. Price have each pointed out some objections to the use of zinc in the various ways in which it is being employed by dentists, Dr. Grieves placing special emphasis upon the difficulty in alloying zinc perfectly, and Dr. Price mentioning the electrolytical properties of this metal. Dr. McCauley and Dr. Bliss have each condemned the use of zinc, apparently upon the opinion of Dr. Black that it does not alloy perfectly, and Mr. Atkinson seems to have condemned it because it did not alloy perfectly and because it did not work in well with his hypothetical alloy Ag_2SnCu. I am willing to admit that many of these arguments would hold true if we were considering zinc alone; but why treat zinc as an individual metal, when we are discussing alloys, any more than we would silver? We can point out some objections to silver if we desire to do so, but no one seems to think that there are any reasons why it is not desirable. The same may be said of copper, and of tin. It is true that we may expect the behavior of zinc alone to be imparted to the alloys of which it is a part, but we must consider it in the ratio of approximately 2 parts of zinc to 198 of the other metals, and the question at once arises, Is zinc one of the controlling metals in such a minute quantity? In view of the evidence, we must answer, No. It is a modifier of a well-balanced alloy, imparting to it what appears to be its tendency unalloyed to form light-colored salts—when it forms salts at all—and to improve the consistence of the amalgam mass while combining the alloy and mercury. These modifications must likewise be considered in approximately the above-mentioned ratio.

Dr. Grieves says that he is under the impression that I favor the use of zinc in alloys. I want to modify that statement a little by saying that I am not ready to condemn it until we have more evidence that it is detrimental to our alloys. We seem to agree that the use of zinc in as small quantities as now employed, 2 per cent., facilitates amalgamation, the result being long expansions. We also seem to agree that the use of zinc in the quantities mentioned results in a better-colored filling, in most mouths, after it has been in for several years. I believe that most of those who condemn zinc will admit that it will take at least five years for a properly manipulated filling to have its usefulness destroyed by the expansion which they attribute to zinc. The question. then, for us to consider before condemning zinc, is, Which of these properties is of most value? My personal opinion is that the profession has reached a point where it will no longer tolerate black fillings in most of the places where they are required to insert plastics, even though they know that the black ones remain longer useful. Those who are now unconditionally condemning the use of zinc seemed to give the impression that the present methods of handling the metal were in a state of perfection, and that nothing more was to be expected in this phase of the work, but with this I cannot agree.

The real objection to the use of zinc in alloys for amalgam is that those alloys containing it seem to expand more than most of those without it, and my attitude is to control these expansions by more intelligent manipulation—if the manufacturers are unable to control them in the manufacture of the alloy—and by so doing avoid taking a step backward to the alloys of forty or fifty years ago, many of which were as black as coal in some mouths.

The latter part of my paper has to do with a problem which the profession has been confronting several times—viz, Are alloys made by combining the constituents in atomic ratios more desirable than those made otherwise? I think the paper is evidence enough that there is little basis for the assumption that they are.

In closing, I will say that I think there is no mistaking my position regarding the publication of results that are detrimental to our very best manufacturers.

Section I then adjourned until a later session.

(To be continued.)

REPORT OF THE N. D. A. COMMITTEE ON ARMY AND NAVY DENTAL LEGISLATION.

To the Officers and Members of the National Dental Association:

Your committee has the pleasure of again reporting more advanced legislation. We were fortunate in having the Naval Appropriation Bill amended in 1913 as in 1912, though the conditions were unfavorable in both instances. The chief features of the dental amendment of 1913 are—

(1) The creation of a Dental Reserve Corps, which was sought in 1912 and desired for many years, which shall differ in no respect from the Medical Reserve Corps, except that the qualification clause shall be extended to include D.D.S.

(2) A provision whereby the dental reserve corps may be utilized as a provisional corps of more experienced men while awaiting the selection of the best available young men for permanent service in the regular corps.

(3) A provision which prescribes that no dental surgeon shall render service, except temporary service, until his nomination shall have been confirmed by the Senate.

(4) That dental corps appointments of permanent tenure shall be made from the membership of the dental reserve corps as in the case of medical corps appointments from the medical reserve corps;—this includes a term of preparation at the Naval Medical School in Washington.

These features should be regarded as of exceeding importance, more especially as the administration of the law of 1912 might easily result in the selection of men by methods so questionable as to prohibit the idea of impartial sympathies and a kindly disposition to cooperate with the dental profession in its efforts to obtain the most worthy of its better-educated young graduates to represent it in the naval service. Announcements of impartial competitive examinations through the dental journals and the dental colleges and societies would reassure the profession of its opportunity to show its vital interests and its friendly disposition toward the object of securing to the service those best equipped by education and high professional character to meet the dental needs of the navy *personnel* and the economic interests of the government.

Another and material advantage intended by Congress to be more certainly accomplished by the new law than the law of 1912, namely, the emphasis it gives to the method of compelling the scrutiny of the Secretary before appointing, and of the Senate before confirming, will doubtless give the profession a proper and highly useful influence in regard to the passing on the qualifications so essential to the welfare of the profession as well as to the further advancement of the status of the dental service. In any event, these means and opportunities of scrutinizing the fitness of appointees must be recognized as wholesome and proper precautions, as against methods of unrestrained and practically non-competitive selection. Though these beneficial results may not be as quickly realized as may be desired by those who view the interests and ambitions of the profession as of easy attainment, there is no doubt that they will be realized in large measure and at an early date.

We fear there are but few who realize fully the immense importance of the recent army and navy dental legislation to the status of dentistry as a profession among the professions represented in the military and naval services, and we therefore offer for your information and fuller appreciation the following analysis of the effect of the previous non-recognition and the present legal recognition of dentistry.

Before the enactment of any army and navy dental laws was secured by your committees, the situation was simply as if the words "dentistry," "dental profession," and "dental surgeon" had no significance. Having no recognition in law, the dental surgeon in the military service could have no professional rights under the law. In the few individual and unauthorized cases of the assignment of men to do military dental service, the graduates in dentistry of our great universities and the enlisted man in the navy stood on equal social and professional footing, not merely in theory but in law and in fact, as was demonstrated by actual experience in particular cases. They had no right to their civil title or benefit of their college degree, nor to a position indicative of their function, nor to any degree or equality with "an officer and a gentleman," from whose social position theirs differed as widely as does that of the non-English-speaking laborer from that of the manufacturer who employs him, or as that of the valet from his employer. These are not exaggerations, but easily demonstrable illustrations of the condition that prevailed—surely a reflection on the civil status of dentistry!

What of the present—and, for that matter, of the future—of dentistry in its relation to the other professions in the naval service? Under the recent act of Congress, passed in pursuance and in consequence of fair hearings on the real issue, namely, the recognition of dentistry as a profession on a social and educational basis with other professions, the United States government is committed to the official recognition of dentistry. Therefore it is provided by law that the navy dental surgeon "shall take rank and precedence in the same manner and in all respects as in the case of appointees to the medical corps," and shall have "the same pay and allowances as officers of corresponding rank and length of service in the medical corps," and shall be entitled to retirement "in the same manner and under the same conditions as medical officers." They are also eligible, under the provisions of the law of 1912, to membership in the medical reserve corps of the navy, and additionally, to constitute a dental reserve corps under act signed by the President March 4, 1913, which creates a dental reserve corps differing in no respect from the medical reserve corps, except that the qualifying degree is extended to include that of Doctor of Dental Surgery.

Could any act of Congress be so phrased as to more forcibly and impressively carry the government's stamp of approval of dentistry, and more emphatically remove the stigma attached to it previously? or could any single act of the government more definitely or forcibly acknowledge the value of the educational course of the dental schools of America, or more gracefully acknowledge the importance of the function of the dental surgeon, than has been done by the recent acts of Congress?

There is now authorized the expenditure of about $500,000 per annum to meet the dental requirements of the army and navy, with an automatic proportional increase as the army and navy *personnel* is increased.

We are not to rest on the advantages gained. There must be promotions of dental officers in both the army and the navy, and we are confident that we are justified in assuring you that our work has made this next step probable at an early date.

In conclusion, we desire to inform the association that on April 23, 1913, the President of the United States appointed and the United States Senate confirmed the following gentlemen: Dr. Wms. Donnally, Dr. V. E. Turner, and Dr. G. E. Küsel to commissions in the navy dental reserve corps, and we offer the following resolution as part of our report:

RESOLVED, That the National Dental Association in convention assembled at Kansas City, Missouri, July 8 to 11, 1913, directs the secretary, under the seal of the association, to express our appreciation of President Woodrow Wilson's recognition of our profession by his recent appointments to commissions in the United States Navy dental reserve corps.

Respectfully submitted,

WM. CRENSHAW, *Chairman*,
CHAS. W. RODGERS,
WM. H. DEFORD,
Committee.

Subsequent to the reading of the report the following resolutions were adopted:

RESOLVED, That the National Dental Association, in annual session assembled at Kansas City, Mo., July 8 to 11, 1913, hereby expresses approval of the appointments made April 23, 1913, by President Woodrow Wilson, by and with the advice and consent of the Senate, of Dr. Wms. Donnally, Dr. Vignes E. Turner, and Dr. Geo. C. Küsel to membership in the dental reserve corps of the navy, and to acknowledge the recognition of the dental profession thereby implied.

RESOLVED, That the National Dental Association, in annual session assembled at Kansas City, Mo., July 8 to 11, 1913, hereby approves the provisions of the act of March 4, 1913, creating a Navy Dental Reserve Corps of dental surgeons who shall be appointed by the President and confirmed by the Senate, and hereby commends co-operation of the dental profession with the Navy department in an effort to attract to the navy dental service those best equipped and most suitably qualified to meet the needs of said service.

RESOLVED FURTHER, That this resolution be forwarded to the Hon. the Secretary of the Navy, Washington, D. C.

Also, at the meeting of the Southern Branch of the National Dental Association at Old Point Comfort, on July 22, 1913, the following resolutions were passed:

RESOLVED, That the Southern Branch of the National Dental Association, representing the state societies of Alabama, Arkansas, Florida, Georgia, Kentucky, Louisiana, Maryland, Mississippi, Missouri, North Carolina, South Carolina, Tennessee, Texas, Virginia, and West Virginia, and assembled July 22, 1913, at Old Point Comfort, Va., in annual session, hereby strongly approves the Dental Reserve Corps Act of March 4, 1913, because said act provides that all appointments shall be made by the President and confirmed by the Senate; and further authorizes the Secretary of the Navy to order the members of the said reserve corps to temporary active service, thus providing a ready means of meeting the dental needs of the *personnel* of the navy and marine corps with the service of men of the required skill and experience while developing a regular dental corps from men whose age at entrance precludes their having the required skill and experience; and be it further

RESOLVED, That this resolution be forwarded to Secretary Daniels, under the seal of the Southern Branch, and with the assurance that the profession of the several states represented will, if permitted, gladly co-operate with the Navy department in all efforts to attract to the navy dental service the best-equipped and most suitably qualified dental surgeons available through co-operative effort and a patriotic pride and interest in the welfare of the navy.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

Forty-fifth Annual Meeting.

(Continued from page 1042.)

FIRST DAY—*Evening Session.*

The Thursday evening session was called to order at 8.30 o'clock by the vice-president, Dr. W. W. Smith.

Dr. H. J. BURKHART, chairman of the Business Committee, reported the program for Friday.

The first item on the program for the evening session was the reading of a paper by Dr. T. B. HARTZELL, Minneapolis, Minn., entitled "The Operative and Post-operative Treatment of Pyorrhea."

[This paper is printed in full at page 1094 of the present issue of the COSMOS.]

Discussion.

Dr. R. H. HOFHEINZ, Rochester. To discuss pyorrhea alveolaris from any standpoint seems almost hopeless. I am more and more convinced that, whenever one has to vent an opinion on the writings of others, unless this be done with a certain one-sided enthusiasm or with a loving interest in the writer and the work, the result is hardly worth while. The most difficult task is presented to the debater when he is asked to discuss not only a paper or essay, but an elaborate lecture such as has been presented to us by Dr. Hartzell.

In reading some of the writings of Dr. Hartzell on this subject, I find that he is of the opinion that the pathology of the jaws and teeth have received little consideration. In this statement I differ with him; there is possibly no dental subject which has received more intelligent attention than the pathology of the jaws and teeth. The dental profession has never received a greater compliment than that which was paid to it by one of the famous Mayo brothers, who, at Chicago, read a paper on pyorrhea in its relation to systemic diseases. The indefatigable work of such men as our essayist, Dr. Rhein, and others, has compelled the medical world to recognize the importance of dental lesions in relation to general disease.

Dr. Hartzell laid great stress on the eradication of infection by not producing or at least not increasing raw surfaces, and thus establishing an abnormal condition. This is a cardinal point. It is a rather difficult question to establish what we call normality. Normality, after all, can only refer to a group, and not to the entire race. What may be normal in one mouth is abnormal in another. Look at the mouth of dogs after biting bones—a process which must leave raw surfaces of the gums, and yet infection does not necessarily follow. The tooth-brush, for instance, is neither a provision nor a product of nature, and its use renders oral conditions supernormal. What state would mouths be in, however, without its use? We are paying the price for our higher state of civilization and higher living.

The very bacteria which Dr. Hartzell has found in pyorrheal pockets are, according to Miller, frequently present in the normal oral cavity. In his famous book, "Micro-organisms of the Human Mouth," he says that, in the course of a few years hundreds of kinds of bacteria would become established in the mouth if the majority of them did not perish, sooner or later, in the struggle for existence. To what extent bacteria are a cause or result of pyorrhea still remains a question. Pathogenic organisms are remarkably well taken care of at the extremities of the alimentary canal. If it were not for these compensating agencies we would all be dead long ago.

At the beginning of this paper, the essayist says that operative treatment of pyorrhea was firmly established, but no crystallized method of practice had yet been in use. The treatment of pyorrhea seems more or less a dental specialty. I listened to a suffragette's speech a few evenings ago; she said that she disliked nothing more than a wabbling woman. I say the same of a practitioner, and above all of a teacher. During the years of my teaching I occasionally found it better to fit a case to the argument than to allow an assertion to stand on weak legs.

The essayist tells us that one of the most important essentials in surgery is to have a clear conception of the underlying philosophy. It seems to me less a question of philosophy than of science, and in this particular instance, of technique.

Pickerill, as Dr. Hartzell mentions, has convinced us that normal enamel is not smooth. The previous studies of Leon Williams, and I believe of Black, have shown us that smoothness of the enamel is not a normal condition. Its corrugated surface is a product of growth. Growth is an interrupted process, one of the best examples of which is the clam.

The essayist speaks of skinning the root, but skinning the enamel is another question. In the former instance we take off diseased tissue, but in the case of enamel we remove healthy tissue. Though it may be easier to keep off deposits and bacterial plaques from a smooth enamel surface in case of disease, rugged enamel is but an incident and not a cause. Corrugated enamel surfaces are normal in health, though they may become abnormal in pyorrhea. Both before and after treatment the interproximal space and gingival line will always remain the hotbed for bacterial accumulation. The starting-point of the *disease*—meaning the real change from a physiological to a pathological condition—remains the peridental membrane.

Many years ago I quoted a case of replantation in pyorrhea. Though this disease had affected practically every other tooth within a short time, the replanted tooth remained sound until the natural causes of absorption expelled it from the human economy.

I strongly agree with Dr. Hartzell in condemning the application of pumice in pyorrhea pockets. If used, however, it should be followed by an injection of hydrogen dioxid, or, what I consider still better, a ten per cent. solution of lactic acid and a saturated solution of sodium bicarbonate.

The absence of leucocytes in the pericementum is mentioned by the essayist as a factor that greatly favors bacterial proliferation. I beg to advance one step farther. We may find leucocytes in the cementum where the vessels are large enough to carry them, and that is particularly the case at the tip of the root. Death and destruction of the pericementum, therefore, means absence of leucocytes in the cementum. Skinning of the root is certainly a very original expression, which the pyorrhea specialist should not forget.

There are very few dental practitioners who can make a correct digital diagnosis. Fingers that work with rubber files and inlay casting apparatus are not the ones to detect and determine the different stages which Dr. Hartzell enumerates. A special digital education is necessary. This reminds me of what Oliver W. Holmes told a mother when she asked him at what time a child's education should begin: "One hundred and fifty years before it is born."

It is an acknowledged fact that the most skilful workman uses the finest instruments. Whether this can be applied to the operative treatment of roots, I doubt very much. Every unnecessary injury to the tissues is in itself an aggravation, and may lead to exacerbated pathologic conditions. Though the former doctrine of the periosteum being necessary for bone formation has been exploded, as we have been told, the periosteum still remains a medium for vascular supply. It is, therefore, very essential that the operator be well prepared with the proper instruments and have the fitting touch.

I am in almost full accord with the essayist's remarks regarding the technique of skinning the root. I also agree with him that it is unwise to disturb all teeth at the same sitting, thus crippling the entire denture. It is much like the tumor which the late Dr. Morton was asked to remove from a negro's neck. He said, "I could have taken it out at one time, but there would have been no negro left."

Vaccines seem to be still too much in the experimental stage to be accepted as a sure means of cure. If ever they prove so, I sincerely hope our colleague will sell for less than our beloved German friend, Friedmann, sold his turtle product.

I need not dwell on the splintering of loose teeth; it seems too natural. Any serviceable, even if crippled, organ should be retained. A club-foot is better than a wooden leg, a loose tooth is better than none.

Dr. Hartzell says in his paper, "Teeth often are very loose although they have ample bone to hold them. After the operation of root-skinning is successfully accomplished, this type of tooth regains its rigidity in a marked degree in from twenty-four to forty-eight hours." I have seen quite a number of such teeth regain their rigidity even without root-skinning. This class of pyorrhea is more frequently associated with constitutional causes than any other. This, however, might lead us to an endless discussion. Though the essayist did not dwell on this subject with great emphasis, he has in his previous writings expressed himself very clearly. In one of his papers he says: "I restrict the constitutional causes (1) to excessive use of mercury in syphilis, (2) to lead poisoning, (3) to a large and persistent increase of urea in the daily production of urine." I somewhat disagree with this statement of my learned friend. In the first two instances we have specific pyorrhea; the third phenomenon enumerated makes its appearance frequently in connection with rheumatism, gout, etc. I believe that any faulty metabolism, any disease that lowers the tonicity of the system, will in time act on the delicately constructed peridental membrane, and thus predispose to pyorrhea. Long ago I accepted and I still adhere to the view of Miller and others that three factors are always to be considered (1) predisposition, (2) local irritation, (3) bacteria. As a predisposing cause we must consider any disease that reduces the resistance of the tissues involved in pyorrhea, some acting with greater virulence than others.

Miller mentions one in which, three weeks after the teeth had begun to loosen, all upper incisors were hopelessly lost. He mentions no special cause, but the disease certainly was not of local origin.

A patient of mine presented himself some four weeks ago with all of his anterior teeth alarmingly loose, with plenty of bone surrounding them. "What is your internal trouble?" was my first question. "Eight per cent. of sugar." "Eliminate the sugar, and in two weeks we will start the local treatment." At the appointed time, though the local condition was not perfect, I found the teeth normally tight. "How much sugar?" I inquired. "Not any;—but do you know what tightened my teeth? Alcohol did it; my sister's dentist recommended it." Sweet innocence! I felt a tendency toward anger, but instead thought of Carlyle, to whom someone brought the news that Margaret Fuller had agreed to accept the Universe. Carlyle's only comment was, " 'Gad, she'd better."

Such papers as we have listened to induce us to regard pyorrhea as a curable disease. And, though there are instances where all scaling may prove futile, almost all cases can be bettered if treated in such a scientifically skilful manner as Dr. Hartzell recommended to us today.

Dr. W. S. LEWIS, Brooklyn. It is a cause of great satisfaction to me that I have been permitted to meet Dr. Hartzell, to hear him read his paper, and to take part in this discussion. I have read other writings of Dr. Hartzell's on this subject, but, in the paper under discussion he has given us in riper form the best of all his other writings—has given us what may be styled an "up-to-the-minute" paper on this subject. This paper could not have been written a decade ago, and it bears witness to the great advance that has been made in dental science, and especially in the treatment of pyorrhea alveolaris, during the last few years.

Most papers dealing with this subject have been to me more or less unsatisfactory in that they were written, in a greater or lesser degree, in general terms, and discussed different hypotheses at length, but have not, like our essayist's paper, suggested a definite and crystallized mode of treatment, nor explained, like the essayist, step by step a perfected and finished technique.

In our profession there is today a vast difference of opinion on the subject of the treatment of pyorrhea. There are still those—and their number is not small—who hold that very little, if anything, can be done to ameliorate this condition. There are others who hold the belief that a cure can be effected. There are those who operate with one or two pet instruments, and claim that, with these, all the scaling possible can be done. There are others who insist that the scaling shall be done with a pushing motion, and that the root surface should afterward be smoothed with files, if necessary. There are those who treat almost entirely with vaccines, and others who pin their faith on some particular dentifrice, mouth-wash, or other form of medication.

I can discuss this paper not from the standpoint of the specialist in pyorrhea alveolaris, but from the angle of view of a general practitioner of dentistry who has taken a deep interest in the subject, and who for years was groping in the dark and trying to find the light. As such, Dr. Hartzell's paper specially appeals to me, as he suggests a definite mode of treatment which, if mastered and followed faithfully, will enable us to give great aid and comfort to patients suffering from pyorrhea.

I am heartily in accord with most of the essayist's statements. I became a convert to the idea of planing the root-surface, as advocated by Drs. Hartzell, James, Buckley, Carr, Tracy, and others, several years ago, and although I know many skilful operators who use other methods and produce beautiful results, I found that for my purpose the system of planes was what I had been looking for, and that with them I could attain to results that had been before out of my reach.

I am much impressed with our essayist's method of treating the crowns of the teeth first; this has not been my usual technique, but Dr. Hartzell's logic seems good. It is undoubtedly true that roughened enamel margins and etched enamel surfaces, with their adhering bacterial growths, keep the gingivæ in a state of inflammation, unless they are absolutely smoothed and polished.

In speaking of the structure of the cementum, our essayist contends that the outer roughened layer to which the ligament of suspension is attached must be planed away. This is a most important feature, and can, I believe, be accomplished with more certainty by the use of planes than by any form of scalers or files. Once the pericemental fibers are separated from their cemental attachment by acute inflammation, they become necrotic and must be removed absolutely. We must not hope that upon the removal of deposits the pericementum will re-attach itself to the cemental surface, for the teaching of Black and others has shown that this cannot take place. Our aim, therefore, should be to remove all pathologic tissue, and if this be done the space will be filled in with new osseous and connective tissue. In all cases where there has not been too much loss of tissue before operating, the tooth thus treated will be held firmly in position once more.

Hypersensitiveness of teeth after operating is one annoying feature which appears after some months. I believe that over-instrumentation is the chief cause of this condition. Silver nitrate is very efficacious in the treatment of this condition, but it is open to the serious objection that it stains the root surface. I have found that from 50 to 100 per cent. zinc chlorid, also 50 per cent. formalin, will control a large percentage of the hypersensitiveness met with. These medicaments should be applied and vigorously burnished into the root surface, the warm-air blast being applied at the same time and the burnishers warmed somewhat.

I have not met with any great degree of success in attempting to seal the pocket after operating, but it has been my habit to fill all deep pockets with bismuth paste. I realize, however, the desirability of the procedure suggested, and, as our essayist tells us that it can be done successfully, I will try again.

In the after-treatment of the soft tissues I do not believe in any long-continued medication, having found that only for a time will such treatment restore the tonicity of the tissues; that if it be continued they fail to react to it, and in fact lose tone. Proper massage of the gums with suitable brushes—the patient to be impressed with the necessity of brushing the gums rather than the teeth—will do more to sustain the tone of the tissues than gallons of medicaments.

The problem of establishing immunity to bacterial growth is the greatest of all the problems which confront the dental profession today. Pickerill's careful investigations have brought to light many interesting facts, and his deductions deserve the most careful consideration. The hypotheses which he presents and the methods of treatment which he advocates have not been before the profession for a long enough time, nor have they been given enough publicity as yet for us to pass judgment on them, but to me his investigations are especially interesting in that they seem to link together immunity to bacterial growth in the mouth, immunity to caries, and immunity to the deposition of calculus. If Pickerill is correct, we shall by further research be able to control all these factors to a greater or lesser degree.

In closing I wish to impress on you that the essayist has given us a crystallized, practical method of treatment, which he has carefully explained step by step, and which he will elucidate still further by his clinic. From what I hear, Dr. Hartzell is successful in his work—he obtains results, and his description of his technique should be an incentive to us to go and do likewise.

Dr. F. W. Low, Buffalo. After a very pleasant visit to Dr. Black in Chicago last winter, I have come to believe that for the majority of patients we might add to the treatment, and put them on half rations. Dr. Black demonstrated to my satisfaction that in his own case, in regard to the particular diet which he used for a number of weeks, it did not make so much difference what he ate, as the amount. He proved that the deposits and re-deposits were always excessive unless his regular diet was reduced in quantity to about one-half.

Dr. H. T. Stewart, New Orleans, La. I would not have spoken tonight at all except for the fact that this admirable paper is upon a subject in which I have been particularly interested for the whole of my professional life—the last twelve years having been practically devoted to it. I wish to thank Dr. Hartzell for his paper, and to say that I wish we had in the profession in the United States one hundred men who would give their time to this work and do it as earnestly as he has done it.

A serious drawback, perhaps, in the advancement of this particular work is the disposition to criticize little details, instead of dwelling on the good work a man has done. While there are one or two items in the paper to which I would like to refer, I do not disagree with him, but simply differ with him.

As to the set of instruments which he has designed for this special work, especially for planing the root surfaces, I believe I have the honor of having presented this idea to the profession before anyone else. Fourteen years ago, in New York City, I read a paper before the Odontological Society in which I advocated the removal of the external layer of the cementum in the treatment of Riggs' disease, in a paper entitled, as I remember it, "Partial Removal and Decalcification of the External Layer of the Cementum."

Dr. Hartzell mentioned one point on which I would like to lay special stress, and that was as to curetting the margins of the bone. This curetment is often overdone. I simply wish to call attention to that point.

As to the closing of the pocket, you know that whatever be the method we employ, if we have success—whether our success is on account of the method or in spite of it—we are inclined to think, That is *the* method! Years ago I endeavored to close pockets after operating. My father, who was also a dentist, used for that purpose an almost saturated solution of tannic acid in glycerin, and later on a syrupy solution of tannin in tincture of iodin. I have tried a good many preparations, among them one advocated by Dr. Kirk, and I got results just as I got results in the treatment fourteen years ago by purely local measures. At that time I contended that the disease was a purely local one. I also said that all removable appliances of every description should be wholly condemned. On both of these questions I have changed my mind entirely. I find that I get better results in the end by not closing the pockets and leaving nature to herself.

As to the question of acids: Years ago in my own malarial district I noticed that people who were in the habit of taking, especially in the spring and summer, large quantities of lemon-juice in water, and those who lived largely on fruit, had a better condition of the mouth than others who did not. This was contrary to my teachings and ideas, but facts are stubborn things, and several years ago I began to prescribe, in certain conditions, lemon-juice in water as a mouth-wash, and I have never had occasion to regret it.

As to the instruments used by the essayist, Dr. Hartzell has certainly devised a beautiful and doubtless very useful set of instruments, but for my own part, my individual skill was developed along certain lines before those instruments were devised, and I believe I can produce better results with my own comparatively few instruments. I employ probably only eight or nine to do at least seventy-five per cent. of my operating, although I have many instruments for particular operations and for certain locations. Dr. Hartzell probably could not do so well with mine, and I could not do so well with his.

I have a word to say as to splints. This was brought to my mind by one of the pictures shown. I believe that a splint should nearly always be removable, and in the clinic I will give tomorrow I intend to show both fixed and removable splints, and why each individual tooth should at some time have individual motion, and therefore that our bridge work should be constructed with that idea in view, and so that when the piece is removed for brushing the teeth, each tooth can have individual motion. Of course the bridge acts as a splint while in place, but, in removing it, brushing gives to each tooth a slight exercise and movement in all directions in its socket.

Dr. M. L. Rhein, New York. I would like very much to emphasize the point in Dr. Hartzell's paper with regard to the need of a pathological sense in dentistry. The great difficulty in discussing such subjects before a dental meeting is the impossibility of having the major portion of your audience appreciate the pathological conditions you are trying to elucidate.

We have listened to a magnificent,

detailed, up-to-date technique in the treatment of pyorrhea, but I do not care to go into this phase of the paper because I am in most hearty accord with the essayist. I would like, however, to refer to a point in Dr. Stewart's discussion of the paper. Dr. Stewart said that he formerly advocated fixed splints, but that now he was entirely opposed to any form of splint except a removable one.

Dr. Stewart. My statement was not so positive as that. I did not mean that under no circumstances should we use fixed splints, but I meant that on general principles we should not.

Dr. Rhein. If that is the case I agree very heartily with Dr. Stewart, because I believe there are cases where there is an insufficient amount of alveolus left to make a removable fixture practicable, and in many of those cases the usefulness and health of these teeth cannot be restored unless absolute fixaation be resorted to. Recognizing the fact that such cases do exist, then I most heartily agree with the view presented both by the essayist and by Dr. Stewart, that not only is the fixed bridge to be avoided as a rule, but that fixed bridges are one of the most frequent sources of trouble with which we have to contend in pyorrhetic conditions.

When we analyze this subject thoroughly we cannot fail to be impressed by the fact that there are two factors lacking in the present-day dental curriculum, making this subject such a difficult one for the dental practitioner. The most important is the lack of instruction in diagnosis in the dental school—in every dental school, more or less; and it is impossible to correct this unless the entire curriculum is changed, because it is impossible to teach diagnosis when the teaching of pathology is confined to a portion of the body. Until the time arrives when the dental student is as familiar with every part of the body as he is with the parts in which he is being instructed, it will be impossible to convey to him the diagnostic sense which is so essential in order to handle this subject intelligently. Treatment cannot be properly pursued until an accurate diagnosis is made, consequently the lack of a diagnostic sense is so closely related to the lack of a pathological sense that they cannot be separated, and that is the one reason, from my point of view, why the subject remains the complex one to the average dental practitioner that it does today.

Dr. L. M. Waugh, Buffalo. I shall not attempt to discuss the paper, but wish to refer to one or two items mentioned by the two previous speakers—that is, that we are not teaching pathology. The Institute of Dental Pedagogics realizes that the branch in the dental curriculum which needs the most attention at the present time is not that of technique, but that which has to do with function and health; so that this subject of pathology is one to which dental teachers are more awake and to which they are devoting more energy than almost any other subject. They feel that the technical branches are pretty well developed, and I believe that pathology is now coming into its own, and that our students will be given a better grounding in pathology than heretofore.

Dr. R. Ottolengui, New York. I would like to ask Dr. Stewart one question. He spoke about splints, and the desirability as a general principle that they should be removable. I think I am not far from the truth when I say that some of the most difficult cases we have to deal with are those in which the lower incisors are involved, and I have been wondering, since Dr. Stewart spoke, how a removable splint could be applied to that particular part of the mouth. If the principle is right it seems to me that it should be applicable there, and while I have never heard of it, such splints may have been made in such cases. I would like to ask Dr. Stewart if he would make a removable splint for the four anterior teeth.

Dr. Stewart. Dr. Ottolengui seems to have assumed that I *must* splint these lower incisors. In the first place I wish to say that I think ninety-nine out of one hundred men who treat Riggs' disease attempt to save too many teeth, and that is especially true with regard to the lower incisors. When we first start out we are inclined to try to save every tooth that has any sort of attachment. We are greatly tempted to do so, especially as we know that is what the patient wants, and it is particularly embarrassing to the specialist to say that he must extract this or that tooth. The patient immediately says, "Dr. So-and-so could extract the tooth; I came to you to have it saved." That is what we meet with constantly, but the more I treat this trouble the more I come to extract teeth—those which are worse than useless, and especially lower incisors. Suppose we heal the tissue around the teeth and get what appears to be a healthy condition, and still have one tooth there which is acting as a foreign substance fastened in with a fixed splint—what does it do? It will set up inflammation which spreads to the adjoining teeth and sooner or later will give trouble.

I do not believe that splints should be put in in the majority of the cases where they are now used. I have been in the habit, where a splint is necessary, of putting tubes in inlays, when found possible to do so, in the incisors. It is a tedious piece of work, and difficult from an artistic and hygienic point of view, but usually this can be done so that the splint will be removable. I do not mean that we should *never* put in a fixed appliance; sometimes it may be necessary and advisable, but there are very few cases where the removable appliance cannot be made. Where you have two teeth standing together and you think they should be braced, you can insert two inlays—put an inlay in an inlay with tube and split pin—and still make a removable piece which the patient can cleanse, which will give the teeth individual motion, and will permit of the use of silk between them.

After all, it is a matter of common sense and good judgment in each individual case that is required to make a man successful in treating this disease, and he who adheres blindly to any method or appliance must certainly fail of the best results.

Dr. Hartzell (closing the discussion). You have indeed dealt very kindly with me, and I really should not take any more of your time, but I cannot allow Dr. Stewart's remarks to go without some little comment.

Regarding the use of acids, you will recall that I tried to make the point that immediately following the scaling of the root surfaces acids increase sensitiveness, but aside from that I am in accord with his ideas. I recommend orange-juice and water before breakfast, and of dietetic measures I think that is one of the best that we can employ.

Regarding instruments, I would say, By all means use the one with which you can produce the best results. I insist on no special set of instruments; I only attempted to crystallize a method. Why? Because so many men operate without any particular method, and if you can give them one with which they can intelligently carry out the ideas they have grasped, then they are that much ahead. In teaching we must have some method or system, and the more simple the system is the more readily you can impart your ideas. So far as being wedded to any style of instrument, I would say, Use that with which you can best accomplish the object that you are endeavoring to bring about. I would only offer this suggestion in comparing the multiple with the single-bladed instruments: If you are going to use the multiple-bladed instruments they should be dull, because you cannot realize what you are doing with the multiple blade, and you can with the sharp single-bladed instrument. You can readily train yourself to discriminate between a variety of substances with the single blade, and I do not think this is true with the multiple-bladed instrument.

One other point I would like to comment upon. Dr. Hofheinz seems to have received the idea that I did not think there has been a great deal of pathological research done by the dental profession. What I had in mind in this regard was that the courses in dental colleges in this country are trivial, and I am prepared to back up that statement. Talk of "dental pathology"—there is no such thing as dental pathology; there is just pathology, and the man who does not recognize that, in its truest sense, is not fit to be in dentistry, because dentistry today is on the threshold of a great era which can be utilized for its uplifting, and, unless benefited by teaching, the dentist cannot but stay in the ranks of the artizan. There are individuals practicing dentistry who have given great thought to pathology, but as a profession, are we laying the proper pathological foundation in the colleges? I believe all present will agree that we are not. I hope, however, that this great state of New York—which, as we have been told today, is the leader in dental thought and knowledge—will work out in the field of pathology that which the case really demands, teaching pathology of the whole body, not of the jaws and teeth—because the man whose training has not included general pathology, in attempting to diagnose cases is almost as much at sea as though he has had no pathology. That, I think should be nailed down good and hard, and these centers of dental thought, which so much influence the rest of creation, should be willing to expend their energy in the direction in which it will do the most good.

A MEMBER. Dr. Hofheinz asked a question with regard to bifluorid of ammonium.

Dr. HARTZELL. If you do not care to use surgery on the roots, and wish to decalcify materials on the root surfaces, I think bifluorid of ammonium will do it if you keep it there long enough.

The Secretary then read the minutes of the previous sessions, which were approved as read.

Motion was then made and carried to adjourn until the Friday morning session.

SECOND DAY—*Afternoon Session.*

The meeting was called to order Friday afternoon, at 2.30 o'clock, by the president, Dr. Baylis.

The first order of business for the afternoon session was the report of the Committee on Practice, by the chairman, Dr. W. D. TRACY, New York, as follows:

Report of the Committee on Practice.

During the past year very little has been written on the side of scientific investigation. It is therefore extremely difficult, and along some lines impossible, to get together enough subject matter to bring to the attention of this honorable body. It seems to the writer that in many instances such a repetition is a waste of valuable time which could be better devoted to other things.

The Committee on Scientific Research gives to us all that is new, and this in itself would seem sufficient for our needs.

PYORRHEA ALVEOLARIS.

Much has been written in regard to the etiology and treatment of this disease. Latterly a great deal has been accomplished in the amelioration of its destructive influences. Most of us are prepared to admit that it is a local manifestation of a constitutional disorder. From clinical experience it would seem that, in order to accomplish permanent relief for any considerable interval of time, each case should come under treatment in the incipient stage, as the loss of the gum tissue in the interproximal spaces and the surrounding bony support of the teeth are serious conditions to combat. As this is quite impossible to regulate, the disease is seen in all its destructive stages. Attention has therefore been called to the constitutional treatment as well as the local. In the gratification excited by the beneficial results obtained by the local treatment, it is possible for us to forget the constitutional. The features of treatment are—

(1) Constitutional: The correction of the eliminative processes of the body.

(2) Local: *a*, Raising the resistance of the parts involved against bacteriological invasion. This includes strict

hygiene and prophylactic measures, followed by the vaccine treatment. *b*, Removal of all deposits from the surfaces of the teeth. *c*, Correction of irregularities. *d*, Systematic prophylaxis. *e*, Stimulation of the cells by the Dunlop treatment. *f*, The use of splints.

The scaling process gives relief in proportion to the thoroughness of the technique, and is a very great contributing factor in the curing of the conditions.

The vaccine treatment is valuable in raising the resistance of the tissues against the susceptibility of the action of bacteria. It probably hastens a reaction of the parts more quickly. This condition could be brought about through proper diet, mouth hygiene, exercise, and plenty of fresh air.

The Dunlop treatment consists of forcing ethyl borate by means of oxygen gas into the tissues. It has a decidedly stimulating effect upon the mucous membrane and the contiguous parts.

Splinting has not received the attention which it should have done. It appears to be a valuable adjunct where the teeth have lost much of their bony attachment.

ANATOMIC OCCLUSION.

The face-bow is the keynote to anatomic occlusion. It enables the operator to transfer the wax bite plates to the articulator, so that when the plaster models are in place their planes bear the same relation to the articulator's joints that the alveolar planes bear to the temporo-mandibular articulation. This is the great scientific principle involved.

SYNTHETIC CEMENT.

Great progress has been made in the manufacture of this cement. One interesting point in the synthetic cement is that while the initial setting needs an acid reaction, yet this condition may be brought about by a very much smaller percentage of acid than is used in other mineral cements.

Further, that the reaction through simple hydration can, in a measure, take the place of an acid reaction. The reaction brought about by hydration does not permit of an excess of free acid after the cement has hardened. This renders the cement much less irritating to the pulp, and would therefore lessen the dangers of exciting the cells of the pulp tissue to activity.

PREVENTIVE TREATMENT.

Perhaps the most practical if not the most scientific treatment of the oral cavity is the hygienic treatment, as a barrier against disease. A discussion of any scientific subject in dentistry today deals with cleanliness as a basal principle of success. The outcome of the propaganda of oral hygiene is beyond computation. Its value as a preventive zone against bacteria invasion will be one of the greatest in dental disease.

CHEMICAL EROSION.

The attention of the investigators should be directed toward the treatment of this dental disorder. Its destructive influences are much harder to cope with than are those of dental caries.

THE SALIVA.

The writer has been unable to get any information in regard to the deduction which will be made from the recent investigation of saliva. What little has appeared during the past year is known to all and cannot well be elaborated upon here. The Committee on Scientific Research will no doubt give us something exceedingly interesting upon saliva at this meeting. It is hoped also that the tonsil will some day be thoroughly studied as a possible contributing cause of dental disease.

ORAL SEPSIS.

The literature relating to the field of oral sepsis, during the past year, has been abundant. Its being, its causes, its effects, its reduction and eradication, have all been comprehendingly and instructively written upon; in fact, the worth and brilliancy of some of the papers on this subject have placed them on the plane of the classics.

Not a little of the activity and excellence of the year's literary output has been inspired by the sting and pique of merited criticism passed over from members of the medical profession regarding the neglect, or carelessness, or incompetence apparent in many mouths which have been under the care of dental practitioners.

In answering these accusations the dental writers have taken an admirable stand, condemning visible malpractice and commending and pointing the way to honest, intelligent dentistry. That modern dentistry, of a certain sort, is responsible for many septicemic conditions, is not to be denied.

Even though badly neglected, the virgin mouth—that is, one which has not been raped by ill-fitting crowns and bridges whose septic roots rest in infected and necrotic surroundings—is not so dangerous a possession to its owner as the one acquired through malpractice.

The improper treatment of root-canals and its sequelæ of necrosis and suppuration, locking-in or walling-up lacunæ or cesspools of pus and infection in the alveolar process—later to be carried and distributed through the entire human body, to reinforce other pus foci in remote regions and bring about disturbing and perhaps fatal pathological changes—is to be strongly condemned.

Regarding more frequent and scenic manifestations of oral sepsis, there may be mentioned our old and constant companion, Riggs' disease—*aliases*, pyorrhea alveolaris, infectious alveolitis, and latest but not least, chronic alveolar osteomyelitis. Its etiology and cure are still the battle-ground of the "constitutionals" and "locals." When the author has the M.D. before the D.D.S., is erudite and of long experience in pathology, we shall find a great leaning toward the systemic causes and treatment; while the nimble-fingered, thoroughgoing dentist, through his complete, delicate, and patient instrumentation, finds a great percentage of his cases cured by wholly local means.

The year has abounded in excellent papers on the causes of this lesion, and treatment has covered all methods from vaccine therapy, intestinal cleansing, feeding, and Fletcherizing, to scalers, pumice, orange-wood sticks, and referring your patient to the other fellow.

The practitioners of vaccine therapy for the cure of pyorrhea are divided between the employment of autogenous and stock vaccines. As bacteriological examination of pus pockets will show many kinds of micro-organisms, while stock vaccines are pure, individual cultures, it would be necessary to have recourse to a multiple stock vaccine in order to neutralize and minimize the multiple germs found in the pockets. The autogenous vaccines are manifestly more efficient, for even identical germs obtained from other sources fail to give the beneficial results which those taken from the case in hand do. The care, competence, and experience necessary to prepare the autogenous virus does not obtain in many offices, and anything less than a perfect preparation is dangerous to use. Therefore, etc.

The recent treatment of pyorrheal cases by the injection of a vapor or gas under and into the free margin of the gum, and which passes into the weakened and diseased arterioles, revivifying the glandular and circulatory apparatus of the part, seems to offer one more efficient method of attacking these cases of oral sepsis.

The pendulum has swung so far to the left during the year, that septic conditions of the oral cavity have been accused, either as principal or accessory, of disturbing or unbalancing nearly every organ or function in the body, infecting everything on the way from alopecia to ingrowing nails. Oral septic conditions are held responsible for infections of the gall-bladder, for pathological changes in the heart and kidneys, and for disturbances in the functioning of the ductless glands.

To the swallowing of pathological organisms are attributed several cases of gastro-enteritis, and the daily migration through the intestinal tract of staphylococci, streptococci, pneumococci, *et al.*, from the oral cavity, causes the quiet little appendix to sit up, add -itis to its name, and send a C. Q. D. call for the surgeon.

The most insistent appeal running through the literature of oral sepsis, for the year, is for a broader and better pathological knowledge and sense, and its application to the case in hand. The call is for ability on the part of the general practitioner to correctly diagnose cases of suppuration, maxillary cysts, alveolar abscesses, perforated and infected antra, necrosis, osteomyelitis, epithelioma, and faucial lesions, and syphilitic and other secondary manifestations in their initial appearance in the mouth, referring cases beyond his jurisdiction to proper sources of relief, and seeing well to it that the oral work he undertakes and performs is thoroughly done.

OPERATIVE DENTISTRY.

The general trend of development in operative dentistry, as in other departments of the profession during the past year, seems to have been toward a bigger, broader, and more comprehensive view of the great possibilities of the work.

There are signs of an awakening on the part of the profession to a realization of the great importance of the restoration of occlusion. The study of the nutritional processes, and the relation that proper mastication and insalivation bear to their normal activity, has forced home the fact that prosthetic pieces and restorative operations on teeth *in situ* are practical failures unless proper occlusion is established.

It is not sufficient that the teeth should come together firmly. They must come together in a manner that will permit the normal mandibular movement that is necessary for the proper trituration of the food. In mutilated cases where elongation of certain teeth seems to have locked the bite and limited the freedom of mandibular movement, such teeth must receive radical treatment looking toward a proper adjustment, or else the bite must be opened and all occluding surfaces be built up.

The serious consideration of the problem of restoring occlusion is in no sense a new idea, but the fact that more is being said and written upon the subject today than ever before seems worthy of mention. And the fact that more men in the rank and file of dentistry today realize the importance of this feature of their work certainly gives promise of a higher standard in restorative operations on the natural teeth, as well as a higher standard of masticating efficiency in all prosthetic work.

Probably the most important factor in the recent development and improvement in the standard of restorative operations has been the perfection of a scientific system of casting gold with accuracy and precision, as brought before the profession in 1907 by Wm. H. Taggart. Considering the perfected process of gold-casting in the abstract, it is safe to say that no one thing in modern dentistry has done so much to stimulate dentists in their work, or to elevate the accepted standard of operative procedure, as has the gold-casting process. With the facilities now available to every dentist, the day of the ill-fitting, malshaped, nondescript plug of gold must soon pass. It must give way to the perfect-fitting, well-contoured gold inlay, in which the cusps and planes, the grooves and sulci, are present, and the natural anatomical lines of the tooth surfaces are reproduced.

If the masticating efficiency of a broken-down molar or bicuspid is to be restored to normal, the metallic or porcelain restoration must reproduce in detail the characteristic outlines of the occlusal surface of the tooth. While a good general contour and a firm contact point can be obtained with either an amalgam or a good gold foil filling, or even a porcelain filling, it is impossible, with any of the three mentioned, to obtain a perfect reproduction of the occlusal surface. This can, however, be obtained by using a cast gold filling or restoration, because it is entirely possible to carve the wax model to a nicety, showing all the anatomical lines. It is concluded, therefore, that a perfect-fitting, well contoured and properly carved cast gold inlay is the most perfect filling for compound cavities in bicuspids and molars that we have at our disposal.

Essays dealing with all sides of the subject of occlusion in its relation to cast gold fillings have been written by Dr. H. W. Gillett and Dr. J. Lowe Young, of New York.

ROOT-FILLINGS.

Numerous special pastes and patented preparations, the acclaimed virtues of which seem to place a premium upon slipshod root-surgery and canal-filling, are offered to the profession. Fortunately, however, our dental literature is replete with articles dealing with the problem of the scientific treatment and filling of canals, and it is believed that only those who knowingly desire to follow the so-called quick and easy methods will resort to mummifying pastes and other similar methods of uncertain virtue.

It is well recognized that a tooth in which the pulp has become devitalized is valuable to the patient only in proportion as the root-canal or root-canals have been carefully and skilfully treated and filled. In fact, the thorough treatment and filling of all roots and devitalized teeth is the real foundation upon which the superstructure of filling or crown or bridge is to rest, and it is gratifying to know that our better dental educational institutions are now giving more and better scientific instruction along these lines.

The recognition on the part of dentists and physicians of the serious results that may accrue to the health, or even the life, of a patient through foci of infection in the mouth has also had a stimulating effect on the better class of dentists throughout the country.

It is possible that a fuller understanding of bacteriology and a wider knowledge of the source of infections in the oral cavity will result in the more common use of restorative and prosthetic methods in which the elements of danger to the patient are reduced to the minimum.

It is, perhaps, needless to prophesy that unless dentists themselves realize the danger that lurks in a chronic abscess, or under a badly designed bridge, or about an ill-fitting crown, the time is not far distant when they will have their attention called to it by their brothers of the medical fraternity. The latter may, on just grounds, order the removal of dental work that appears to be having an unwholesome effect on the patient; and it were better, therefore, that dentists take advantage of the present-day knowledge on this subject and safeguard themselves and their patients from embarrassment.

W. D. Tracy, *Chairman,*
D. H. Squire,
F. F. Hawkins,
Committee.

Discussion.

Dr. A. R. Starr, New York. Your essayist states that perfect occlusion cannot be obtained with gold or amalgam fillings or even with porcelain inlays. I cannot agree with him on that point. I will admit it would be difficult to get perfect occlusion with an amalgam filling in complex cavities, especially when a matrix cannot be left in place until crystallization is complete, but I see no reason why perfect occlusion cannot be obtained with a gold filling, and even with a porcelain inlay, if the inlay be tried in the cavity before the final baking. While I realize the advantages of gold inlays in difficult cases, I am not one of those who believe that gold inlays are destined to supersede gold or amalgam fillings in all cases. I have not thrown away my gold pluggers; I keep them within easy reach, and they are not getting rusty.

I may be *passé* or ultra-conservative, but I cannot bring myself to believe that a gold inlay is better in ordinary cavities than a good gold filling. With the inlay, the cement layer is an element of weakness as well as an element of safety. It is weak in that no matter how infinitesimal the amount at the margin, it is liable to wash out in time, and leave an opening for the entrance of food, saliva, and micro-organisms; and it is only an element of safety in that it affords protection to the pulp. I am confident that I can make a gold filling in ordinary cavities in much less time or in about the same time that it would take to make a wax model and to fit and set a gold inlay, using the direct method, which I consider to be the better one.

The essayist very properly emphasizes the importance of the skilful treatment and filling of root-canals, and advises against the use of mummifying pastes or similar materials in place of the more permanent canal fillings. I prefer to use gutta-percha in all canals large enough to permit of its proper introduction, or a combination of cement and gutta-percha in smaller canals. I consider that the pastes are of use only for temporary work, or as a last resort in cases where a canal seems impenetrable. Many failures in root-canal work are due to imperfect knowledge of dental anatomy. How often do we open into an upper bicuspid or a lower incisor or canine and find only one canal filled in cases where there are two! How often do we find the facial canals of upper or the mesial canals of lower molars entirely empty or only partially filled in cases which have been under treatment.

Many of us who imagine we are quite uniformly successful in filling root-canals would receive quite a shock if we would make a radiograph of every such operation. The X ray should be used more frequently in that connection. In regard to the treatment of abscess caused by devitalized teeth, I believe we are more prone to over-treat such cases than not to treat them sufficiently. It is my custom to fill the canals in cases of fistulous alveolar abscess just as soon as those canals can be kept clean and free from moisture long enough to permit the introduction of a pellet of gutta-percha in the apex. In cases of non-fistulous abscess I frequently follow the same method, and if necessary convert the case into a fistulous one, by perforation of the alveolus. With this method many cases which have been under treatment for months will heal in a few days. In regard to pyorrhea alveolaris, that subject was so thoroughly discussed at last night's session that I shall have very little to say about it in this discussion. If pyorrhea be due to malocclusion, I would suggest correcting that malocclusion as nearly as possible, or, better still, anticipate the trouble and put the teeth as nearly as possible in proper occlusion before pyorrhea develops. The less we move the teeth after the disease is well advanced, the better. If the teeth are much loosened and displaced I find I get better results in fixation if I try to hold them in the position in which I find them.

No doubt the vaccine treatment of pyorrhea has a future, but as yet most of us are so wofully ignorant in regard to the proper use of this therapeutic method that it is not likely to come into general use. I believe some cases may be benefited by this treatment, if the proper medium can be found, to combat the diminished opsonic properties of the blood serum and improve the phagocytic action of the polymorphonuclear leucocytes, but until we are more familiar with the subject of general bacteriology and with the etiology of pyorrhea, I fear we cannot make much progress in this direction.

I should imagine that one factor which would interfere with the correct application of this treatment would be that of securing a perfectly typical and uncontaminated sample of bacterial invaders from which to make our autogenous vaccine. Since we have so great an assortment of micro-organisms in the mouth, and since we do not know which of these bear an etiologic relation to pyorrhea, I should think it would be difficult to make a selection of any special culture or cultures, in case we did not use all.

In regard to silicate or synthetic cements, I believe that pulp irritation from their use is due not so much to their chemical activity as to the fact that, being less adhesive than the ordinary cements, they require more extensive cavity preparation.

Most of the other subjects appearing in this paper have been discussed or will be discussed in connection with other papers, so I will not refer to them.

Dr. B. S. Hert, Rochester. Occlusion, which is the first phase of dentistry considered in this report, is fully as important as the committee claims, and while many practitioners have always realized its value, a constantly increasing proportion of the members of our profession are, fortunately for their *clientèle* and themselves, appreciating the fact. Our education along this line has been influenced more by orthodontia than any other one factor, although a number of other causes have been active in this connection.

The prominent place gold inlays occupy in restoring lost or correcting improper occlusion is not overestimated; however, the method of carving the planes, grooves, sulci, and cusps is in many cases not the best method of restoring the occlusal surface, as we must usually be guided by the surface of the opposing tooth, which in probably the majority of cases does not present an aspect of that character; and in such instances to make a gold inlay as described in the report—namely, having cusps, sulci, and grooves and planes carved on its surface—would defeat one of the principal objects which it was designed to attain.

Oral sepsis, its harmful effects both local and systemic, and the frequency of this condition as the result of dental operations or the lack of operative procedures by the dentist when indicated, was brought to our attention with almost dynamic suddenness and force by a member of the medical profession a number of months ago. This gentleman rendered a service both to the public and dentistry, and let us hope that more such shocks will be given to our calling, until each member of our profession realizes the important place he and his work should occupy in the healing art. It is unquestionably true that many of even our intelligent practitioners of dentistry fail to appreciate the great influence which we all should, and some now do, exert on the general physical and mental welfare of our patients.

Oral hygiene has by some dentists been called a fad; they say that it has passed over the ridge and that its importance is waning. But the committee evidently do not believe such to be the case, and anyone who has faithfully carried out the idea in his practice, who has educated his patients to do their part and to realize its value, not only locally but systemically, cannot fail to become more and more convinced of its great worth. That it is a cure-all or a preventive for all oral ills is not true, but it is a great aid in both these directions.

While the committee did not mention the administration of oxygen and nitrous oxid for the practice of humanitarian dentistry, it is a branch of our occupation which is of so much merit that it is entitled to have attention drawn to it. By its use, with very few exceptions, cavities can be prepared, teeth with live pulps ground down for crowns, and other dental operations performed without pain and without the slightest danger to the patient. It is one of the most important advances made in dentistry in recent years. With any of the various kinds of apparatus made for the purpose its administration is so simple that a beginner in its use can obtain excellent results, and one with experience will seldom fail in obtaining the desired freedom from pain. When the effect is carried only to the analgesic stage, which is sufficient in almost all cases to prevent pain, we have opinions of eminent medical men that there is absolutely no danger.

The report of the Committee on Practice has always been of a high standard, and the committee for this year has maintained the standard set by its predecessors and done its work admirably.

Dr. Henry W. Gillett, New York. I would like to say a word concerning the point which Dr. Starr raised in regard to occlusion. It seems to me that he has not entirely grasped the full significance of Dr. Tracy's statement when he speaks of the possibility of restoring the occlusion as perfectly with gold, amalgam, or porcelain as it is now possible to do with the cast gold inlay. No previous generation of dentists has ever had at its command the possibility of restoring the cusps and sulci of teeth to the degree that it is now possible with the cast inlay. Or if, for the sake of argument you consider it to have been possible, it has at least not been feasible within the physical capacity of the patient and operator. To me it seems evident that the restoration of cusps, inclined planes, and sulci is the essential part of the restoration of occlusal efficiency in bicuspids and molars, and I cannot conceive that it is feasible with foil fillings, amalgam, or porcelain, even with all our present knowledge, to anywhere near approach the results in anatomical restoration that we readily get in the adaptation of the wax, which can be so easily duplicated in cast gold.

I wish also to make a second point in connection with what Dr. Starr has said. He has drawn a comparison between the direct and the indirect processes. Limiting consideration to the simplest cases, I would be ready to admit the contention which he has advanced that the average operator may probably do better with the direct process, but it seems to me that one of the very important advantages provided for us by the cast metal process is the opportunity to make large restorations effectively. And while for some time I took the ground that the same care, skill, and attention to detail would produce similar results by either process—the indirect or the direct—for a year or two I have been drifting strongly toward the indirect method as the one capable of producing the best results, and more easily for both the patient and operator—and particularly is this true with regard to extensive restorations. Even if the operator has the skill to carve in the mouth restorations of whole occlusal surfaces, it seems highly undesirable that he should do so, because of the possible accidents which may befall his work before it reaches completion, with the consequent embarrassment of going back to the patients, confessing failure, and asking that they submit to further work in the matter of carving. These are the two points I particularly wished to emphasize.

Dr. Tracy (closing the discussion). I am sorry that more have not taken part in the discussion of the matter presented in the report. It is hard for me to believe that so many men agree implicitly with everything presented, and should they not agree with it, I should have been glad to hear from them.

I was interested to hear Dr. Starr express himself in the matter, and would not have him infer for a moment that I have cast aside my gold pluggers or that I have lost my appreciation of the good gold filling in selected places, but my conclusion is that the best possible restoration for compound cavities must be based on what we see and what we do ourselves. I know that I cannot, try as I will, with the foil filling get the results I feel I should get in these cases, and I know I can get the results with the casting process that these cases demand. I am speaking not of small cavities on buccal or approximal surfaces, but of large restorations, compound cavities, mesio-distal cavities where a large portion of the tooth structure is involved, and I know in filling these cavities with gold foil, while we have sealed the cavities and beautifully restored the contact points on the approximal surfaces, we have not restored the masticating efficiency of the teeth, because we have not reproduced the occlusal planes, sulci, and pits that nature put there for a purpose. If we can do that by any method, that method is better than we have been using in earlier years. It has been said that one of the marks of wisdom is a willingness to give up an excellent thing for a better thing. We know that the gold filling is an excellent thing, and many of those who have had a modest degree of success with it have had better success with the inlay. So it seems to me the part of wisdom for all operators to take up the method, and see if they cannot do better. I have profited very much in listening to the suggestions in the reports which followed mine, and hope that more men will take up the feature of reproducing the anatomical occlusion of the teeth either by the indirect or the direct method. As experience accumulates in the use of the indirect method, we find that we can get results with it that we cannot get by the direct process. I know of many instances where proper care has been exercised in the preparation of the cavity and the technique of making the inlay by the direct method has been carefully carried out, but these fillings did not fit the cavities as well as when made by the indirect method with the amalgam die.

I do not wish to further discuss the methods of making inlays, but I do want to express the belief that the gold inlay is the best possible means of restoring badly broken-down teeth today. Teeth can be restored by the cast gold method in such a way that it enables the operator to reproduce the anatomical outlines of the teeth and thus provide the greatest efficiency in mastication.

EDITORIAL DEPARTMENT.

OLD WINE IN A NEW SKIN.

A RECENT writer deplores the fact that things are not as they used to be in the earlier days of dental development. He feels that organization in dental society work, as now operative, is tending to inhibit the activities of the individual worker and to exercise a disheartening influence upon those who would otherwise, and under less restrictive society regulations, be stimulated to add something to the sum total of our knowledge through the medium of society contributions or in debate thereon. The direction and control of society effort collectively and individually to any degree whatsoever is regarded as an infringement upon the inalienable right of free speech, and as tending only toward destruction of the society as such by reason of its deterrent effect upon the individual effort of its members. The case under critical consideration is the new *régime* resulting from reorganization of the National Dental Association and the inauguration of a new order of things in the governance of the activities of that important body.

It is always a difficult feat for the human mind to adjust itself to new conditions, just as it happens to be a common experience that a new hat or new pair of shoes become less obtrusive after they have been worn for a while and have adapted themselves to the wearer's individual peculiarities of physical conformation. So also when, as the result of long and more or less trying experience of a certain way of doing things in connection with our dental society work, and after careful and due consideration, a radical change of arrangements is brought about for the purpose of securing higher efficiency in that work, it is naturally to be expected that many among those habituated to the old order of procedure will find themselves for the time being somewhat uncomfortable under the altered conditions, until mutual adaptation has brought about more harmonious action and a better understanding of the practicality of the new arrangement.

It is yet too early to decide as to the probable success or failure of the reorganization plan of our National body; its efficiency has not been tried out, and the proper attitude of mind for all of us is that of the pragmatist—viz, to test it unemotionally by its results, not by what we may think it may do, nor by how it may appear in comparison with the older and discarded order of procedure.

If the Essay Committee will exercise its prerogative of excluding irrelevant and unworthy papers from the program, and the presiding officers will fearlessly exclude the garrulous and diffuse talkers who waste the time and try the patience of the audience and bring discredit and ridicule upon the association as a whole by talking about what they don't know, a long stride toward a higher plane of usefulness for our National body will have been achieved by the reorganization plan.

It is objected that the new plan means a more centralized control of society affairs, and a consequent impetus toward more objectionable political activity upon the part of those who are aspirants for political favors and emoluments. We can see no real difficulty in that connection. The only value that political office can have to the politically-minded aspirant for honors in the association is dependent upon the success and dignity of the organization itself; therefore the relation of the political worker as such to the non-political worker as such, in the association, is, to use a biological term, a symbiotic one. Consequently both must stand or fall together. It is or should be of small consequence to the non-political scientific worker—and there are a few —*who* the officers of a society may be, so long as he is able to present his communications to an intelligently critical and appreciative audience; and, *per contra*, it is more than likely that it matters but little to the political worker who reads the scientific papers or carries on the debates, so long as he can console himself with the evanescent glory of holding offices. Hence it is that both are mutually dependent and their respective activities balance each other in the machinery of society organization and work.

The conditions in dentistry today are not those of a generation or even of a decade ago. Never before has there been such an awakening along the lines of scientific interest in connection with all departments of dental work as is shown at the present time. The scientific method is gradually but surely being applied in every department, and the man who is content with empirical methods or who advertises his contempt for anything bearing the scientific label is being relegated to the scrap-heap in the great industry of present-day dental science and art.

It is inevitable as a result of this great awakening and the demand for more knowledge of actual conditions upon which to found a rational system of dental practice, that the older order of conducting our society work should give way to methods more in conformity with the needs of the times, for which reason we hail with much pleasure and satisfaction the materialized expression of this need for a new way of getting larger and better results by the reorganization of our National Dental Association. When it has been tried and if in the trying it should show defects or weaknesses, it will then be ample time to cry "Failure." But the body is wise, and can be trusted to correct its errors of organization as by fair trial they are made evident, just as it was competent to regenerate itself by casting aside its antique garments and donning its more modern garb. The thing to do now is for each man to help to energize the whole organization by giving to it the best of his individual effort.

Bibliographical.

John Hunter and Odontology. By J. F. Colyer, L.R.C.P., M.R.C.S., L.D.S. Illustrated. Pp. 214. Price, net, 20*s.* London: Claudius Ash, Sons & Co., Ltd., 1913.

Mr. Colyer has done the world of dentistry and of medicine a signal service in producing this excellent record of the work of an unusual man, one who, though claimed by England as among her distinguished sons, nevertheless belongs to the world of science as a pioneer in the field of the scientific study of anatomy and surgery. John Hunter well deserves the title of "Father of Modern Surgery." His work as a comparative anatomist placed him well in the front rank of contemporary naturalists, and his remarkable achievements in the study of comparative odontology is a benefaction to that department of anatomical science for which he has not received the full meed of gratitude and approval to which the high character and extent of his work justly entitle him.

Mr. Colyer has set forth in interesting manner and attractive style the record of Hunter's contribution to odontology, together with much data relative to the personal characteristics of the man which serve to enlist and maintain the interest of the reader in the study of the scientific features of his work. It is gratifying to note from time to time the growing interest which is being manifested in the rescuing of the history of dentistry from oblivion by the production of works of this character, and after the record of the lives and life-work of those constituting the early pioneers in blazing the pathway along which modern dental science was to have its growth is completed, dentistry will have every reason to be proud of its ancestry.

Mr. Colyer's work is a notable contribution to the literature of dental history. We are promised in the near future a translation of Professor Viau's great work "Pierre Fauchard," and others are to follow. No student of dental history or member of the dental profession having even a passing interest in the history of his calling can afford to remain ignorant of these great characters and their epoch-making work. Colyer's story of John Hunter should find a place in every dental library.

A Text-book of Surgery for Dental Students. By G. Percival Mills, M.B., B.S.(Lond.), F.R.C.S., Surg. Orthopedic and Spinal Hospital, late Resident Surgical Officer, General Hospital, Birmingham; and Humphrey Humphreys, M.B., Ch.B., B.D.S.(Birm.), L.D.S.(Eng.), Demonstrator in Dental Surgery, Birmingham Dental Hospital. Illustrated. Pp. 340. London: Edward Arnold, 1913.

Judged by its contained matter, the title of this interesting volume will be somewhat misleading to American readers, for the reason that it is not a work descriptive of operative methods for the cure of disease conditions, but rather an exposition of the principles and more striking instances of surgical pathology as related to the needs of the dental student. The surgical operation of tooth extraction is not included within the scope of the work, and neither the word "tooth" or "extraction" nor any combination of them appears in the index of subjects; yet no surgical operation is more characteristically dental, nor is any surgical operation more frequently performed in dentistry, nor is any other dental operation so frequently modified by complications fraught with danger to the patient and difficulties to the operator as that of tooth extraction. It is, therefore, matter for surprise that a work bearing the above title should be lacking in systematic consideration of the operation of tooth extraction.

Again, from the American point of view, the book contains much matter which is not ordinarily included in the courses of instruction of surgical pathology given to dental students; for example, the treatment of dislocation of the shoulder joint, the pathology and treatment of goiter, of torticollis, of a variety of ocular disorders having no direct connection with dental diseases, of spinal caries, of cut throat, and a few other instances of a similarly unrelated character do not seem to have any direct bearing of large usefulness in a course of instruction for dental students, excepting upon the principle that all knowledge is useful, even to a dental student.

On the other hand, the major portion of the work, and indeed, nearly all of it in so far as it relates to surgical pathology, is a most interesting and valuable presentation of the subject, and covers a field with which every dental student should be made familiar before he can fairly be considered safe to launch upon the public as a qualified practitioner. As a handy reference book and guide for the practitioner of dentistry the work will also find a useful and valuable place for itself. As indicated by the preface, it will be more particularly useful to the student preparing himself for the licensing examination in dentistry, the scope of which is determined by the General Medical Council of Great Britain. An occasional departure from the standards of terminology to which we are accustomed in America is observed; for example, the "superior maxilla" is discussed in a paragraph immediately preceding that in which the "mandible" is described, which is an apparent incongruity. Making full allowance for differences in terminology and in the conceptions of the relative importance of the data which would enter into a course of instruction in surgery for dental students as exemplified in the practice between Great Britain and this country, the work is a most excellent one, and intrinsically valuable for its matter as well as its teaching qualities.

REVIEW OF CURRENT DENTAL LITERATURE.

[*Lancet,* London, March 29, 1913.]

HYOSCIN-MORPHIA ANESTHESIA FOR ALCOHOL INJECTION IN TRIFACIAL NEURALGIA. BY DR. W. HARRIS.

[*New York State Journal of Medicine,* New York, June 1913.]

THE PRESENT STATUS OF NERVE INJECTION. BY DR. O. KILIANI, NEW YORK.

The treatment of severe and intractable trigeminal neuralgia or tic douloureux by alcohol injection has now become fully established as the most practical and efficient remedy for this disease, since its first introduction in Munich ten years ago. Schloesser who first used it, and his followers in other countries, such as Ostwald, Lévy, and Baudouin, and Sicard in Paris, and Kiliani Patrick and others in America, have all practiced the methods without the use of any anesthetic other than a small percentage of stovain or cocain mixed with alcohol, and perhaps a spray of ethyl chlorid to freeze the site of skin puncture. The author himself has practiced alcohol injections for trigeminal neuralgia in 112 cases, and has tried many different methods of making the injection.

The best technique he finds to consist in a dose of $\frac{1}{6}$ of a gram of morphia with one 1/150 gram of hyoscin injected hypodermically into the arm twenty minutes before commencing the alcohol injection. In this interval the patient should be made to lie down and keep very quiet, and sleep if possible. This preparation insures restfulness and apparent absence of all pain during the process. When the needle is approaching the foramen ovale, the patient usually shows some symptoms of sensitiveness, though it is not until the nerve is actually struck that a tingling sensation is felt in the lower lip and the tongue; when this occurs, the stylet should be removed from the needle, a syringe filled with a 3½ per cent. eucain solution fitted on, and a few drops then slowly injected. If there is considerable resistance to the push of the piston, the point of the needle may be within the nerve, but if no resistance is felt, the point is certainly not in the nerve, and the needle should then be moved slightly in different directions until it is thought that the foramen has been reached, when again a few drops of eucain should be injected. If then there is resistance to the push of the piston, the syringe should be changed for another filled with 90 per cent. alcohol, and after the lapse of half a minute a few drops of the spirit should be injected slowly into the same spot, great care being taken to hold the needle quite steady. The patient will usually feel some burning sensation, which may be reflected to the lip and tongue, though not necessarily. Almost instantly, as soon as a few drops of alcohol have been injected into the nerve, sensations of touch and pinprick on the lip become blunted, and slowly, two or three drops at a time, more spirit is injected, until the anesthesia is complete, and the pinprick is not felt at all, even as pressure. Usually from 1 to 1½ cc. are required to produce this effect. After each injection of a few drops of the spirit, the lip and chin should be tested for sensation with a pin, and this method of trial injection and test anesthesia is, in Harris' opinion, the only satisfactory way of obtaining good results. He discountenances chloroform anesthesia and considers the extraordinary calming effect of the hyoscin and morphin as most valuable, since even the most nervous patients will remain quiet and peaceful during the whole operation, and yet will be able to answer at once to the skin tests for anesthesia. Of ill effects he has seen none, except in one case of extreme old age and idiosyncrasy. Vomiting occurs in some patients, but this tendency may be diminished by the addition of atropin 1/75 gram to the preliminary injection.

KILIANI reports on the treatment of facial neuralgia by injecting into the branches of the trigeminal nerve, either peripherally, where they enter the face through their respective foramina, or at the base of the skull, where they emerge, or into the ganglion itself. The success of this operation necessitates two things, in his opinion; first, a more intimate knowledge of finer anatomy and topography, and secondly, development of a technique which is decidedly more minute than we have been accustomed to heretofore. In his own experience of four hundred cases, the time which has elapsed since the alcohol injection has been at least one year. Wherever feasible, he has tried to produce the desired effect by peripheral injection, without one failure within the last few years. The fluid injected is eighty per cent. alcohol, the amount varying from 1 to 2.5 cc. The writer employs a 5 cc. Record syringe to which Schloesser's needles of rather heavy caliber with non-cutting point are attached by a bayonet lock. The needles are straight, of different length, or bent at different angles. He avoids curved needles, because the point is too difficult to locate during insertion.

This treatment is a cure only in so far as it frees the patient of his pain attacks and anxiety, but recurrences are frequent, if not the rule. According to the writer's experience about twenty-two per cent. have remained free longer than three years, including patients who have been free for five years, and in whom one might feel tempted to consider the result as permanent. In the remaining cases the recurrent attacks were much milder, of less frequency, and usually submitted easily to a renewed treatment by injections. Extirpation of the ganglion is deprecated, since it does not prevent recurrences, the nerve branches being entirely regenerated. Kiliani makes his injections without narcosis or local anesthesia, because the patient is thus enabled to tell if the needle has struck the nerve. In several more sensitive patients 5 cc. in 1 cc. of two per cent. novocain-suprarenin was injected, but the result was not so certain, the alcohol having been too much diluted by the preceding injection. Only one death has occurred in the writer's practice following alcohol injection. Other accidents are amaurosis, facial paresis, oculomotor paresis, and more or less marked stiffness of the jaw. One very peculiar feature of some of the cases where the third branch is involved is striking—namely, a snow-white coating of the tongue on the affected side, ending abruptly with the median line of the tongue, this coating disappearing with the pain within twenty-four hours after the injection. In regard to diagnosis it is important to note that, if the patient complains of constant pain with no free intervals, it is at least doubtful whether we have to deal with a true case of facial neuralgia, since in typical cases the pain comes in spasms.

Direct injections into the Gasserian ganglion, as suggested by Haertel, of 5 cc. of two per cent. novocain-suprarenin are very favorably indicated in resection of either jaw and carcinoma of the mouth, doing away with a great many of the dangers that were formerly connected with these operations.

In summing up, Kiliani states that the treatment of trifacial neuralgia by alcohol injections has come to stay, and it is desirable that more oral surgeons should familiarize themselves with this technique. The method is practically without danger, and the results in nearly all cases are exceedingly gratifying to the surgeon as well as the patient, who is thus relieved of his frightful suffering.

[*Correspondenz-Blatt fuer Zahnaerzte*, Berlin, April 1913.]

GUNSHOT FRACTURES OF THE MANDIBLE AND THEIR TREATMENT. A STUDY ON DENTISTRY IN WAR. By Prof. Dr. H. Schroeder, Berlin.

The frequency with which gunshot fractures of the maxillæ, especially the lower, occur in modern warfare, has brought about the appointment of dental surgeons in the armies of every civilized nation. In the civil war gunshot fractures of the maxillæ amounted to no less than 60.6 per cent., in the Japanese-Chinese war to from forty to sixty per cent. of all gunshot fractures. The mortality from jaw fractures amounted in the Crimean war to 46.9 per cent., in the civil war to 8.1 per cent., in the Franco-German war to 9.3 per cent. The danger from these fractures has been gradually decreased, owing to the use of steel-jacketed bullets. The data gathered in past wars, and the experiments with cadavers show that two kinds of fractures are most common, viz, separation of continuity in the mandible with considerable comminution, and complete shattering of the bone. In the former case the surgeon's aim is to fix the bone fragments and to await healing; in the second case the splintered bone must first be resected, and the remaining sound portions of bone supported.

The writer rejects Port's splint of tin, owing to the complicated technique involved in its use; he considers also all other splints that necessitate prolonged closure of the mouth as being contra-indicated. In the Russo-Japanese war, the Japanese employed an aluminum splint with swallowtail enlargement at each end, which was attached to the bone stumps by means of silver wires. The center of the splint which comes to lie on the lingual side of the bone was perforated to permit of drainage of the secretions. Owing to the risk of subsequent necrosis due to this form of fixation, this splint seems indicated only if interdental splints are impossible owing to lack of abutment teeth.

When teeth are left, Schroeder employs a German silver wire of 2-millimeter thickness which, like an Angle arch bow, is fastened to the molars with strong bands. If the mandible is fractured distally to the remaining teeth or between the molars, the bow is reinforced by means of an articulation plane or a sliding guide, the latter of which necessitates, however, the insertion of an upper arch, thereby enabling the patient to eat without pain. In edentulous mandibles, or if an insufficient number of teeth be left, the writer employs bone suture or a modification of the Japanese aluminum splint described, a number of which are kept in stock, and which by means of a metal saw and bending pliers can be adapted to individual cases. If resection of a considerable portion of the mandible is necessary, Schroeder employs his *prothèse immediate*, consisting of a reproduction of the jaw in vulcanite, with hollow ends which are slipped over the bone stumps and sutured with aluminum bronze wire. Remarkably quick healing has been generally observed in these fairly desperate cases. Schroeder's interesting paper is liberally supplied with instructive illustrations, and in concluding describes his most practical and concise instrumentarium.

[*Le Laboratoire et le Progrès Dentaire*, Paris, March 2 and May 11, 1913.]

ANOMALIES OF THE LOWER THIRD MOLAR. By A. L. Whitehouse.

RADIATION OF PAIN FROM THE THIRD MOLAR. By Dr. A. Therre, Lyons.

The general application of radiography in dental surgery has incidentally revealed numerous anomalies of the lower third molar, which may be divided into five groups; First, misplacement of the tooth in various portions of the ascending ramus; second, anomalies in position, the crown pointing mesially, distally, lingually, rarely buccally, or the tooth being totally inverted; third, combinations of the first and second anomalies; fourth, in anomalies of the second group, the third molar is often found in more or less close contact with the distal surface of the second molar, producing phenomena of resorption; fifth, partial eruption.

This last and most frequent anomaly seems to be due to a lack of eruptive force, the tooth, which is otherwise normal, erupting only with the anterior portion of its crown, the posterior portion remaining covered by gingival tissue, under which food débris may and usually does become impacted, producing a chronic local gingivitis together with a syndrome of other local or referred painful symptoms, resulting, in extreme cases, in Ludwig's angina complicated by trismus, when extraction without delay becomes imperative. In milder cases with purely local pain, treatment consists in extirpation of the food pocket by repeated daily syringing with a hot, weak solution of hydrogen dioxid, and touching the free border of the overlying gingiva with silver nitrate, this gradual treatment being preferable to excision.

Therre, in reporting four cases of pain referred from the lower third molar, states that this troublesome tooth is the most fruitful source of pain radiation, which in many instances has led to false diagnosis and treatment. Facial, cervical, and occipital pain, also earache, should always make the operator suspicious of the lower third molar. In the writer's four cases, the pain was referred to the central and lateral incisors and the canine, which is explained by the distribution of the inferior dental nerve. Infection or compression of this nerve by way of the lower third molar may produce various symptoms, either in form of simple odontalgia in the tooth, or in pain noted in the tooth itself as well as in the neighboring tissues, or finally in purely reflex pains which are perceived in more or less distant tissue, or in one or several distant sound teeth, while the culprit tooth itself is free from pain.

RADIO-ACTIVE SUBSTANCES AND THEIR APPLICATION IN DENTAL DISEASES, INCLUDING PYORRHEA ALVEOLARIS. By Zahnarzt M. Levy, Berlin.

THERAPY OF PYORRHEA ALVEOLARIS, WITH SPECIAL CONSIDERATION OF RADIUM. By Zahnarzt H. J. Mamlock, Berlin.

[*Deutsche Zahnaerztliche Wochenschrift*, Leipzig, September 6, 13, and 20, 1913.]

RADIUM AS A THERAPEUTIC AGENT IN THE TREATMENT OF PYORRHEA ALVEOLARIS. By Zahnarzt R. Neumann, Berlin.

THE FIRST BIOLOGIC ACTION OF RADIUM. By Professor Dr. Walkhoff, Munich.

REPLY TO NEUMANN'S "RADIUM AS A THERAPEUTIC AGENT IN THE TREATMENT OF PYORRHEA ALVEOLARIS." By M. Levy, Berlin.

CARE OF THE TEETH AND MOUTH, AND RADIUM. By Dr. Krause, Kassel.

[*Zahnaerztliche Rundschau*, Berlin, September 28, 1913.]

RADIO-ACTIVE SUBSTANCES AND THEIR APPLICATION IN STOMATOLOGY. By Dr. Windmueller, Berlin.

Levy publishes the encouraging results obtained in eighteen cases of dental disease by radium treatment, which he employed in the Radium Institute of the Royal Charité for Biologico-therapeutic Research of Berlin. He discusses very interestingly the physical properties of the radio-active substances radium, thorium, and actinium, and their effects upon healthy and diseased tissues. Of the two chief methods available—viz, irradiation and emanation—this writer prefers the latter for the treament of oral disorders, applying the radio-active salts in the form of charged water for drinking and rinsing, of a radio-active massage paste, of compresses, and injections, or combining these forms of treatment with radium and mesothorium irradiation or inhalation. Successful results were obtained in cases of psoriasis of the oral mucous membrane, pyorrhea alveolaris, looseness of the teeth with or without pus, marginal gingivitis, leukoplakia of the tongue and mouth, dental abscess, and ulcerous stomatitis, while irradiation alone was found inefficient in chronically recurrent aphthæ as well as pyorrhea alveolaris.

While fully convinced of the valuable therapeutic properties of radio-active substances, Levy warns against overenthusiasm, and emphasizes the necessity of correct application and dosage, also avoidance of the ineffective radium preparations with which the market is being flooded. The biologico-therapeutic action of radium upon the oral mucosa not being as yet sufficiently understood, closer research in this promising field, to be carried on in co-operation with general medicine, is most desirable.

NEUMANN'S attitude toward the use of radium in dental disease is a rather critical one. He not only considers the period of observation in the cases treated by Trauner and Warnekros (see DENTAL COSMOS, August 1913, p. 853) as ridiculously short for anything like a final verdict, but remarks that in the cases of pyorrhea alveolaris reported by Levy, equally good results could have been obtained without radium. In twenty-seven cases of pyorrhea alveolaris treated by him after the methods recommended by the three above-named observers, no progress of healing was noted in any case, and it was only after a most careful scaling that healing slowly occurred, in the same way as if no radium had been used, while treatment with fifty per cent. lactic acid instead of radium produced a notably rapid advance in healing. In five refractory cases which had not yielded to even the most painstaking local treatment, no improvement occurred in spite of radium treatment applied in every suitable form.

Neumann concurs with WALKHOFF, who, as early as 1900, in collaboration with Professor Dr. Giesel of Braunschweig, the first manufacturer of radium in Germany, made observations with radium which preceded those of Becquerel and Madame Curie by a full year, although the latter are popularly given credit for the discovery of this new element. WALKHOFF noted especially the biological effect of radium upon vital cells, and, in discussing MAMLOCK'S paper, remarks that the experiments with radio-therapy in pyorrhea alveolaris are by no means very encouraging as yet, and that any improvement or eradication of pus pockets should not, in his opinion, be expected from radium application.

In rebuttal of Neumann's criticism, LEVY, in his second paper, defends his optimistic views, though he disavows any claim for radium being a panacea in pyorrhea alveolaris. Failures, in his opinion, are to be expected, but negative criticisms such as Neumann's are premature and bound to discourage others in the earnest research with a most promising element.

To this NEUMANN, in defending his critical attitude, replies that he, just like Mamlock, regards radium not as a cure, but simply as an adjuvant in the treatment of pyorrhea, the same as lactic acid or ammonium bifluorid. He shares the view of other authors, such as Sachs, that ninety-five per cent. of cases of pyorrhea can be cured or improved only by surgical treatment.

The problematic status of the radium question in connection with pyorrhea is further evinced by KRAUSE'S interesting investigation into the physics of radium and its biological action. He describes one of the many emanation apparatus on the market for the convenient preparation of radio-active rinsing or drinking-water, and prophesies an epoch-making future for radium in dentistry.

WINDMUELLER, on the other hand, reports almost uniformly negative results with radiotherapy in all its forms, which he ascribes to the altogether too low concentration of the radium preparations heretofore employed.

PERISCOPE.

Increasing the Bactericidal Action of Hydrogen Dioxid.—The bactericidal action of hydrogen dioxid can be considerably enhanced if a three per cent. organic acid, such as tannic or tartaric acid, is added to the hydrogen dioxid solution.—*Igiena Moderna*, per *Monatsschrift fuer Zahntechnik und Verwandte Gebiete.*

Allaying Pain After Extraction.—To allay pain following the extraction of a tooth, the wound is rinsed with a warm solution of hydrogen dioxid, followed by insufflation of orthoform powder. If no sprayer is available, the wound can be coated by means of a cotton tampon dipped into this powder.—*Oesterreichische Zeitschrift fuer Stomatologie.*

Case of Sepsis, Following Dental Treatment, with Fatal Termination.—The wife of a physician had several carious teeth filled. Several weeks afterward, pain was experienced in a molar, which, upon opening, showed purulent pulpitis. Though the root-canal was treated, yet ulcerous endocarditis and swelling of the liver and spleen supervened, the patient succumbing four months afterward to general sepsis induced by way of the small pus focus in the pulp.—DR. HIS, *Zahnaerztliche Rundschau.*

Obtaining an Accurate Bite in Plate Work.—In order to obtain an exact bite, the patient is asked to place his tongue at the posterior border of the introduced wax, and then to bite, which will obviate the necessity of having him bite several times into the wax. The efficiency of this method can be increased by asking the patient to bite very slowly, and swallow at the same time, while the operator applies strong pressure on the chin in order to hold the condyle in the glenoid fossa.—*La Odontologia*, per *Sud-Est Dentaire.*

A Simple Festoon Carver for Vulcanite Plate Work.—A very handy little tool for festooning the wax around the necks of the teeth is made in a moment by just putting a pen nib in the holder the reverse way. A broken steel pen, also, presents two miniature cutting-edges, which a touch or two of a carborundum wheel will convert into an instrument very useful in removing little bits of rubber from places which one cannot get at by any other instrument.—*Edwards' Dental Quarterly.*

The Use of Cement with Amalgam.—Experiments with amalgam in cavities so made that the fillings, when completed, could be removed without destroying any part of the cavity surface, show that it is extremely difficult to fill a cavity with amalgam that will seal the margins and stop caries. Therefore I consider it good practice to use soft cement in every cavity to be filled with amalgam. I use just enough to cover the cavity surface, removing any surplus with an instrument before starting to use the amalgam; then I begin with the amalgam, being extremely careful to pack it well. One need not be alarmed at the cement that oozes out at the margins of the cavity, as it may be removed, and the mixture does no harm. This method in my practice gives good service, and amalgam fillings may be made of which no operator need be ashamed.—F. J. RYAN, *Journ. Allied Dental Societies.*

Sterilization of the Right-Angle Handpiece.—It is very important that the right-angle attachment be sterilized after each use, inasmuch as it comes in contact with the mucous membrane of the mouth and the saliva. A method which I have followed during the past five years is to boil it thoroughly in water to which has been added powdered Castile soap, about one teaspoonful to the quart. After boiling, the excess of soapy water is shaken from the instrument, and a small drop of oil placed upon the gearing. The soap prevents rust and furnishes a certain amount of lubrication for the running parts. This method can also be used for the straight handpiece if it can be detached from the engine. If there are hard rubber parts connected with either handpiece, they can be boiled for a long time without essential damage.—WM. H. POTTER, *Journ. Allied Dental Societies.*

Bending Metal Tubes.—To prevent kinks in bending thin metal pipes, it is a common practice to fill them with sand or resin, the latter being poured in while in a melted state.

Both methods are open to serious objections. The sand must be dry, and either substance must be very carefully filled in, so as to touch every part of the interior surface of the pipe. There is yet another and a greater difficulty—the emptying and cleaning of the pipe after it has been bent. Any resin or sand left in the pipe may cause serious trouble when the tube is in use. All these difficulties can be got rid of by substituting water under pressure for sand or resin, short lengths of pipe which include a tap being fixed on to each end of the tube to be bent. It is easy then to get the pressure inside up to 20 atmospheres, even with a hand pump. When the pipe has been bent the taps are opened, the short lengths are removed, and no cleaning of the inside is necessary. The process has the further advantage that the pressure serves as a test of the strength of the pipe, especially during the bending.—*Zeitschrift fuer prakt. Maschinenbau*, per *Brit. Dental Journal.*

Misplaced Lower Canine.—The patient, a boy of sixteen years, complained of a tender swelling under the chin. A few days later, the crown of a tooth made its way through the skin, partly erupting on the outside below the chin. The greater part of the crown of the tooth, which was obviously a canine, projected through the skin almost vertically downward, in a position immediately below that usually occupied by the lower right canine. Except for some hypoplasia of the enamel, the form of the tooth was normal. Examination of the mouth revealed the fact that both the right lateral incisor and canine were absent. Incidentally it was noted that the maxilla was much contracted, and the upper teeth were very crowded and irregular. The boy was undersized and a mouth-breather. The history given was that, between two and three years of age, the boy received a blow on the chin in falling on some stone steps, and that subsequently an opening was present for some considerable time, through which a piece of bone was eventually removed. The cause of the misplacement would therefore appear to be that the sinus has apparently directed the tooth in its course.—F. R. Smyth, *Proc. Royal Soc. Med., Odont. Section.*

Stains from Silver Nitrate Removed with Potassium Iodid.—The operator not only gets silver nitrate on his fingers, but frequently upon the lips, and in some cases small spots appear upon the faces of his patients, indicating that in some manner he has accidentally dropped a minute quantity of the drug in making applications in the mouth. Stains which have appeared three hours after using the nitrate can be removed with iodid of potassium. A small quantity of the powdered potassium is placed upon a glass slab, and with a moist pellet of cotton the powder is carried to the desired spot and rubbed in gently. Usually the stain will disappear in a few minutes. After washing the part carefully in order to remove all trace of the potassium, the application of cold cream is usually very acceptable to the patient, especially if the stain is located on the lips or face. Most patients will experience a slight sensation on the lips or skin from the most minute quantity of silver nitrate; others will not, and, for this reason, when the operator has any suspicion that the preparation has come in contact with exposed tissue, it is well to have the patient return in from two to three hours, at which time any stain can be successfully removed.—M. T. Chambers, *Dental Digest.*

Modifying Pulp Broaches for Small Root-canals.—Much pain will be avoided by using the finer sizes of barbed broaches. By so doing one is enabled to slip the broach farther into the canal without crowding, and a better grasp of the pulp is effected. Even with the finest broaches on the market, it is often difficult to secure one fine enough to penetrate the very fine root-canals. In such a case the broach is laid flat on a wooden block, and then, with a fine file, the barbs on one side are carefully removed. The broach, having been reduced fully one-third in diameter, will now freely enter the canal, which was before considered impossible. This is really a valuable suggestion, and will bear repetition. To those who have not tried this plan of reducing the diameter of a broach, there is much satisfaction yet to come. Many root-canals are oval in shape, as shown in cross section, and the filing of one side of the broach tends to leave it also oval, and entrance is thereby more easily effected. One word of caution as to procedure: One should not, in removing the barbs on one side, allow the file to dig into the body of the broach and thereby weaken it. The broach thus prepared should not be rotated to any extent; being small, it can be carried to the apex, and thus grasp the pulp in its whole length, and rotation will not be found to be necessary. In this connection it may be added that there is less danger of breakage with a broach thus prepared; the tendency with the operator is to crowd, and with the prepared broach slipping the whole length of the tooth so easily the temptation to force the broach, and thereby bind it, is lessened.—C. B. Warner, *Dental Brief.*

Quinin and Urea Hydrochlorid Hypodermically and Tetanus.—Recently the bimuriate of quinin and urea has been very largely employed as a local application, and still more commonly as a hypodermic injection for the purpose of producing local anesthesia, so that minor operations could be performed without pain, the claim being made that this preparation is efficient, that it is not followed by ill effects, local or general, and, furthermore, that it possesses none of the dangers of cocain when that drug is given hypodermically. A number of clinical observers have reported instances of tetanus developing after major or minor operations, in cases in which no opportunity for infection by another cause than quinin could be discovered. These seemingly inexplicable infections with the tetanus bacillus have, however, been explained, in part at least, by the discovery that tetanus spores are sometimes found in the healthy alimentary canal of man, and if, perchance, there occurs a solution of continuity in the mucous membrane of the intestine, auto-infection of a traumatic or surgical wound may result. This certainly has an important bearing upon the safety and value of quinin when given by the hypodermic needle, either for the purpose of producing local anesthesia or to overcome the malarial parasite. Boiling of quinin for the purpose of sterilization not only produces deterioration of the drug chemically, but it materially impairs its therapeutic efficiency. Moreover, it seems to be pretty well proved that quinin produces some change in the tissues which renders them a singularly favorable site for the growth of the tetanus bacillus. It is the damage to the tissues produced by the injection, because a hypodermic injection of morphin or any other local anesthetic does not produce similar results. It will be interesting to note whether the widespread use of quinin hypodermically as a local anesthetic results in more tetanus cases being reported.—*Therapeuic Gazette.*

Some Errors in the Technique of Injection of Novocain-Suprarenin.—Most of the mishaps still attending the use of even the least injurious of local anesthetics, such as novocain, are due either to carelessness or to lack of foresight. The first condition of a successful injection is the absolute sterilization of the anesthetic. Solutions of novocain can be boiled and reboiled at will and for a sufficiently long time to insure absolute safety in this respect. Synthetic mixtures—even suprarenin—cannot be treated in this manner. The very popular and convenient ready-to-use phials have against them that, though they are guaranteed to be sterile, it is a work of art to keep them so in the process of use. Perhaps the best way is to pour off the needed amount of solution into a sterilized measuring-glass. Tabloids may be boiled with the necessary quantity of water. (Tabloids of suprarenin may be once boiled in this way without being injured.) A further objection to the phials is that their contents deteriorate comparatively rapidly. Novocain and suprarenin both suffer from the alkali contained in common glass. This difficulty may, it is true, be surmounted by confining ourselves to the use of those made of non-alkaline Yensen glass. They are, however, of course, much dearer than the others.

That solutions kept in bottles may be inadvertently exchanged or mistaken we have learned from a recent fatality reported from Berlin. This possibility can be guarded against by keeping, in a circular, colored bottle a 1½ per cent. Fischer's mixture of novocain, while a twenty per cent. solution for ordinary purposes is kept in an hexagonal wide-necked brown bottle. Injections should never be made in the neighborhood of a subperiostal or submucous suppuration. Sometimes it happens that a bloodvessel is pricked and a hematoma ensues. This undesirable circumstance, which can easily occur in the cheek or palate, is due to a lack of care in keeping the needle in contact with the bone. These blisters are not only very uncomfortable in speaking and in swallowing, but, though they will generally, under treatment, disappear in a few days, will sometimes fester and cause serious trouble.

The breaking-off of needles is a grave difficulty, and has led many dentists to prefer iridio-platinum and nickel needles. These, however, are rather too easily bent. A thoroughly aseptic needle-fragment will probably heal-in without causing trouble, and in some cases a greater risk is run in trying to remove it than in allowing it to remain undisturbed.

In the course of the discussion following the lecture by Dr. Williger from which the above is quoted it was remarked that the hermetic sealing of the small phials was technically difficult, that minute openings were bound sometimes to occur, and that the use of phials, therefore, was to be condemned. It was also suggested that Dr. Williger had omitted to point out the importance of taking a freshly sterilized needle in cases where a single injection proved insufficient.—*Deutsche Monatsschrift fuer Zahnheilkunde*, per *Dental Record.*

Obituary.

DR. CHAS. A. MEEKER.

Died, at the Homeopathic Hospital, Newark, N. J., September 8, 1913, following an operation for gall-stones, Dr. Charles A. Meeker.

Dr. Meeker was born in Troy, N. Y., July 13, 1846. Nearly all of his life was spent in Newark, where his professional activities found their largest expression. Endowed with a fondness for organization and with a practically unlimited capacity for work, Dr. Meeker concerned himself in the furthering of the more important dental activities of his state, and was for a long time active in the national aspects of the work of the various dental examining boards.

He was one of the founders of the New Jersey State Dental Society and of the Central Dental Association of Northern New Jersey, of which latter organization he was president for one year and treasurer for thirty years, and its secretary for twenty-seven years. He was a member of the State Board of Dental Examiners for New Jersey, and was its secretary from 1893 until a few months ago, when he resigned. He was a member of the First District Dental Society of New York, the Odontological Society of Manhattan, the New York Institute of Stomatology, and the American Academy of Dental Science, which latter association he helped to found in 1884.

Dr. Meeker was deeply interested in public dental service, and was one of the founders of the Newark free dental clinic, for which he obtained the passage of the necessary state legislation. He was vice-president of the clinic at the time of his death.

Outside of his professional activities, Dr. Meeker was connected with the old Essex Art Association and the Newark Camera Club, as secretary; the old Home Dramatic Association, of which he was one time treasurer; the National Arts Club and the Lotus Club of New York, and the Museum Association of Newark.

Dr. Meeker was a member of St. Paul's Episcopal Church of Newark. He is survived by a widow.

The funeral services were held on Thursday, September 11. Interment at Orange, N. J.

DR GEO. S. TIGNER.

Died, July 9, 1913, at the Imperial Hotel, in which he was residing, at Atlanta, Ga., Geo. S. Tigner, D.D.S.

Dr. Tigner, the report of whose death has caused the deepest regret in the minds of the large circle of his friends, was born at White Sulphur Springs, Meriwether county, Ga., being the son of Benson F. and Martha J Tigner. He studied at Emory College, Oxford, Ga., securing the B.A. degree, and after being graduated from that institution spent one year in the Atlanta Dental College, and then two years at the department of dentistry in the University of Maryland, receiving his D.D.S. degree with the class of 1895.

Shortly after receiving his diploma he elected to settle in Atlanta for the practice of his profession; and here his reputation as a dentist, together with appreciation of his character as a man, grew apace, and with the progress of the years he came to enjoy the patronage of a numerous and excellent *clientèle.* None had a wider circle of friends in Atlanta, nor was a more genuine favorite. He stood high in the community, while his character and talents were freely recognized by his professional brethren, among whom he was a prominent figure. He had recently been elected a vice-president of the Grady Hospital trustees. For many years he filled one of the chairs in the Southern Dental College. He was a member of the National Dental Association and of the Georgia State Dental Society, being elected president of the latter in 1911; also a member of the Atlanta Dental Society, serving as its president in 1910. He was a fraternity man and a Mason. At Trinity Methodist Church, of which he was a communicant and member of the board of stewards, he was a constant attendant.

Dr. Tigner married, in 1898, Miss Lula Singer, of Atlanta, who survives him. There are no children. His father also survives him, living at White Sulphur Springs, and he also leaves three brothers and three sisters, one of his brothers being Dr. Edward A. Tigner, Milledgeville, Ga., who is now the president of the Georgia State Dental Society.

After the funeral services at Trinity Church, the remains were taken to White Sulphur Springs and interred in the family burying-ground.

DR. ALLEN B. BRADLEY.

Died, September 2, 1913, at his summer home at Guilford, N. Y., Allen E. Bradley, D.D.S., of Norwich, N. Y., from an attack of angina pectoris.

Dr. Bradley had been somewhat indisposed for several days, but had been able to attend to his professional duties and was at his office on the Saturday previous to his sudden death.

Dr. Bradley was born in Guilford, N. Y., January 1861, was educated in the public schools of his native town, and secured his dental education at the University of Pennsylvania, from which institution he was graduated in 1882. The same year he located in Norwich, where he practiced his profession continuously.

April 22, 1896, he married Dora Elizabeth McCrea, daughter of Levi and Cordelia Maxson of West Burlington, N. Y. One child, Edward Maxson, was born to them, but died in infancy. Dr. Bradley is survived by his wife and his aged mother, to whom he has been devoted through the long years of her invalidism.

Dr. Bradley was a member of Emanuel Church. He several years ago attained the thirty-third degree Scottish rite in Masonry. Quiet and reserved in manner, and modest at all times, his life was largely given to the service of others, and his kindliness of heart evinced in many acts of self-sacrificing devotion toward his family and others won for him the admiration of all who knew him. He possessed remarkable mechanical ingenuity, and he was always ready and willing to use his talents in the service of a friend. His fondness for children was remarkable, and his kindliness and sympathy, his helpfulness and tenderness toward all with whom he came in contact, closely touched the lives of many of his townspeople who now mourn the loss of a loyal and helpful friend.

Society Notes and Announcements.

INTERNATIONAL DENTAL CONGRESS.

It has been thought advisable to arrange so that those who wish to attend the International Dental Congress, in London, next summer, may go on the same steamer, if they wish.

The plan is to arrange to sail on a steamer leaving New York immediately after the closing of the National Dental meeting, which will be held in Rochester, New York, early in July.

Those who wish to join the party sailing at that time will please notify me, at 560 Fifth ave., New York City, at as early a date as possible, in order that the steamship company may know how many to provide for.

Herbert L. Wheeler,
Transportation Committee, N. D. A.

INSTITUTE OF DENTAL PEDAGOGICS.

The next annual meeting of the Institute of Dental Pedagogics will be held in Buffalo, N. Y., January 27, 28, and 29, 1914. The Executive Committee is planning to present an exceptionally interesting program, which no dental teacher can afford to miss.

J. F. Biddle, *Sec'y*,
Pittsburgh, Pa.

NATIONAL DENTAL ASSOCIATION.

Date of 1914 Meeting Advanced One Week.

At the urgent request of the Local Committee of Arrangements at Rochester, the Trustees of the National Dental Association have advanced the date of the next meeting one week; therefore the eighteenth annual session will be held in Rochester, N. Y., July 7, 8, 9, 10, instead of July 14, 15, 16, 17, 1914, as originally selected. The officers, the local committee, and all other committees are going to put forth every effort to make this meeting, which is the first under the reorganization, the best in the history of the association, and we feel confident that the increased membership and interest in our association will prove a decided advantage in many ways.

Homer C. Brown, *President*,
Columbus, Ohio.
Otto U. King, *Gen. Sec'y*,
Huntington, Ind.

Research Workers Wanted.

Competent research workers are wanted by the National Dental Association. State qualifications, experience, languages read, and preference for pathological, biological, pharmacological, metallurgical, or anatomical work.

Address Weston A. Price, D.D.S., Chairman of the National Dental Scientific Foundation and Research Commission, 10406 Euclid ave., Cleveland, Ohio.

Back Copies of N. D. A. Transactions.

There are a few copies of the '07, '08, '09, '10, and '11 "Transactions of the National Dental Association," in the possession of Dr. Arthur Melendy. These copies, while they last, may be secured by libraries and other educational institutions and members of the N. D. A. by sending thirty cents per copy (to cover postage) to Dr. Arthur R. Melendy, Holston Bank Bldg., Knoxville, Tenn.

Otto U. King, *Gen. Sec'y*,
Huntington, Ind.

SCIENTIFIC FOUNDATION AND RESEARCH COMMISSION.

Research Bodies Consolidated.

The success attained by the Scientific Foundation Fund Committee in the securing both of money for a Foundation Fund for research and of the free use of many thoroughly equipped laboratories was so marked that the House of Delegates—which is the official body of the National Dental Association under its reorganization—by unanimous vote changed its constitution to provide for a commission of twenty-five men to immediately put into operation the complete plan of the Scientific Foundation Fund Committee for supporting and establishing exhaustive research and for securing funds for the endowment of a National Dental Research Institute.

The constitution was amended as follows:

The Committee on Scientific Foundation Fund shall be changed to a commission to be known as the National Dental Scientific Foundation and Research Commission. It shall consist of twenty-five members, who shall be elected by the Board of Trustees, not more than two of whom shall be from any one state. They shall serve for five years, except that of the first commission five shall serve for one year, five for two years, five for three years, five for four years, and five for five years, as shall be designated when they are elected. They shall meet annually at the time of the meeting of the National Dental Association, and at such other times as shall be designated by their Executive Board.

The duties of the commission shall be to raise funds for carrying on exhaustive dental and oral research, to disseminate scientific knowledge, to support, establish, and encourage research, and such other duties as shall pertain to the furthering of this cause. They shall select from their number an Executive Board of five members, which shall, when the commission is not in session and has not given specific directions, have general control of the administration of the affairs of the commission and general supervision of all arrangements for administration, research, and other matters undertaken or promoted by the commission. They shall organize and incorporate a corporation to be known as the National Dental Research Foundation and Institute, or such other name as the commission shall select, which corporation shall receive, invest, and disburse all the moneys provided by the commission and by themselves. They shall organize this corporation in accordance with the laws and requirements controlling such institutions, except that not less than one-third of the trustees of said corporation shall be provided by the National Dental Association. This corporation shall seek bequests, endowments, fellowships, and such other contributions as shall perfect the purpose of the National Dental Association. They shall make a written annual report to the commission and to the National Dental Association.

The commission was elected, met and organized, selecting their officers and Executive Board. The *personnel* of the commission elected is as follows:

WESTON A. PRICE, Cleveland, O., *Chairman.*
THOMAS P. HINMAN, Atlanta, Ga., *Vice-chairman.*
CLARENCE J. GRIEVES, Baltimore, Md., *Secretary and Treasurer.*
JOHN V. CONZETT, Dubuque, Iowa, Member of Executive Board.
E. R. WARNER, Denver, Colo., Member of Executive Board.
EDWARD C. KIRK, Philadelphia, Pa.
WM. CARR, New York City.
TRUMAN W. BROPHY, Chicago, Ill.
G. V. BLACK, Chicago, Ill.
M. H. FLETCHER, Cincinnati, O.
THOMAS B. HARTZELL, Minneapolis, Minn.
ARTHUR R. MELENDY, Knoxville, Tenn.
EDWARD S. GAYLORD, New Haven, Conn.
HENRY C. FERRIS, New York City.
CHARLES C. ALLEN, Kansas City, Mo.
FRANK O. HETRICK, Ottawa, Kans.
MARCUS L. WARD, Ann Arbor, Mich.
FRANK L. PLATT, San Francisco, Cal.
C. S. VAN HORN, Bloomsburg, Pa.
R. H. VOLLAND, Iowa City, Iowa.
C. M. MCCAULEY, Abilene, Texas.
GEORGE E. HUNT, Indianapolis, Ind.
EUGENE H. SMITH, Boston, Mass.
J. E. CHACE, Ocala, Fla.
SAMUEL H. MCAFEE, New Orleans, La.

The plan pursued by the Foundation Fund Committee was adopted, *i.e.* to raise funds from three sources—First, from the members of the dental profession, by their giving, as nearly universally as possible, a voluntary contribution each year for five years to start the work. This becomes necessary both for immediate funds and for indorsements of the work. Second, a popular fund from the laity, to be obtained largely by the activity of the members of the dental profession. Third, an endowment fund to make the work permanent.

The committee has already secured contributions exceeding $15,000 in signed individual pledges covering a period of five years, or $3000 per year, from the few societies to which the chairman was able to go and present the matter, as follows: Cincinnati, $2767, with the first year's payment entirely paid in; Columbus, $1200; Toledo, $500; Cleveland, $4010; Alumni Association of the Dental Department of the University of Iowa, $500; St. Louis Dental Society, $500; Alumni Association of the Louisville Dental College, $500; Indiana State Dental Society, $800; Washington, D. C., $705; Pennsylvania State and Susquehanna Societies, $782; contributions at the Kansas City National meeting, $2600; miscellaneous, $500; total, $15,364. It is expected that each state will provide in voluntary contributions an amount equal to five times the number of dentists in the state. On this basis, Ohio with 2400 dentists has already provided over $9000 of her $12,000 proportion.

The need for immediately assisting dental and oral research is such that the commission will begin work at once by providing technicians or laboratory assistants to make possible a much larger output from some of the men who are already voluntarily devoting a part of their time in dental researches and doing excellent work. This definite assistance to research work will be done to the amount of resources already available; however, present contracts will have to be limited to a total of $4000 for one year. This will be used to hire expert assistants for helping those who are doing excellent work and with available good laboratory equipment in the following subjects: Systemic infections having dental origin, pyorrhea alveolaris and kindred affections, etiology of caries, salivary analysis, etiology of erosion, dental amalgams, metallurgy for substitutes for platinum, etc., and the relation of foods to defective tooth structure. Ten of these expert laboratory assistants or technicians are greatly needed at once, and the $4000 available now will only permit of four or five of these. It is greatly desired that the members of the profession will arrange to have the subscription plan thoroughly organized at once in their respective conventions, so that the others can yet be placed this fall. It will require about an average of $5 per active member of dental societies to make up for those who cannot be reached. The subscriptions are running from $1 to $100 per year for five years. Literature and subscription blanks will be furnished by writing to the chairman of the commission.

This is only preliminary work, and the commission will engage the part or entire time of some expert research workers as soon as the funds can be obtained. The chairman has already secured for the National Dental Association privileges for research in the following laboratories and institutions: Cushing Laboratory for Pathological Research, Cleveland; Case School of Applied Science Research Laboratory, Cleveland; Iowa State University Research Laboratories; Michigan State University Research Laboratories; Hygienic Department of the United States Department of Health of Washington; Bellevue Hospital Research Laboratory, New York; Cincinnati Hospital Research Laboratory; Parke-Davis Research Laboratory, Detroit; University of Chicago, and several other competent institutions.

There are also a number of men with the research spirit found to be available whose heart is so engrossed in that work that they are now devoting much of their time and energy to it without compensation, but who have to struggle for the necessities of life. The commission will place some of these men in these available equipped laboratories as soon as funds can be secured. We do not present it as a professional duty, simply, but as a great personal opportunity; we do not ask of you self-sacrifice, but self-realization —for it is our privilege by supporting this work to help to emancipate society from its most universal malady and also the one that probably causes more total suffering, directly and indirectly, than any other.

WESTON A. PRICE, *Chairman*,
10406 Euclid ave., Cleveland, Ohio.

THE PANAMA-PACIFIC DENTAL CONGRESS.

THE work of the Committee of Organization of the Panama-Pacific Dental Congress is rapidly assuming definite form, and the entire general plan of the congress will shortly be announced.

The floor plans of the new municipal auditorium, in which the congress will meet, will be sent to all prospective exhibitors within the next thirty days. The exhibits will be held in the main hall of the auditorium, a room 190 feet square, affording ample space and light, and from present indications, all of this great area will be fully occupied. It is planned to make these exhibits and their accompanying clinics one of the great features of the congress, and they will, aside from the general program, afford a liberal education to anyone interested in modern dentistry.

Space in the auditorium has been reserved for the general sessions of the congress and for the meeting of its sections, and also for the dental societies and fraternities which will meet in San Francisco during the congress.

Three hundred thousand gum stickers, bearing the seal and date of the congress, will shortly be placed in the hands of dental dealers throughout the country, and every dentist who receives goods or letters from them will in this way be reminded that it is time to prepare for a trip to San Francisco in August of 1915, to attend the Panama-Pacific Dental Congress and the Panama-Pacific International Exposition.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

THE regular meeting of the Academy of Stomatology will be held Tuesday, November 25, 1913, at the College of Physicians, Twenty-second above Chestnut st., Philadelphia, Pa., at 8 P.M. Dr. Philip Fischelis, Philadelphia, will read a paper entitled "Present Status of Our Conception of the Peridental Membrane."

NORMAN L. JAMESON, *Sec'y*,
1429 Spruce st., Philadelphia, Pa.

FIFTH, SIXTH, SEVENTH, AND EIGHTH DISTRICT (N. Y.) DENTAL SOCIETIES.

UNION MEETING.

THE Fifth, Sixth, Seventh, and Eighth District Dental Societies of the State of New York will hold a union meeting at Elmira, N. Y., on November 20, 21, and 22, 1913.

H. H. TURNER,
Syracuse, N. Y.

OHIO STATE DENTAL SOCIETY.

THE forty-eighth annual meeting of the Ohio State Dental Society will be held in Memorial Hall, Toledo, December 2, 3, and 4, 1913. The program of papers and clinics carries the names of men of worldwide reputation. At a "Health and Science" conference on Wednesday evening we expect the governor of the state, James M. Cox; the presidents of the National Dental Association and of the American Medical Association; Dr. Kirk, editor of the COSMOS; Dr. Simon Flexner of Rockefeller Institute, and Dr. McCampbell, secretary of the State Board of Health.

Make hotel reservations early and arrange to attend the best and biggest meeting this society ever held.

F. R. CHAPMAN, *Sec'y.*

MARYLAND BOARD OF EXAMINERS.

THE Maryland Board of Dental Examiners will meet for examination of candidates for certificates November 6 and 7, 1913, at the Baltimore College of Dental Surgery, Baltimore, at 9 A.M. For application blanks and further information apply to

F. F. DREW, *Sec'y,*
701 N. Howard st., Baltimore, Md.

MICHIGAN BOARD OF EXAMINERS.

THE next regular meeting of the Michigan State Board of Dental Examiners will be held at the Dental College, Ann Arbor, commencing Monday, November 10th, and continuing through the 15th. For full particulars and application blanks address

F. E. SHARP, *Sec'y,* Port Huron, Mich.

PENNSYLVANIA BOARD OF EXAMINERS.

THE next regular examination of the Pennsylvania Board of Dental Examiners will be held in Philadelphia and Pittsburgh on Wednesday, Thursday, Friday, and Saturday, December 10, 11, 12, and 13, 1913. Application papers can be secured from the Department of Public Instruction, Harrisburg.

For further information, address

ALEXANDER H. REYNOLDS, *Sec'y,*
4630 Chester ave., Philadelphia, Pa.

INDIANA BOARD OF EXAMINERS.

THE next meeting of the Indiana State Board of Dental Examiners will be held in the State-house, Indianapolis, Nov. 10 to 15, 1913. All applicants for registration in the state will be examined at this time. No other meeting will be held until June 1914.

Notice. All persons legally registered for the practice of dentistry in Indiana are required, under Section 9 of the new statute, to register with the secretary of the State Board of Dental Examiners, ANNUALLY, on or before the 31st day of December. The annual registration fee is $1.00. Blanks will be mailed to each qualified dentist on December 1st. This act applies to those dentists who have left the state or are now not in practice.

For further information apply to

F. R. HENSHAW, *Sec'y,*
508 K. of P. Bldg., Indianapolis, Ind.

NEVADA BOARD OF EXAMINERS.

THE Nevada State Board of Dental Examiners will hold the regular semi-annual meeting November 21, 1913, at Carson City, Nev.

D. W. RULISON, *President,*
W. H. CAVELL, *Sec'y,*
Carson City, Nev.

DENTAL COMMISSIONERS OF CONNECTICUT.

THE Dental Commissioners of the State of Connecticut hereby give notice that they will meet at Hartford on Thursday, Friday, and Saturday, November 13, 14, and 15, 1913, to examine applicants to practice dentistry. Application blanks, rules, etc., will be mailed by the Recorder upon request.

EDWARD EBERLE, *Recorder,*
902 Main st., Hartford, Conn.

VIRGINIA BOARD OF EXAMINERS.

THE next meeting of the Virginia State Board of Dental Examiners, for the examination of applicants, will be held in the city of Richmond, Va., November 17, 1913, commencing at 9 A.M.

For further particulars address

J. P. STIFF, *Sec'y,* Fredericksburg, Va.

ILLINOIS BOARD OF EXAMINERS.

The semi-annual meeting of the Illinois State Board of Dental Examiners for the examination of applicants for a license to practice dentistry in the state of Illinois will be held at the College of Dentistry, University of Illinois, corner Honore and Harrison sts., Chicago, Ill., beginning Monday, November 10, 1913, at 9 A.M. All applications together with fee—twenty-six dollars—must be filed with the secretary at least five days prior to date of examination.

Address all communications to

O. H. Seifert, *Sec'y*,
49–50 Ridgely Bank Bldg., Springfield, Ill.

ARIZONA BOARD OF EXAMINERS.

The Arizona Board of Dental Examiners will meet at Phœnix, Ariz., beginning November 10, 1913.

Prospective candidates for examination should apply at once to Sidney P. Osborn, secretary of state of Arizona, at Phœnix, Ariz., for an application blank, and return same to him, properly filled out, together with the fee of twenty-five dollars.

The board also wishes to announce that the next meeting of the board, after the November 1913 meeting, will probably not be before October 1914.

As no temporary licenses are granted, it is desirable that all who contemplate applying for a license in Arizona, in the near future, should avail themselves of the next meeting of the board.

J. Harvey Blain, *Sec'y*,
Prescott, Arizona.

NEW JERSEY BOARD OF EXAMINERS.

The New Jersey State Board of Dental Examiners will hold their regular annual meeting and examination in the assembly chamber of the State-house, Trenton, N. J., on December 1, 2, and 3, 1913. Applications must be filed at least ten days prior to date set for examination.

After January 1, 1914, all applicants for a license to practice dentistry in New Jersey—"Shall present to said board a certificate from the superintendent of public instruction showing that before entering a dental college, he or she has obtained an academic education consisting of a four years' course of study in an approved public or private high school, or the equivalent thereof."

Also, after January 1, 1914, a bridge, consisting of three or more teeth exclusive of abutments, and one Richmond crown, will be required as a practical test in prosthetic dentistry, in place of a full set of teeth soldered upon a gold or coin-silver plate hitherto required.

For further particulars, apply to

Alphonso Irwin, *Sec'y*,
425 Cooper st., Camden, N. J.

IOWA BOARD OF EXAMINERS.

The next meeting of the Iowa State Board of Dental Examiners for the examination of candidates will be held at Iowa City, Iowa, commencing at 9 A.M., December 1, 1913. For particulars and application blanks write

J. A. West, *Sec'y*,
417 Utica Bldg., Des Moines, Iowa.

CALIFORNIA BOARD OF EXAMINERS.

The next meeting of the Board of Dental Examiners of California for the purpose of examining applicants for a license to practice dentistry will be held in San Francisco at the College of Physicians and Surgeons, beginning on December 3, 1913, at 10 A.M. All applications must be filed with the board on the morning of December 3d. Each application must be accompanied by a fee of twenty-five dollars, and the necessary credentials—diplomas or licenses from other states—together with a recent unmounted photograph of the applicant.

For further particulars, address

C. A. Herrick, *Sec'y*,
133 Geary st., San Francisco, Cal.

SOUTH DAKOTA BOARD OF EXAMINERS.

The next regular semi-annual meeting of the South Dakota State Board of Dental Examiners will be held at Sioux Falls, S. D., on Tuesday, January 13, 1914, at 1.30 P.M. Application for examination should be made between the dates of January 1st and 10th. For further information address

Aris. L. Revell, *Sec'y*,
Lead, S. D.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending September 13, 1913—(No changes).

For the week ending September 20th:

First Lieut. George D. Graham, on arrival in the United States, will proceed to Fort Ethan Allen, Vt., for duty.

Harry M. Deiber, ACT.D.S., relieved from duty at Fort Thomas, Ky., effective at such time as will enable him to comply with this order, and will proceed at the proper time to San Francisco, Cal., and take transport on November 5th for Honolulu, H. T., for assignment to duty.

First Lieut. Robert F. Patterson, relieved from duty in the Philippine Department, effective January 15, 1914, and will proceed to the United States.

First Lieut. Frank P. Stone, relieved from duty at Fort Ethan Allen, Vt., and will proceed to the Philippine Islands on December 5th, for duty.

First Lieut. R. E. Ingalls, August 14th, arrived at Fort St. Michael, Alaska.

First Lieut. J. R. Ames, September 12th, arrived at Fort Morgan, Ala.

H. M. Deiber, ACT.D.S., September 11th, arrived at Fort Crockett, Texas, for temporary duty.

First Lieut. F. L. K. LaFlamme, September 17, arrived at Fort Hancock, N. J., for duty.

For the week ending September 26th:

By Paragraph 4, S. O. No. 185, Headquarters Eastern Department, September 24th, First Lieut. F. P. Stone, granted twenty-five days' leave about November 3d.

For the week ending October 4th:

By Paragraph 6, S. O. 187, Eastern Department, September 26th, H. M. Deiber, ACT.D.S., granted twenty days' leave. Relieved from Crockett, and ordered to proper station before taking leave.

First Lieut. Robert T. Oliver, now on sick leave absence, is relieved from further duty in the Philippine Department.

For the week ending October 11th:

First Lieut. Robert T. Oliver is relieved from treatment at the Letterman General Hospital, Presidio of San Francisco, Cal., and will proceed to Fort Worden, Wash., for duty.

DENTAL COSMOS.

VOL. LV. DECEMBER 1913. NO. 12.

ORIGINAL COMMUNICATIONS.

FUNDAMENTAL ERRORS IN ANATOMIC ARTICULATORS.

By JOSÉ VALDERRAMA, D.D.S. (Univ.Pa.), Madrid, Spain.

[Translation by the DENTAL COSMOS.]

AFTER a hasty perusal of the remarkable article on Anatomic Articulation published by Dr. Gysi (see "The Problem of Articulation," by Alfred Gysi, DENTAL COSMOS, January, February, March, April, 1910), I concluded that the problem of the articulation of artificial dentures had been definitely settled. The amount of data furnished was so great that, startled at first by the importance of his discovery, I felt that it would be impossible to add to the findings of this distinguished investigator. After a more careful study of his work, however, and having acquainted myself more thoroughly with his latest model, the Simplex articulator, I determined to make a thorough examination of the subject. To my great disappointment I found that the last word on this important subject had not as yet been spoken—that, in fact, the most important questions remained still unsolved.

PROFESSOR GYSI'S ONE INNOVATION.

Dr. Gysi seems to base his principle largely upon the studies of former investigators, but he further suggests a modification of the anatomic forms of artificial teeth;—this, in fact, appears to be the only innovation presented by Dr. Gysi. Although he succeeds in combating the common mistake of considering the curve of Spee as a compensating curve instead of a subsidiary curve, his work seems to lack the importance which it originally seemed to have in the construction of artificial dentures. The original part of his work consists in his clear determination of the compensating cusp and the modification of the occlusal surface of the molars, as well as the measure of inclination of the lingual surface of the upper incisors.

It is not my intention to minimize the merit of Dr. Gysi's work, for after many years of laborious study on this difficult problem he has given us some useful data that have contributed to a better understanding of the actual conditions of the temporo-mandibular articulation. Since Dr. Gysi, however, has overlooked some very important facts, I consider it my duty to attempt to rectify some of his mistakes by further research in this field.

BONWILL'S TRIANGLE.

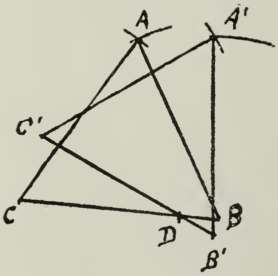
The gross error of all those who have undertaken the study of anatomic articulation lies in the fact that they have not given due consideration to Dr. Bonwill's remarkable ideas. They all try to demonstrate that he was wrong in his deductions regarding the anatomic articulator, thereby doing great injustice, I believe, to this investigator. In my opinion, all future efforts at designing an anatomic articulator will greatly profit from a more thorough study of Bonwill's maxillary triangle. In measuring some of Bonwill's triangles it is found that hardly any of them are equilateral, and this observation has led some to believe that Bonwill's statement was purely hypothetical. When judged from this point of view it is of course clear that Bonwill's law will not stand; but nobody has taken the trouble of finding out why this law does not hold good. Had efforts been made in this direction, the conclusion would have been reached that the maxillæ present a certain irregularity of occlusion, and naturally a law which is the expression of an ideal condition will not hold good in an anomalous case.

Even the ancient writers knew that there are mouths with teeth of abnormally large size, but in their observations they took into account merely the irregular arrangement of the teeth in the arch, without giving due consideration to the dimensions of the arch and of Bonwill's triangle. This relationship, of the significance of which I shall speak presently, is faithfully representable in accordance with Bonwill's triangle, for it is impossible to place the teeth correctly in the dental arch when the maxillæ are not of the proper dimensions. As soon as the maxillæ are restored to their normal proportions there will be sufficient space to accommodate the teeth in the arches, and all irregularity will disappear. There are cases, however, in which the proper relationship of the size of the teeth and the maxillæ is altered; then we have irregularities not exactly of position, but of lack of proportion in size, and this requires a special study.

ERROR OF ANATOMICAL ARTICULATORS IN LATERAL MOVEMENTS.

In the course of this investigation I shall discuss several points which have heretofore been misapprehended, and the consequent misrepresentations accepted almost as axiomatic truths. It is generally believed that the mandible in its lateral movement swings in the condyle; all the anatomic articulators were equally defective until Dr. Gysi in his articulator adopted an improvement in this respect. I shall prove, however, that he failed to profit from the teachings of Dr. Walker, who pointed

Fig. 1.



out the error in the lateral movements of the anatomical articulators (see Fig. 1).

The triangle A B C swings in point D instead of B. These points which in nature are true axes, we shall denote as axes of rotation. Dr. Gysi, however, studied the slant of the condyle through the eminentia articularis of the temporal bone so carefully that we owe to his investigations the present anatomic molds, which are correct as far as the inclination of the occlusal planes is concerned, though they are defective in their mesiodistal dimensions. The only cause for Dr. Gysi's error, as far as I can see, is that he failed to study Bonwill's triangle, and concentrated his efforts upon less important, though perhaps interesting details.

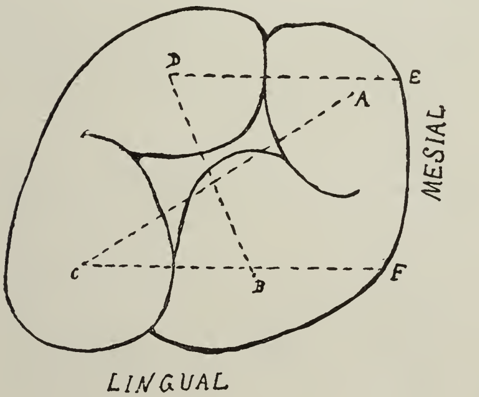
It has been fully established that a correct articulator must not only represent the movement of the condyle, but must also permit of setting up the models in such a manner that the alveolar borders occupy the same distance from the condyles as in the human mouth. It is furthermore of the greatest importance to maintain the greater or lesser parallelism of the alveolar borders in relation to the position of the condyles. Careful study of these details by investigators of note has resulted in the designing of articulators which facilitate the study of this relationship between the condyles and the alveolar arches. Preference is given, however, to the ideal arrangement of the teeth in relation to the condyles during the process of mastication, while in reality the relations of both of these factors, statically considered, should have been studied first.

DIMENSIONS OF OTHER TEETH REPRESENTED IN CERTAIN DIMENSIONS OF THE MOLAR.

We should first consider the simplest relation, viz, that of the teeth toward one another. If there be such a relation, how is it that, though we have anatomic articulators and aim to copy anatomic articulation, our artificial teeth are not made accordingly?

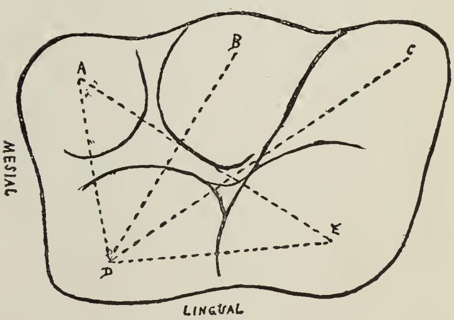
A macroscopic study of the teeth tends to show that the molars are a combination of simpler forms of teeth, and that, as can be seen in Fig. 2, the dimensions of other teeth are represented in this most complex tooth. For the purpose of our deductions we shall study the first molar, which is the most complicated but has the most important masticatory function and occupies the most important position in the arch.

FIG. 2.



The upper central incisor is equal in mesio-distal dimension to the distance between the mesio-buccal and the disto-lingual cusp, or A C. The lateral incisor is equal to the distance between the mesio-buccal angle and the disto-buccal cusp, or E D. The canine is equal to the distance between the mesio-lingual angle and the disto-lingual cusp, or F C. The first bicuspid is equal to the distance between the mesio-lingual and the disto-buccal cusp, or B D, and the second bicuspid is equal to the distance between the disto-lingual and the disto-buccal cusp, or D C. I have observed that when the first bicuspid is wider mesio-distally than the second bicuspid, which is most commonly the case, the first molar shows a greater distance from the disto-buccal to the mesio-lingual cusp than from the disto-lingual to the disto-buccal cusp.

FIG. 3



In the lower teeth the central incisor is equal to the distance between the mesio-buccal and the mesio-lingual cusp, or A D (Fig. 3). The lateral incisor is equal to the distance between the mesio-lingual and the disto-lingual cusp, or D E. The canine is equal to the distance between the disto-lingual and the mesio-buccal cusp, or E A. The lower first bicuspid is equal to the distance between the mesio-lingual and the middle buccal cusp, or D B, and the lower second bicuspid is equal to the distance between the mesio-lingual and the disto-buccal cusp, or D C. It is peculiar though less frequent, that when the lower first bicuspid is equal to the second bicuspid, the disto-buccal cusp is either absent or very rudimentary.

NATURE'S PATTERN FOR THE MORE IMPORTANT DIMENSIONS OF ARTIFICIAL TEETH.

Thus nature furnishes us with a pattern from which we should be able to reproduce artificially the most important dimensions of the teeth for our anatomic purpose. It is useless to try to obtain perfect results with sets of artificial teeth which resemble the natural teeth merely in color.

New molds have recently been put on the market which show an improvement over the old ones, this improvement consisting in the size of the molars and their masticating surfaces, which occlude with their antagonists in such position as to save the operator the tedious task of grinding off the unnecessary surplus of porcelain. I have noticed, however, that while some molds conform to the above-mentioned rule in regard to the mesio-distal dimension, this important rule has been entirely disregarded in other molds. This deficiency I am convinced, could be corrected if my observations were duly considered. This is not a presumptuous claim—for by moving forward and backward the first molar, and either narrowing or widening the mesio-distal diameter of the teeth as compared with what they really should be, we shall never be able to obtain the exact relationship between the condyles and the occlusal surfaces of the molars. The compensating cusp, therefore, will not have the right place either as regards position or as regards dimensions in relationship to the axes of rotation. The three points of contact demanded in the occlusal and incisal surfaces will not be correct, because the articulator is directly influenced by the models, viz, by the alveolar arches, so that these may allow room for teeth of sizes different from those which are naturally required.

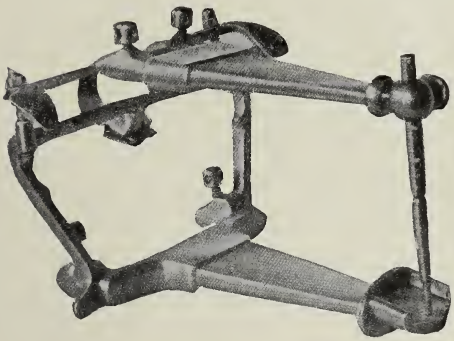
It seems strange that no special rule is followed in the selection of teeth for every individual case. There is a rule which has some merits, but is not scientific enough to be relied upon by the dentist who wishes to obtain accurate results. This rule is used for determining the position of the distal surfaces of the canine by the commissure of the lips when closed, but it is evidently unsatisfactory for obtaining exact results. It is ridiculous to employ a complicated arc to learn the exact position of the models on the articulator and the condyle path, and afterward use a method of more or less the same nature for the selection of the teeth.

Here we have to turn once more to the equilateral triangle. It has been emphatically asserted that articulation is not a haphazard movement, but one that is immutably based on well-established principles. If this is so, why do we not apply the same rule to the selection of artificial teeth? Each mouth requires a special size of teeth. The length of the side of the triangle may vary in different persons, as has been noted by Bonwill, who assumed a side of four inches to be typical, but the relative length of the side of the triangle as compared to the mesio-distal width of the teeth is always constant.

SHORTCOMINGS OF DR. GYSI'S "SIMPLEX" ARTICULATOR.

Dr. Gysi, in his endeavor to simplify all the operations necessary for obtaining the desired results, and to establish an anatomic articulation, introduced the Simplex articulator (see Fig. 4), with several accessories. But the problem is really not solved if we compare the efficiency of this apparatus with that of other anatomic articulators. The conditions to be taken into account in each case vary so greatly that it is unscientific to disregard their significance and to argue, like Dr. Gysi, that it is impossible to induce all practitioners to familiarize themselves with all the scientific detail necessary for the use of his articulator and for the exact reproduction of the movements of the mandible. If, of course, he is looking only for financial success, I have nothing to say against his Simplex articulator. On the other hand, if his idea was to present this articulator as an improvement over others, even though it be free from some of the imperfections of the Kerr, the Gritman,

Fig. 4.

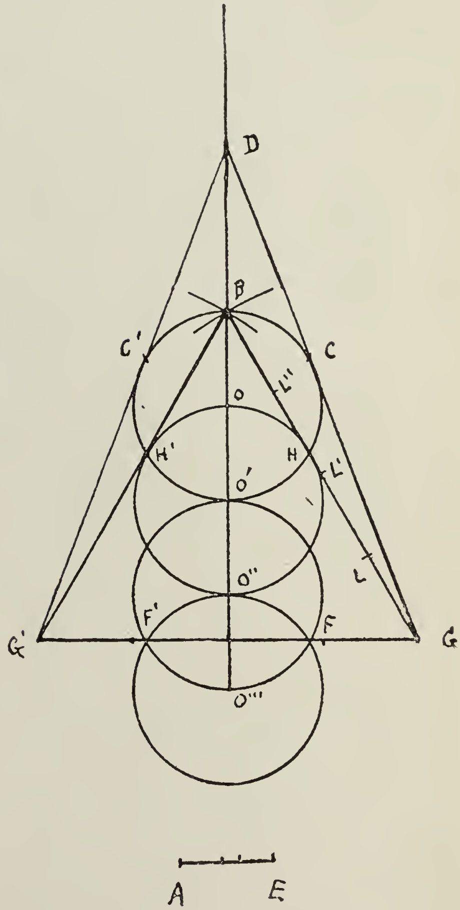


and other articulators, it possesses other defects in contradiction of Dr. Gysi's own statements which make it even worse than the others. Why should we emphasize the importance of the compensating cusp and of the axes of rotation, etc., and then proceed to say that these factors are not so essential?

ON THE RELATION BETWEEN THE SIDE OF THE BONWILL TRIANGLE AND THE MESIO-DISTAL WIDTH OF THE TEETH.

What, then, is the relation between the side of the triangle and the mesio-distal width of the teeth? I have formulated this relationship by saying that the sum of the mesio-distal widths of the central and lateral incisors and of the canine on one side of the mouth is equal to one-fourth of the total length of the side of Bonwill's equilateral triangle. Let us see how we deduct, *a priori*, the size of the three teeth mentioned from the one-fourth of the equilateral triangle (see Fig. 5). Let B G be the side of the equilateral triangle, and let the distance L G be equal to the line A E, below, or the sum of the mesio-distal widths of the central, lateral, and canine. With A E as radius, a circle O is drawn, B O being equal to A E, and we mark the arcs B C and B C′. Upon the prolongation of the diameter B O′, the distance O′ C is transferred, making B D equal O′ C, and the tangents D C and D C′ are drawn and prolonged. Around point O″ on the prolongation of the diameter B O′ another circle

Fig. 5.

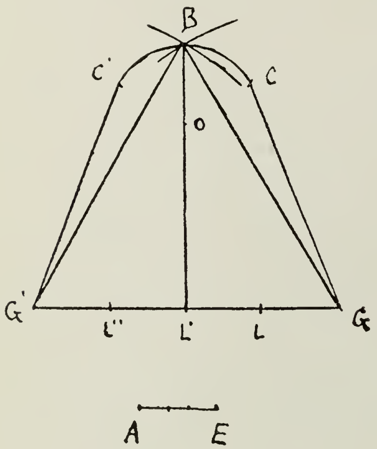


O″ is drawn with radius A E, and in the same way a circle O‴. The circumferences of circles O″ and O‴ intersect each other at F and F′. These two points are united, and the line F F″ is prolonged on either side until it meets the prolongations of the tangents D C and D C′ at G and G′. The lines B G and B G′ are drawn, and on one of the sides of the triangle B G G′ thus formed, the radius

A E is measured off, when it will be seen that A E can be marked off four times on a side, making G L plus L L′ plus L′ L″ plus L″ B equal 4 A E. In other words, the sum of the mesio-distal widths is contained four times in the side of Bonwill's equilateral triangle corresponding to the maxilla to which these three teeth belong.

We may employ Dr. Hawley's method for describing the parabola, it being better known than mine, and simply draw the circle O and the arcs B C and B′ and O′ H and O′ H′, then measure off the distance B D, draw the sectors B H and B H′

Fig. 6.



and the tangents D C and D C′, and prolong both to their intersection at points G and G′, which represent the condyles.

I prefer, however, a simpler method which is based on the previous observation and has the advantage of involving fewer lines and circles, therefore fewer possible errors (see Fig. 6). On the line G G′ starting from the point L′, the distance A E is measured off on either side, making L′ L plus L G equal L′ L″ plus L″ G′, G G′ to form the base of the equilateral triangle. The vertex B of this triangle is obtained by describing circles with radius G G′ around the points G and G′. In order to find the parabola we draw the perpendicular B L′, and from B measure off the distance B O, equal A E. Around O we describe a circle with a radius A E, marking off points C and C′, with a radius B O, which, as we have seen, is one-fourth of the total length of the side of the equilateral triangle. By drawing the lines C G and C′ G′, the parabola is obtained.

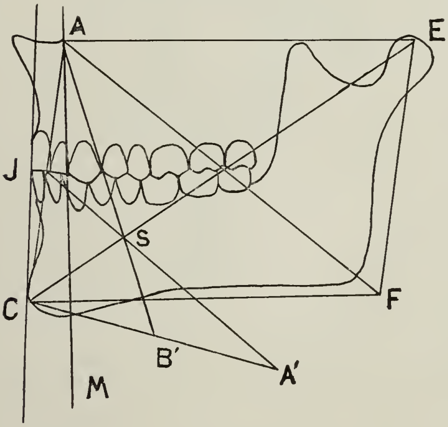
WELL-DEFINED RULES IN THE SELECTION OF ARTIFICIAL TEETH.

We very rarely find a case in which the lower is represented with exactness, but if due consideration be given to this law, little effort is required for discovering all the irregularities in the individual face, and not only those of occlusion—which is the only feature that Hawley, Herbst, and others have been able to establish. Even in fairly perfect occlusion, the law of the intermaxillary parallelogram and the law of the profile, which I have discovered, will be appreciated, though there be no absolute perfection in the occlusion under observation. I do not care to go into the details of this point, not wishing to offer tedious and complicated explanations.

It has been demonstrated that the selection of teeth is not a haphazard matter, but subject to perfectly fixed and well-defined rules. My remarks up to this point refer to the mesio-distal width of all the teeth, and I have proved that Dr. Gysi has overlooked this dimension in forming his new molds of artificial or "anatomic" teeth, as he calls them. It is inconceivable that such an intimate and exact relationship should exist between the side of the equilateral triangle of the maxilla and the sum total of the widths mesio-distally of the lateral, central, and canine, without there existing any relationship between these three teeth and the others of the set.

We know, then, the relative width of the artificial teeth to be used. In the following I shall show that the mathematical accuracy of my findings does not only apply to these dimensions, but holds good in any measurement we may take, and we shall see how the arrangement of these three teeth is related to the maxillæ. In Fig. 7, let us mark the four points of reference A E C F, proposed by me, and after having joined them and formed the intermaxillary parallelogram, let us draw the diagonals A F and E C. After making angle A′ C E equal angle A C E, and A′ C equal C A, C A′ is bisected at B′ and united with A. The line A B′ then forms a tangent to the distal surface of the upper canine in normal cases. The diagram makes us realize what important conclusions we may draw therefrom. A J is equal to J C, which in the perfect skull is equal to the gliding surface of the lingual surface of the upper central incisors. C B′ is equal to B′ A′,

Fig. 7.



therefore the point of intersection of A B′ and A′ J will coincide with the point S of the axis of symmetry C E. If it does not coincide, we at once see whether point S lies above or below the axis C E, that is, whether J C is longer than J A, or the reverse. Therefore without the patient having to open his mouth we note whether the line of occlusion is normal or not. What has been said of angle C A E applies to angle A C F, the line that in angle C A E is represented by A B′ coinciding with the distal surface of the canine, and we can therefore draw the same conclusion regarding point S, which in angle A C F we can call S′. In the diagrams, Figs. 8 and 9, which have been drawn from photographs of natural skulls, it can be seen that the distal surface of the canine is at variance with the rule, which is sufficient evidence for diagnosing mesio-occlusion, as confirmed by the point of intersection of the diagonals and by the line of profile. Supposing my rules to be mathematically correct, it is to the irregular cases that they apply most, because we can see to the

Fig. 8.

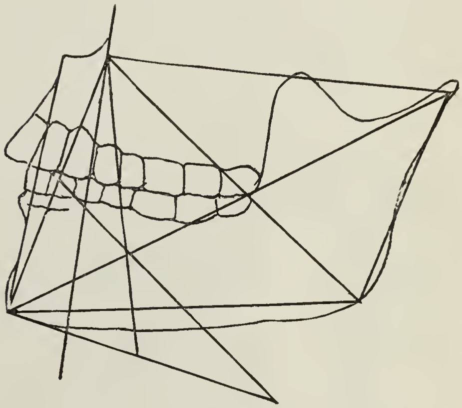


Fig. 9.

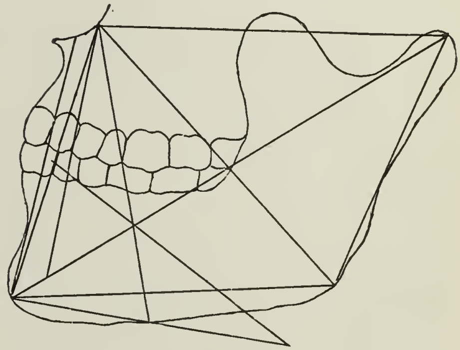


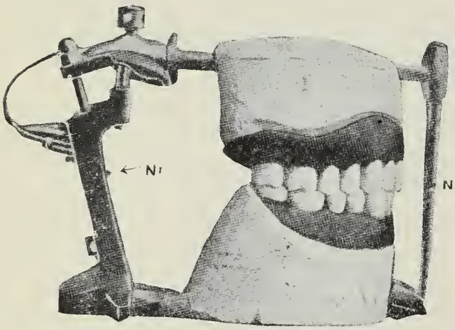
very millimeter how far they differ from the normal, which it has hitherto been impossible to find out, inasmuch as previous to my discoveries nobody knew the size or position of the teeth in the arches, nor their position and relation in the maxillæ, nor their relationship toward one another, nor their relation in regard to the rest of the skull.

Dr. Gysi states that in abnormal cases it is not advisable to make perfect prosthetic pieces; but let me ask, What rules has he given for distinguishing these abnormal cases and determining the imperfections which they present?

THE INCISOR GUIDE BASED ON AN AVERAGE MERELY.

A feature of greater importance in Dr. Gysi's articulator is the incisor guide and the axes of rotation in the mandible. This incisor guide (see N², Fig. 10) is all right as far as it goes, but although he has assigned to it the important function of determining the degree of inclination

Fig. 10.



of the lingual or gliding surface of the upper centrals, he has been obliged to desist from adjusting it in every case, and for this contrivance has determined from average use merely, thereby limiting its exactness. As to the axes of rotation, he first emphasizes the fact that it is impossible to obtain perfect mastication unless we reproduce the free movement of the mandible in our prosthetic work, while he then states that this theory cannot be applied to each individual case, and leaves off from his articulator all changeable and movable parts, adjusting everything to some arbitrary measure which is very different from the conditions actually found.

I cannot understand why all designers of anatomic articulators make the mistake of putting rigid bars between the condyles. Dr. Snow, and after him Dr. Gysi, have used the face-bow to determine the exact distance of the mesial point of the parabola as regards the condyle. He therefore must appreciate the enormous importance of this fact, which is nothing but an interpretation of Bonwill's triangle. Knowing the merit of this triangle, why should these men then insist upon destroying its equilaterality? What weighty reason have they for disregarding so deliberately an established principle?

THE THREE IMPORTANT FACTORS.

The problem of articulation is based on three important factors, the careful

Fig. 11.

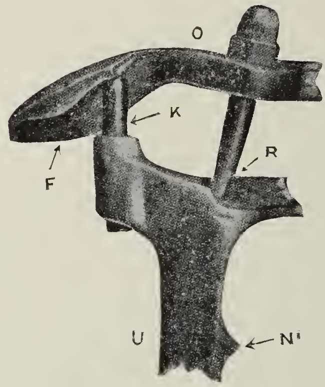


Fig. 12.

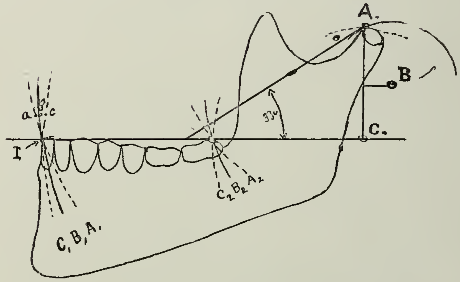

consideration of which will insure perfect results. These are—First, the condyle path. Second, the axes of rotation. Third, the size of the teeth. For a long time it was believed (and all anatomical articulators are based upon this principle) that it is only necessary to know the condyle path, until Walker, and shortly after him Gysi, showed the importance of the axes of rotation. I have demonstrated, further, how essential it is to consider also the mesio-distal width of the teeth.

Gysi remarks that it is very difficult to determine the first two factors—the third one he ignores entirely—since each case requires a great deal of careful testing, and after compiling all available data he formulated tables which enabled him to group into four classes the teeth to be employed, relating them to the condyle path. Each case presents a different condyle path, he says, but the variation is slight as far as these four groups are concerned, and he therefore gives his articulator a fixed and conventional inclination of the condylo-temporal slant (see Figs. 11 and 12). This is rational, since this path only indicates to us the degree of inclination of the slanting cusp surfaces. It does not matter whether we know their inclination or not, because this factor is present in every case, and in testing the articulation we can see whether the error is of any great account. The other two factors Gysi leaves out of consideration entirely. The axes of rotation he has tried to reproduce in his articulator; but, though recognizing the great importance of this factor, he fails to indicate a precise rule for readily determining these axes. He says that without an exact knowledge of these axes the canines cannot be placed in their correct position, which will prevent the lateral displacement of the plates.

Fig. 13.

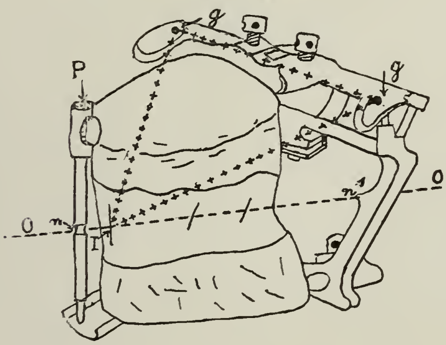

Fig. 14.

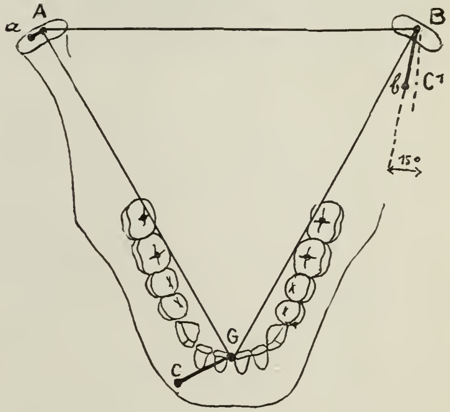
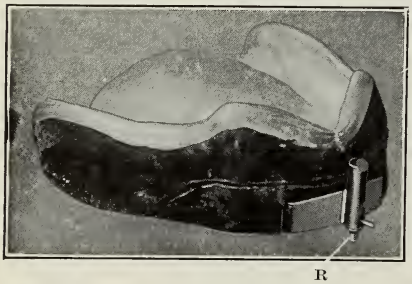


Neither does Gysi refer to the width of the teeth, because he fails to recognize the importance of this factor in its bearing upon articulation. The process of determining the axes of rotation is a rather complicated one, and Gysi was so fully aware of this difficulty that in his last articulator the axes of rotation occupy two fixed points representing the mean distance found in the cases observed by him. Where do we stand, then? Is it, or is it not, indispensable to know the exact situation of the axes of rotation? If it is indispensable, a method for their easy determination must be found, but Gysi should not have made the mistake of making them fixed in his articulator—because thereby he only contradicts himself.

After some study I have devised a method for determining mathematically in a few minutes the correct situation of the axes of rotation in every case.

Gysi employs the following process for determining the movements of the lower incisors over the lingual surfaces of the uppers. He inserts two plates of modeling compound held together by gum tragacanth in the patient's mouth (see Figs. 15 and 16). In the upper plate a graphite pencil, R, is fixed, which being influenced by a spring has a tendency to glide downward. The lower plate carries a horse-shoe-shaped metal plate S, to the upper surface of which a recording card is attached. Placing both plates in the mouth, the median line coincides with R and M. If the patient moves the mandible to one side, one of the lines M K will be marked by the pencil, depending upon whether the mandible is moved to the right or to the left. After learning the path of the lateral movement of the lower incisors over the lingual surfaces of the upper, we only have to remember that this path depends

Fig. 15.



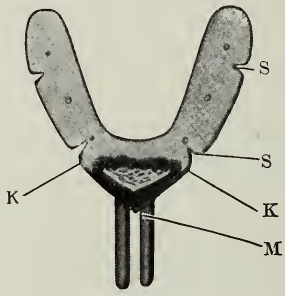
on the relationship of the axes of rotation to the mandible, the condyles being the true posterior guides of the mandible in this movement, in the same manner as the lingual surfaces of the upper incisors are related to the anterior portion of the mandible.

METHOD OF DETERMINING THE AXES OF ROTATION.

In order to determine the axes of rotation, I pick up the recording card on which the incisor path is drawn, and carefully measure the distance between K and the condyle. The modeling-compound plate being in correct occlusion coincides with their median line. After determining these two points, let us reconstruct Bonwill's equilateral triangle (see Fig. 17): Let A B be the base of the triangle, or the distance between the condyles; B C the side of the triangle, the measure for which I have obtained in the patient, and A C, the third side of the triangle with vertex C, on which I place the recording card that I have removed from the modeling-compound plate. As the position of the recording card at point C may vary from normal, I figure the distances between the end of the path C E or C D and the condyle. I have already pointed out that the triangle A B C will furnish us with some valuable data for perfect articulation, and we also know that the side A B gives us the width which the central, lateral, and canine should have.

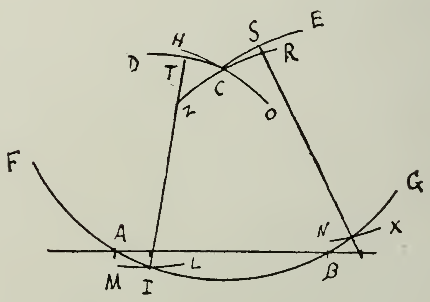
It is well to consider that in the cases in which there is a great difference in

Fig. 16.



the lengths of the sides of the triangle, we should not select at random any one of the sides and divide it into four parts in order to find the total width of the three teeth mentioned. In such cases, the average length of the sides of the triangle must be determined so as to

Fig. 17.



make an equilateral triangle and to obtain an harmonious result.

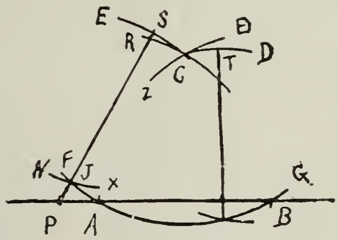
In order to determine the axes of rotation in a given case, I reconstruct the triangle and place the record card in position; using C as center, an arc F G is drawn so that it passes through the condyles A and B. With the same radius and using D as center I draw the arc M L, which will intersect arc F G in I.

Before proceeding farther, I wish to

emphasize the fact that the arcs of the path the centers of which lie outside of the line connecting the condyles are farther away from the base of the triangle than the regular slanting curve of the vertex; if the triangle swings upon each one of its corners—in other words, if the center of the curve C D lies upon the line connecting the condyles A and B —the curve C D will be found nearer the base A B than the curve C H, which is the one that passes through the point C if we make the triangle swing on A.

In the same way, if the path curve C E lies outside of line A B, it will be found

FIG. 18.



farther away from the base A B than the regular arc C R.

We know, then, the point in which the arc M L intersects arc F G. Joining the middle of the arc D C with point I, it will be seen that the line T I intersects the base A B in one point, which is the axis of rotation of the curve D C. In the case of the curve C E, the arc N X is drawn with radius C B around point E; this arc will intersect the arc F G, and when the middle of the curve C E, or S, is connected with this point of intersection, and this line of connection is prolonged, the point in which it intersects the base A B is the axis of rotation of the curve C E.

When the triangle A B C is not equilateral (see Fig. 18) we proceed in the same way, only with the difference that we draw the arc F G with the radius B C when dealing with the curve D C, and with the radius A C when dealing with the curve C E. Thus the arc F G fits only the equilateral triangle, and is independent of the angles A and B when we have a triangle that is not equilateral. In drawing the arc N X corresponding with the cuve C E, we use, of course, the radius C A, and for curve D C the radius C B.

As is seen, this process is neither difficult nor complicated, though it has cost me many hours of hard work.

In the foregoing we have analyzed the three factors that we proposed to study, and the explanations given cover the entire problem of articulation in its most essential points. This means a great deal to the prosthetist who looks for results that guarantee stability and perfect occlusion in this work.

SUMMARY.

In conclusion, I will summarize my studies as follows:

First. The sum of the mesio-distal widths of the central, lateral, and canine on one side is equal to one-fourth of the total length of the side of Bonwill's equilateral triangle.

Second. The mesio-distal dimensions of the other teeth are not arbitrary, but stand in close proportional relationship to the dimensions of the first molar.

Third. The present anatomic articulators should be modified by rendering the distance between the condyles adjustable, so as to enable one to obtain the base of an equilateral triangle.

Fourth. In each case we must determine the axes of rotation, to adjust the set-screws which represent them in the anatomic articulator at the correct distance from the condyles, by means of the calculation herein suggested.

DEFORMITIES OF THE JAWS FOLLOWING TREATMENT FOR SPONDYLITIS.

By Dr. Med. O. TREYMANN, Zahnarzt, Berlin.

[Translation by the DENTAL COSMOS.]

THE paper of Dr. G. Lind of Amsterdam, on "Deformity of the Jaws Caused by the Extension Bandage in the Treatment of Spondylitis," published in the January 1913 issue of the DENTAL COSMOS, page 13, is of general interest to medical as well as dental practitioners, as the writer's observation is not an isolated one, but ever since Calot's therapeutic experiments in the treatment of gibbosity ("hunchback") it has repeatedly given rise to scientific researches in various countries, though no satisfactory solution of the problem has been arrived at.

The progress, however, that has been made in the field of orthodontia, together with the improvements in the orthopedic treatment of scoliosis (spinal curvature), is apparently bound to do away with the undesirable sequelæ by the institution of suitable precautionary measures. In his classic monograph, Ménard[2] in his chapter on "Pathologic Anatomy and Therapy of Spondylitis," speaks of deformities of the jaws being caused more or less frequently by months of wearing a corset with a collar-like head support. (See Fig. 1.) After mentioning the untoward effects upon skin and muscles, chest and abdominal organs, he says of the dental deformities: "Often the angle of the lower jaw is slightly altered, and the dental arches are displaced, the lower posteriorly, the upper anteriorly."

Ménard's statements were supplemented by the demonstration of three cases given by Drs. Spitzer and Werndorff,[3] in 1907, before the Congress of the German Society for Orthopedic Surgery, under the title of "Entropion [introversion] of the Mandible."

These jaw deformities had been produced within from three to six months by Calot's extension bandages extending around the chin, and they exhibited the following similar typical characteristics: "By the leather strap extending around

FIG. 1.

the chin portion of the mandible, the alveolar arches and the lower anterior teeth had been pushed back lingually two centimeters behind the upper teeth." In another case observed by Dr. E. von der Osten-Sacken in Professor Turner's clinic in St. Petersburg,[1] the temporomaxillary joint had been distended so as to produce subluxation of the mandible accompanied by extremely painful ankylosis. Upon cutting away the chin portion of the plaster collar, return to normal occurred within one year.

The investigations of Dr. von der Osten-Sacken published in the statistics of the orthopedic clinic of Professor Turner,[1] furnish us with some interesting data as to the origin of these jaw deformities the consequences of orthopedic treatment by braces, continued careful observation showing that, during the application of various appliances for extension, not only the chin-plate of the supporting corset, but the very weight of the head itself and the impediment in masticatory function, sufficed, especially during the period of second dentition, to produce a deformity of the alveolar arches, anomalies in the position of the teeth, and above all a retardation in the growth of the mandible. "The untoward stimulus need be neither permanent nor intense, only irritating and frequent."

Neither is this surprising, since modern orthodontia has proved how extensively the alveolar arches react not only toward mechanical, but also toward functional stimuli, whether of pathological or of physiological nature. Thus alveolar protrusion in children is produced mechanically by continual sucking of the middle finger, and upper prognathism combined with trapeze-shaped flattening of the mandible and the mandibular arch by sucking of the thumb, which acts as an inclined plane. In this category belong also the deformities caused by macroglossia, neoplasms, and cicatricial tension. Of functional origin are the deformities of the jaws in mouth-breathing, in paralysis of the facial nerve (see Perthes[4]), in ankylosis of the temporo-maxillary joint, in congenital absence or operative loss of the masseter and temporal muscles, as well as all the changes in the direction of growth of the body of the jaw and coronoid process due to changes in the direction of muscle strain during fetal life and after birth.

The published cases show that the faulty construction of the supporting corsets always produces a typical retardation in the development of the mandible longitudinally as well as a retroversion of the alveolar arches, while secondarily prognathism of the maxilla and its alveolar arches occurs.

A side view of the head as carried by the typical kyphotic, or hunchback, reveals a certain resemblance with the "bird face" in the micrognathous,[4] and the so-called Aztec heads described in anthropology, which are also to be ascribed to retardation of growth at an early stage of development. (See Fig. 2).

Fig. 2.

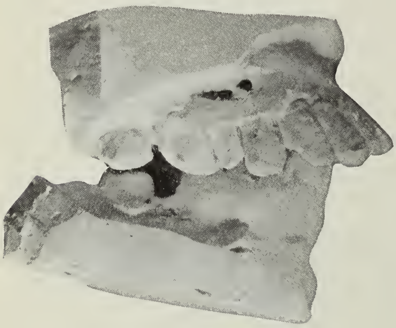
Patient of seventeen, with congenital underdevelopment of the mandible and trismus (v. Langenbeck, *Arch. f. klin. Chir.*, vol. i.)

From the above considerations it seems as if Dr. Lind's proposition,[7] to replace the chin-support of leather by an accurately fitting metal appliance made after an impression, would be as unsatisfactory as a retention coffin plate, unless at the same time the corset supporting the head is shaped so that the anterior mandibular arch is relieved of all pressure, and the burden of the weight is transferred to the occiput and the mastoid processes, so that the head is free to turn and mastication is unimpeded.

A certain degree of improvement in this direction might be obtained with those modern appliances which are employed in the orthopedics of the diseased spine, in scoliosis or kyphosis, by means of the "reclination" method instead of the "extension" method formerly employed.

It should not be left unmentioned that specially careful attention is to be devoted to the alterations in the jaws of tabetics that are being treated by the so-called suspension method, which involves considerable stretching of the spinal column; since, owing to trophic disturbances occurring in the trigeminal area, complete loss of sensation may ensue, followed by atrophy of the alveolar arches, and even brittleness and fracture of the bone. In these cases the employment of interdental splints for temporary treatment, and the most recent Angle appliances (see DENTAL COSMOS, January 1913, page 1) for prolonged treatment, seems to be indicated as a precautionary measure.

FIG. 3.



As an addition to the literature on these cases, the casts from a woman of forty years are reproduced (see Fig. 3) showing a jaw deformity which has remained as a sequel to treatment for spondylitis instituted during the patient's childhood, and which, owing to the application of suitable supporting appliances, has assumed a tolerably stationary character. The lower alveolar arches are shortened and narrowed, the bicuspids and first molars showing considerable inversion. The prognathous projection of the upper jaw is probably of secondary origin, due to pressure of the lower anterior teeth from below upward. Possibly we have to deal with compensating processes of growth according to Wolff's law of transformation. No history of hereditary influences was present in this case.

Judging from our present survey of this field of typical jaw deformities, modern orthodontia undoubtedly commands sufficient technical means to open a fertile field for its activity in co-operation with orthopedic clinics, and to offer the benefit of rational treatment to many of these pitiful cases.

SOMETHING OF THE ETIOLOGY AND EARLY PATHOLOGY OF THE DISEASES OF THE PERIDENTAL MEMBRANE, WITH SUGGESTIONS AS TO TREATMENT.

By ARTHUR D. BLACK, A.M., M.D., D.D.S., Chicago, Ill.

(Read before Section II of the National Dental Association, at its annual meeting, Kansas City, Mo., July 8, 1913.)

THE consideration of diseases of the soft tissues adjacent to the teeth has always occupied a prominent place in the literature of dentistry, and yet a review of many articles cannot fail to impress the fact that there has been little effort to mention in detail and proper sequence the pathological changes which take place in these tissues, nor to separate definitely several of the most common lesions which we are constantly called upon to treat. As a natural result the profession has apparently failed to recognize and differentiate these lesions and has also failed to apply treatment during the early stages, while there is the opportunity to cure them. This seems to be partly due to the fact that the elapsed time between the initial lesion and the serious injury which requires the loss of the tooth for its cure is so great—often so long in a single case as the total number of years devoted to practice by many of our profession. I have records of several cases, the earlier years of these records having been made by men in practice before my time, in which more than thirty years have passed from the time of the original inflammation to the final loss of the teeth. It is, therefore, very difficult to secure complete data for individual cases, but we may learn much from the observation of many cases in different stages of progress.

If the statements which will be hereafter made are true, the attitude of the profession toward this group of diseases must be greatly changed. Instead of years of treatment, generally ending in lost battles, there must be more decisive early action, in which lies our hope of success. It is the intention that this paper shall present in detail information which the writer has been able to gather regarding the etiology and early pathology of three distinct conditions, and to follow each to its termination. This is done with the realization that these tissues are involved from other causes, but with the belief that those to be mentioned cover a very large majority of all cases. This presentation will be principally clinical, and the various suggestions made as to treatment will be those which seem to be rationally indicated by the conditions.

It should be stated that the writer has had access during the past winter to the manuscript of Dr. G. V. Black for a book on the pathology of the soft tissues adjacent to the teeth, and has not hesitated to draw very freely on that manuscript for material relative to deposits of calculus, credit for which is hereby given. It might also be said that the work of investigation in this field which has been done by your essayist during the past few years has been developed under the direction of the above-mentioned gentleman, and it is a pleasure to make acknowledgment thereof also at this time.

If we seek the initial lesions which lead to inflammations of the peridental membrane, we shall find practically all of them in one or the other of two tissues, the pulp of the tooth or the free margin of the gum—the gingivæ. The initial lesion is, then, a pulpitis or a gingivitis; in the one instance the first involvement of the peridental membrane is at the apex of the root, in the other, at the gingival line of the tooth. Except from occasional accidental causes, such as an inflammation resulting from a hole drilled through the side of a root, peridental inflammations do not start anywhere but at the end of the root or the gingival line. In this paper, consideration is confined to the group beginning at the gingival line.

If we recognize the fact that for every such case of inflammation of the peridental membrane there must be a preceding inflammation of the gingivæ, we should look first at the gingivitis, together with the various conditions which cause it, and follow the progress of the inflammation as it gradually involves and destroys the peridental membrane. We should at the same time have constantly in our minds the question of the treatment indicated in the various stages, which might check the further progress of tissue destruction.

SALIVARY CALCULUS.

Recent investigations seem to disprove the theories which have been held by the profession for many years relative to the manner in which salivary calculus is deposited. I quote the following from Dr. G. V. Black: "I am slowly, by each successive step, being driven to the conclusion that the thought of a precipitate of calcium salts from the saliva, so long held—by myself and all the rest—has been a myth. It seems now that calculus comes into the mouth as a finely divided and semi-fluid calcoglobulin, which, with the decomposition of much of the colloid elements, hardens into stony calculus." Particular attention is called to the fact that this calcoglobulin is very soft when it is first deposited, and from twenty-four to forty-eight hours are required for it to become hard. Another very important fact is that the outpouring of the calcoglobulin is decidedly paroxysmal, and each occurrence is of short duration, following within a few hours after a hearty meal. These paroxysms are due to a lack of balance between the amount of food taken into the system and the regular eliminative process. The kind of food ingested seems to make little difference; if the quantity is more than can be properly disposed of through the natural nutritional and eliminative processes, the excess is thrown into the system and is eliminated through the salivary and other glands and fluid excretory routes. These paroxysms are so definitely related to excesses of eating that one may determine in advance with considerable accuracy the time of beginning and the duration of the outpouring of the deposit; in fact, one may control the deposit by the diet. For the benefit of those who may not have read the already published papers on this subject, it may be stated that the study of the deposit is made very simple by the use of specially ground microscopical cover-glasses held in a gold frame in the mouth in the region of the buccal surfaces of the upper molars. These cover glasses may be removed and the deposit prepared for microscopical study without disturbing it.

Deposits of this material occur first on the surfaces of those teeth closest to the openings of the ducts of the parotid and sublingual glands, and in the most sheltered positions on those surfaces which are least affected by the natural scouring processes, viz, near the margin of the free gingivæ on the lingual surfaces of the lower incisors and the buccal surfaces of the upper molars. It may gradually spread to other teeth and other surfaces. Except in cases of long standing, the deposits are usually confined to buccal or lingual surfaces, and do not involve proximal surfaces. This deposit is at first white or very nearly transparent, and quite soft, and while soft it seems to cause no inflammation of the gingivæ. Attention is called to the fact that this deposit occurs on the exposed surface of the tooth, and not under the free margin of the gum. It does, however, encroach upon the free margin sufficiently to cause a slight inflammation of this tissue, as a result of which the gingiva becomes thicker and recedes a little, both of which changes give opportunity for additional lodgment, by presenting a broader shelf adjacent to the tooth. Additional lodgment causes additional inflammation and recession, and so the process continues, gradually destroying, first the gingivæ, then the gum tissue and peridental membrane, together with the alveolar process to which the latter is attached, exposing more and more of the root, until so much of the tooth socket is destroyed that the tooth becomes so loose that it may be removed with the fingers. The inflamed tissue bleeds on the slightest irritation, although there is seldom complaint of either pain or tenderness until the tooth has become quite loose. There is commonly an accompanying pyogenic infection of the soft tissues, but rarely a destruction of the peridental membrane in advance of the destruction of the overlying tissues. Our picture, then, of the typical case of salivary calculus is one in which there is a gradual accumulation of the deposit with a corresponding disappearance of the tissues overlying the crown and root surface, usually without the formation of pockets about the roots of the teeth, but generally accompanied by suppuration.

SERUMAL CALCULUS.

Serumal calculus is different from salivary calculus in the form, color, position, and source of the deposit. The nature of the deposit itself is, however, practically the same. It is thrown out with the serum into the subgingival space, and is deposited on the enamel under the free margin of the gum, or on the root if the peridental membrane has been destroyed. When the deposit is on the enamel, in the subgingival space, it is usually in the form of a dark brown flattened scale, or several of them, attached to the enamel. It is probably flattened while soft by the pressure of the overlying gum tissue. When it is on the cementum, it is more likely to be nodular in form and to present a much rougher surface to the overlying soft tissue. This form has been specially designated as pus-pocket calculus. In many cases these deposits are found on the enamel in the subgingival space, when no previous inflammation of the overlying soft tissue had been noted, and the question might be raised as to whether it is necessary to have a preceding inflammation, or whether the deposit might occur as a result of overfeeding, the excess of calcoglobulin in the fluids of the body being poured out into the subgingival spaces. This would seem likely in cases in which there are deposits occurring on many teeth at the same time. We certainly often see the deposit as a sequence to inflammations of the gingivæ. When the overlying gum tissue is thin, it is usually darker red than normally, or slightly bluish, over these deposits, and the diagnosis of the presence of the deposit can frequently be made on the appearance of the gum tissue. The presence of such deposits may be determined with a subgingival explorer or a scaler suitable in form to be drawn over the surface of the enamel without injury to the overlying tissue. After there is such a deposit, it serves to cause inflammation of the overlying tissue, even though the original cause of the inflammation may have been removed. This in turn causes the outpouring of more serum with additional deposits of calculus. The inflamed tissue becomes infected with pyogenic organisms and there is a gradual involvement and destruction of the peridental membrane. As the attachment of this membrane is destroyed, the gingivæ become shorter. Those fibers of the peridental membrane which are cut off from their attachment to the cementum disappear by absorption, as does the portion of the bone of the alveolar process to which they were attached. There is much variation in the appearance of the soft tissue overlying the deposits on the cementum; in some cases this tissue will appear to be quite normal, although the pockets may reach almost to the root-ends, while in other cases the overlying tissue will be considerably swollen and congested. There will usually be intermittent periods of tenderness and pain, patients being quite free from discomfort at other times.

The most important difference between this process of destruction and that resulting from salivary calculus is, that the deposits of serumal calculus are always under the soft tissue which surrounds the tooth, and the tendency is to form pockets which become gradually deeper, cutting the peridental membrane away from the cementum. With salivary calculus there is the gradual complete destruction of all tissue overlying the portion of the crown and root involved, and generally without the formation of a pocket. With serumal calculus the free gingivæ and gum tissue remain, while the attachment to the cementum is cut loose, and the fibers of the peridental membrane, also the bone to which they are attached, disappear.

TRAUMATIC INJURIES.

Very few of the articles in our literature mention traumatic injuries as a cause of disease of the peridental membrane, yet statistics which your essayist has gathered tend to show that about from one-half to two-thirds of all inflammations of the gingivæ are traumatic. On account of the resistance offered by the gingivæ to the severe punishment to which this tissue is subjected, the irritation is usually kept up practically continuously for years before the tissues are seriously involved, and we have therefore failed to associate the apparently trivial cause with the eventual serious result. It is to this group of injuries that I wish to call particular attention.

The injuries may be divided into two principal classes—those which are caused by foodstuffs which become wedged between the teeth on account of lack of contact or improper contact, and those caused by deviations from the normal smooth contour of the teeth, such as sharp cavity margins, imperfect filling margins, ill-fitting crowns, etc. The interproximal gum septum—the septal tissue—is involved much oftener than the buccal and lingual gingivæ, by reason of the fact that all food lodgments between the teeth involve this tissue, and because caries and filling operations are more numerous in proximal surfaces. In those cases in which there is impaction of food in the interproximal space, there is first a slight inflammation of the septal tissue, followed by a noticeable swelling of the buccal and lingual portions, as the central portion is depressed by the impacted food. Gradually the tissue is destroyed by the pressure and irritation of the food débris, and the process continues, involving peridental membrane and alveolar process. All of the inflammations of this group are very likely to be accompanied, after a time, by deposits of serumal calculus on the enamel or cementum underlying the inflamed area, and this in turn acts as an additional irritant. Cases of this group may progress independently of the trauma, owing to the inflammation caused by the deposits.

The epithelium covering the septal tissue is very dense, and resists to the utmost the irritations to which it is subjected; if not seriously injured, it will usually return to its normal condition in a short time after the irritation is removed. The progress of the destructive process is much varied in individual cases. In those in which the impacted food is removed quickly after each impaction, many years may pass without serious injury. Even in those cases in which the impacted food is not removed, it is surprising how much time may elapse—often years—before the peridental membrane is involved. The difference in the sensitiveness of the gingivæ in different individuals is most remarkable, some complaining severely of the pain caused by the slightest impaction, others insisting that they have felt no discomfort whatever, although they present many interproximal spaces jammed with food débris.

STATISTICS.

For several years your essayist has been collecting records of examinations of mouths which were receiving at least average care both by the patients themselves and their dentists, to determine, if possible, something as to existing conditions. It is apparent that we are not as a profession paying much attention to gingivitis, but delay instituting treatment until after the development of a definite pericementitis. Since a gingivitis must precede each case of pericementitis, and in view of the fact that our treatment of the peridental inflammations has generally been unsatisfactory, it occurred to your essayist that we should pay more attention to the areas of gingivitis.

The effort was therefore made to determine the condition of the average mouth as to gingivitis. A definite plan for mouth examinations was worked out, by which a record might be made of each area of gingivitis, with its apparent cause. The charts used have a space in which to mark the condition for each of the four sides of each root, and a separate space for each interproximal gum septum. The use of a system of numbers makes the recording of such examinations very simple.

In connection with a paper read before the Chicago Dental Society in April 1912,* there were published statistics of 376 examinations made by selected dentists in various sections of the country. Since then more have been added, bringing the total up to more than five hundred. Very careful instructions were sent to each dentist who made examinations, in order that they might be made as nearly uniform as possible. While it is recognized that the examination of the mouths of five hundred persons is insufficient as a basis for absolutely positive conclusions, yet the reports are so uniform in that they record areas of gingivitis in the mouths of most persons, that we cannot fail to recognize the fact that there are presented to each of us in practice, practically every day, several areas which should have more careful consideration and attention than they are receiving.

While considerably more than five hundred mouths have been examined, there will be presented at this time the summary for a tabulation covering exactly 500 cases, selected by eliminating the cards for all persons younger than twenty or older than thirty-five years, also by eliminating cards for all persons having lesions of the peridental membrane. This summary is, then, a record of the areas of gingivitis found in the mouths of 500 young adults, between twenty and thirty-five years of age, the average age being 26.3, none of whom have disease of the peridental membrane.

Of the 500 mouths, 25 were reported as having no gingivitis, viz, just 5 per cent. Of these 25, but 17 had all contacts in good form. Each of the other 8 had one or more open contacts, but no inflammation of the gingivæ at the time of the examination. In the mouths of the remaining 475 persons, there were reported 4265 areas of gingivitis, viz, an average of 8.53 per person for the 500 examined. Is not this statement alone very significant of the fact that the relationship of the gingivitis to disease of the peridental membrane is not sufficiently appreciated?

The 4265 areas of gingivitis may be classified as follows:

There were 1348 areas due to deposits of salivary calculus; these were in the mouths of 198 persons, making an average of 7.8 per person. It should be stated that reports recorded deposits on more than one surface of the same tooth in 123 instances, and the very large majority of these were lower incisors marked as having exhibited deposits both lingually and labially. The percentage of the 500 patients examined, who had deposits of salivary calculus, is 39.6. The percentage of all of the areas of gingivitis reported as due to salivary calculus is 31.6.

There were 563 areas reported as showing serumal deposits, and in which no other cause of the gingivitis was recorded. These were in the mouths of 75 persons, an average of 7.5 areas per person. The percentage of the 500 examined who had deposits of serumal calculus is 15. The percentage of all of the areas of gingivitis reported as having serumal deposits is 13.1.

There were 33 mouths in which deposits of both salivary and serumal calculus were recorded, making a total of 140 persons having either kind or both. This leaves 360 of those examined for whom no deposits were reported.

There were 2354 areas of gingivitis due to other causes than deposits, subdivided as follows: 783 were due to bad margins of fillings or crowns, 496 to lack

* *Dental Review*, vol. xxvi, 1912, p. 861.

of contact of proximal fillings or crowns, 305 to improper contact of proximal fillings or crowns, 263 to malpositions or atypical forms of proximal surfaces, 255 to lack of contact of teeth having no caries of proximal surfaces, 233 to caries of proximal surfaces, and 19 to worn contacts. If the areas due to malpositions, etc., to lack of contact of undecayed teeth, to caries, and to worn contacts, are not counted, there remain 1584 areas, the large majority of which are due to imperfect dental operations. These are more than 37 per cent. of all areas of gingivitis reported. The percentage of all the areas of gingivitis reported as due to trauma is 55.1. For all persons included in the tabulations there is an average of 4.7 areas of gingivitis per person due to trauma.

TREATMENT.

In the treatment of all diseases, we are today looking more and more for preventive measures. The more we know of etiology and early pathology, the better are we prepared to use preventive treatment. In the group of conditions under consideration a division can be made, on the one side of which treatment may be said to be truly preventive, on the other side of which it must generally be considered as palliative. The division rests on the determination as to whether or not there has been a detachment of considerable depth of the peridental membrane from the cementum. Previous to such detachment the prognosis is good for a quick recovery, if proper treatment is instituted; after such detachment there is generally no possibility of restoring to their normal condition the tissues involved, because the detached fibers have disappeared by absorption, as has the alveolar process to which they were attached. It seems rational, therefore, that we should make the utmost effort to apply effective treatment to cure the gingivitis, and thus prevent the more serious lesions of the peridental membrane.

The very simple facts mentioned relative to the character of deposits of salivary calculus indicate clearly that the prevention of gingivitis from this cause is a duty which should be performed by the patient under the guidance of the dentist. The patient may entirely prevent deposits by limiting his diet to his needs, or failing to do this, he may easily remove the deposit with the tooth-brush and plain water, by careful brushing twice daily. It should be made clear that the deposit is so soft at first that it may be very easily brushed off, but that it may become so hard within twenty-four hours that no amount of brushing will remove it. It is not sufficient that the dentist remove these deposits once in six months, and the patient neglect to use the brush properly and with sufficient frequency and regularity in the meantime, for, under such care, there will be some progress in the destruction of the soft tissue each year. A very simple statement to patients concerning conditions under which deposits occur, and the time required for them to become hard, should impress the necessity for conscientious care which many will gladly give. The dentist's duty should be principally that of an instructor in the management of these cases, supplemented by frequent examinations and the removal of deposits in positions which have escaped the brush of the patient. At each visit, the patient's attention should be called to areas which have not been properly brushed, and directions given for the care of such areas.

Cases of gingivitis accompanied by deposits of serumal calculus should be discovered early, and the deposits carefully removed. In each instance a search should be made to find an exciting cause of the inflammation other than the deposit, and this should be eliminated if possible. In those cases in which there is a tendency to the frequent recurrence of these deposits, the patient should be taught to flush out the subgingival spaces twice daily with physiological salt solution, using a large rubber bulb syringe. The end of the syringe nozzle should be so large that it may not be inserted between the free gingivæ and the tooth; it should be held in contact with the enamel, close to the margin of the gingivæ and carried along the margin, at such an angle that the solution will be forced into the subgingival space. This cleanses the spaces thoroughly without irritation and has proved very effective. Records should be kept of the positions in which these deposits are found, and careful examinations should be made at stated intervals to find and remove additional deposits.

Most of those cases of gingivitis which are clearly traumatic may either be prevented by greater care in our routine operations, or they may be cured by performing whatever operation is necessary to do away with the irritation. We all know well enough how to do these things, but their importance is not realized and they are not done. One case in the writer's practice will be cited: A new patient, a man of about forty-eight years, presented a few months ago for examination. No cavities were found, but the septal tissue between the lower right cuspid and first bicuspid, between the two bicuspids and between the second bicuspid and first molar, was slightly swollen and a deeper red than normal, also a little shorter than normal. There were no fillings, nor cavities, in any of these teeth, but the contacts were not tight and food evidently crowded through on to the gum tissue at each meal. The patient was told that it would be necessary to place a filling in one of the teeth. He expressed great satisfaction that something wrong had been discovered, and he added that at almost every meal he had eaten in ten years he had suffered pain caused by every attempt to chew on that side. He also said he had complained again and again to his dentist, but on each occasion he was told that he needed no dental service. A separator was placed between the second bicuspid and first molar, and it required very little movement to close the contacts between the two bicuspids and between the first bicuspid and cuspid. A mesio-occlusal cavity was then cut in the first molar and a gold filling placed, building out the mesial contour sufficiently to keep all three contacts tight. There never was a more appreciative patient than this man. His daughter of sixteen has since told the writer that a little jar of toothpicks, which had for years occupied a place on the table near her father's plate, has been dispensed with. Dozens of similar cases might be mentioned.

Where there is an open contact, causing food impaction, it is clearly our duty to close it, by whatever procedure seems best. It is not often necessary to cut a cavity in a sound tooth. Sometimes casts of the mouth will show that a certain cusp is striking in such a way as to force a contact open and a little grinding of the planes of one or two cusps will permit the closure of the open contact. Oftentimes the open contact is due to a "flat" filling in a neighboring tooth, and it will be necessary to correct the contour of the filling, either by replacing it or building it out. As in the case mentioned above, several contacts may be tightened by building out a single surface, and where there are open contacts there are usually fillings in nearby surfaces. If there is any one thing which more than all others has contributed to our failures to restore proper contacts in our operations, it has been our neglect to secure proper separation previous to or in connection with the placing of crowns and proximal fillings. The records which have been collected show an entirely too large number of inflammations from this cause.

It should be recognized that some cases present in which it will be inadvisable to attempt to maintain tight contacts, particularly where teeth are gradually moving apart following the extraction of a neighboring tooth, or where peridental inflammations have progressed far enough to cause a continued movement. In a limited number of cases, where proper contact cannot be maintained, a tooth should be extracted. Most cases of this type are those in which a third molar is loose enough to permit the force of the bite to push it away from contact with the second molar and allow food to be crowded into the interproximal space. In some of these cases contact, if restored, will be maintained but a short time, and the best procedure may be the extraction of the third molar.

The discussion of the treatment of all

of these cases should not be passed without mentioning the importance of doing whatever may be necessary in each case to promote the cleanliness and consequent health of the soft tissues adjacent to the teeth, in order to secure the best results to be derived from the fullest and most vigorous use of the teeth in mastication—which is only possible when all areas of tenderness or sensitiveness have been eliminated.

THE DENTIST'S DUTY IN COMBATING GINGIVITIS.

Consideration of the treatment of these conditions has been purposely limited to the treatment of gingivitis, for therein lies our hope for the future in combating diseases of the peridental membrane. Attention is now called to the fact that this work is not the work of the specialist in the treatment of diseases of the peridental membrane, but lies necessarily within the field of the general practitioner. He must be careful in his examinations of the mouth to make a record of the inflammations of the soft tissues; he must study the causes of these inflammations, and he must undertake at once the treatment necessary for their eradication and to prevent, so far as may be, their recurrence. He must at the same time be ever alert to the important part which his patients must undertake, and must be painstaking and indefatigable in teaching them the value of proper contacts and the serious conditions which eventually result from slight and seemingly trivial inflammations, to the end that he may secure and hold their co-operation in his efforts in their behalf.

In considering this group of diseases, attention is called to the large number of valuable contributions during the past few years to both medical and dental literature, by leading scientists, in which the relation of the local focus of infection to general systemic conditions is clearly established. The dental profession cannot turn a deaf ear to the declarations of these men. When a physician of known reputation in the field of clinical pathology,* announces positively several cases of death from endocarditis due to peridental infection, and other men, such as Mayo† and Billings,‡ have expressed themselves so positively on the relationship of the pyorrhea pocket to many serious lesions elsewhere, it is surely the duty of the dental profession to prevent and to eliminate such foci from the mouths of their patients.

In closing, let it be said again that the dental profession is not so much in need today of more specialists in the treatment of pyorrhea as it is of more dentists who will make it their specialty to prevent disease of the tissues attached to the teeth.

CANCER OF THE MOUTH: THE RELATION OF DENTAL AND GENERAL PRACTITIONERS TO ITS EARLY RECOGNITION AND SUCCESSFUL TREATMENT.

By G. BETTON MASSEY, M.D., Philadelphia, Pa.

(Read before the Section of Stomatology, American Medical Association, at Minneapolis, June 19, 1913.)

THIS clinical study is based on personal observation and notes of 68 cases of malignant growths of the mouth, of which 7 were sarcomas, 27 carcinomas and 34 epitheliomas.

As to the particular situation of the initial growth in the oral cavity, they may be classified as follows:

	Cases.
Gums and alveolar processes of lower and upper jaws	34
Tongue	18
Buccal surface of cheek	5
Floor of mouth	3
Fauces	3
Situation not stated	5
Total	68

Diagnosis.

A few words may be said of the early recognition and clinical characteristics of each group thus arranged:

GUMS AND ALVEOLAR PROCESSES.

(Thirty-four cases.) A large majority of these patients were first seen by me in a late stage, many after the inevitable result of neglect had occurred—the development of daughter tumors in the lymph nodes beneath the mandible. But 6 of the 34 patients were women. I have a strong general impression that these patients neglected their teeth for years before the appearance of the growth, and the prevalence of greater neglect in this respect among men than among women may account for the greater incidence of the disease in this situation in that sex.

Importance of a tentative diagnosis in a suspected case, and precautions to be observed. The first evidence of epithelioma on the gums is apt to be a raised, pinkish-white nodule that is insensitive to touch, and painless. It may or may not arise in an area already occupied by a leucoplakial infection. Ulceration follows, the ulcer having an indurated base and edges. An early carcinoma presents a greater resemblance to an inflammatory swelling, becoming quickly ulcerated and proliferant, with a tendency to bleed on touch. It is also insensitive and painless in the early stages and until secondary infection by pyogenic organisms, or the extension of the disease itself, invades sensory nerves.

A sarcoma, or an osteosarcoma, presents a smooth elastic submucous swelling without change of color, and with, later, it may be, ulceration. Induration and painlessness characterize each variety.

Pain may appear somewhat early in both carcinoma and sarcoma, but *an invariable characteristic of all malignant growths is lack of tenderness on pressure.*

Dental practitioners share with general practitioners the responsibility of seeing cases of mouth cancer in these early, curable stages—I do not say "precancerous" stages, for a cancer is as much a cancer at birth as a wild animal or any other entity. The responsibility of early recognition of cancer of the mouth is, in fact, placed more on the first practitioner consulted than usual, for patients recognize external cancers themselves at an early stage. Suffering from neglected teeth for years, they are slow to make personal diagnoses in these cases.

What, then, is the proper procedure on the part of the dental or general practitioner on discovering an elevated, pinkish-white, non-tender tumor, an indolent ulceration, or a proliferant growth, or a smooth tumor, each unaccompanied by pain or tenderness? On the course to be pursued by him at this time rests the patient's chance for life, and our only means at present to lessen the increasing mortality from these affections.

His first duty is to add careful palpation to intelligent inspection, and if induration is found to accompany the other symptoms mentioned, *he should make a tentative diagnosis of malignancy at once.*

Having made such a diagnosis—a diagnosis that requires alone the exclusion of syphilis in a few cases to be usually correct—he should prescribe radical treatment at once, meantime protecting his patient from detrimental procedures likely to increase the disease.

These detrimental procedures are—wounds or irritations of any kind short of complete destruction. He should not remove or permit to be removed a specimen for more complete diagnosis until preparations are made for immediate operation. He should under no circumstances extract a tooth near the growth, as this will lead to immediate extension into the cavity vacated by the tooth, and possibly cause infection of the regional lymph nodes. He should, in fact, treat such an incipient growth as he would a nest of hornets found by the wayside until all preparations for destruction are made.

You will notice that I insist that the way to give the patient the benefit of any doubt at this first examination is to assume malignancy until this grave diagnosis is disproved. The patient is safe under no other course. The history of some of the patients embraced in this study shows too often an opposite course, dictated by a natural disinclination to alarm, but leading to sad results. Questions to bring out these points were not always asked, but my records show the following facts:

Four teeth were extracted one after the other, as they became loose, from a beginning sarcoma of the upper jaw, before the condition was recognized.

A bicuspid was extracted for what appeared to be an ulceration about its root, in the case of a woman physician. In two weeks the growth had extended to and filled the antrum.

A third molar was extracted from the lower jaw of a woman, followed quickly by aggravation of the growth just appearing.

Case 13—"Dr. —— has been treating the gum since teeth were drawn, five or six months ago."

Case 14—"Noticed swelling in roof of mouth in latter part of August simulating an abscess. Had two teeth extracted; since that time it has grown progressively worse."

Case 27 had a tooth extracted before recognition of carcinoma alongside it.

Case 29 had a "sore mouth" for years.

Case 33 had "vile gums for years." His dentist discovered a white spot on gum one year ago, but no alarm was felt.

Case 39 had all his teeth extracted before a diagnosis of epithelioma was made.

Case 41—"One week after discovering sore in mouth had upper tooth extracted. The pain continued. Ten other upper teeth were extracted without avail."

Case 51 developed a crack or fissure after the extraction of a third molar, and when first seen had an incurable secondary growth in the neck.

Case 56 knew of no injury except extraction of teeth at site of growth, six months before being seen; at time of admission there was an incurable secondary growth in the neck.

TONGUE.

(Eighteen cases.) The etiologic connection of irritation from sharp edges of teeth was shown in three cases, according to the notes, and was doubtless true of others. Pipe-smoking was uncertain as a causative factor.

From the point of view of early diagnosis, absence of pain and tenderness was equally prominent as in growths of the gums. Palpation as a means of early diagnosis in tongue cases is even more valuable than in the former owing to the extreme softness of the normal tongue. Syphilis alone may be suspected by those not over-familiar with the wide difference in the appearance of the two infections, but it is not safe to waste much time in the medicinal test, for fear of glandular infection. A Widal test would not have this objection.

BUCCAL SURFACE OF CHEEK.

(Five cases.) Two of these cases appeared to follow a biting injury from the teeth.

TREATMENT.

The treatment of malignant growths of the oral cavity resolves itself at present into a selection of the most radical method of immediate removal or destruction of all the infected cells, together with any secondarily infected lymph nodes, if present, in the neck. My own experience corroborates that of others that the Roentgen ray cannot be relied on to produce permanent results in growths within the mouth, in spite of its value in skin cancer. Good results have been reported of radium in epitheliomas in this situation, but the cases observed by me have not been permanently benefited.

In considering radical treatment, I wish to urge as a cardinal principle the acceptance of the theory of the parasitic nature of these affections as a present working hypothesis. Endocellular germs have not as yet been conclusively demonstrated in human cancer, it is true, though Dr. Erwin F. Smith, of the Bureau of Plant Pathology at Washington, has demonstrated them in plants. Yet the life-history of malignant growths gives conclusive proofs of the presence of specific germs in the stimulated cells of the human host, doubtless differing for each variety of growth, the chief indications of germ origin being the auto-inoculability of cancers, their growth by erosion of surrounding tissues, and their production of colonies in distant organs. Until parasiticism has been disproved it is wise to assume that it is true, and to take all precautions dictated by the hypothesis in guarding against operative reimplantation of living cells.

Excision, the accepted operation at present, should be successful in the early stages if the entire growth be removed without its being wounded. The difficulties attending the fulfilment of this condition of removal without wounding are necessarily great in a cavity of this nature, but they must be met if we are to avoid reimplantation of the disease in the fresh wound.

My own work has been entirely by the *electrical method* of ionic destruction *in situ,* in which the growth is devitalized and simultaneously impregnated with the ions of zinc and mercury developed from soluble electrodes of these metals thrust beneath the base of the tumor. Complete destruction may be accomplished in growths of considerable size in from fifteen to thirty minutes. The fact that the necessary current can be conveyed to the site of application by electrodes of any shape or curve permits an operation of this nature to be done in any part of the mouth through the labial opening without injury to overlying facial structures. Aside from the slight hemorrhage caused by the preliminary removal of a specimen for microscopic study, there is no operative hemorrhage whatever, even in extensive ionic operations, thus removing a fruitful cause of operative pneumonia, and permitting a better study of the field of operation.

For the information of those already familiar with this form of treatment I should state that in all recent malignant growths of the mouth of any magnitude I have employed the bipolar method of ionic destruction, in which the active, soluble needles are thrust beneath the growth and the inactive negative pole placed directly on or into its middle. This permits of any strength of current desired being employed, since it is a purely local circuit, no current traversing outside vital structures.

In growths too small for this procedure the unipolar method is still employed effectively, the indifferent pole being beneath the patient's back.

In these small growths, in fact (and it is with them and their early recognition and prompt treatment that this paper is chiefly concerned), general anesthesia is usually unnecessary, a current of a few milliampères, under local anesthesia, destroying an incipient harbinger of death in from ten to thirty minutes.

The sole element of danger in this method, in the more serious cases, is that of secondary hemorrhage, which may occur from the tenth to the eighteenth day after operation. This risk can be obviated at times by a preliminary ligation of the external carotid artery.

The danger of secondary hemorrhage is usually too great to permit of an extensive use of this method in the fauces, particularly in an extensive growth in the region of the tonsils.

Results of ionic method in mouth cases. Of the 68 cases studied, 49 were placed under the method of ionic destruction, many of them as a last chance in otherwise inoperable cases, with the following results:

	Cases.
Without manifest evidence of disease at present (3 to 16 years after operation)	15
Died shortly after operation	6
Improved	16
Unimproved	12
	49

The mortality percentage was 12.2.

Conclusions.

(1) Early malignant growths within the mouth are apt to be seen first, and in their curable stage, by dental practitioners. A reasonably certain diagnosis may be made in this stage by touch alone, detecting evidence of induration without tenderness.

(2) The discovery of a hard, non-tender growth within the mouth, of relatively slow appearance, should compel a tentative diagnosis of malignancy, and cause the patient to be immediately referred for further study.

(3) No teeth should be extracted near a suspicious ulcer or tumor of this nature, as a fresh wound in or near it will cause quickened growth.

(4) The growth should not be wounded for the purpose of verifying the diagnosis until all preparations are made for immediate and effective destruction. Wounds or irritating treatment invite lymph-node infection and distant metastases.

(5) A radical operation, which may be of slight severity in incipient growths, is indicated as soon after discovery as possible. In selecting the method of radical destruction or removal, the safest course is to regard all malignant growths as parasitic in origin—and therefore readily reinoculable by a defective operative technic—until this hypothesis is disproved.

DENTAL EDUCATIONAL HARMONY.

By G. S. JUNKERMAN, A.M., M.D., D.D.S., Cincinnati, Ohio,
DEAN OF THE CINCINNATI COLLEGE OF DENTAL SURGERY—DENTAL DEP'T OHIO UNIVERSITY.

(Read before Section II of the National Dental Association at its Annual Meeting, Kansas City, Mo., July 8, 1913.)

I CAN plainly hear the grunt and see the cynical smile of skepticism on the faces of those, if there be any, who have read the title of this paper, as the conviction reaches their minds that *there is no dental educational harmony.* In others, concern displaces cynicism, as with straining eyes they look and hope for a Moses who will lead the children of Israel from darkness into light. The golden opportunity for bringing the profession into renewed respectability surrounds us on all sides, yet internal contention and civil strife preclude the possibility of presenting to the enemy the solid and uniform phalanx that will attain the ideal goal for the profession and those it serves. I do not desire to censure, but to criticize, and above all, to be truthful as I see the truth. If any are hurt, my justification will lie in the old axiom that the truth usually does hurt, consciousness of which fact will be conveyed to me by the knowledge that, if a stone is cast among a pack of hounds, the yelp will come from the one that has been hit. Not being, however, of the class who are justified in casting the first stone, nor yet a stranger to the painfulness of the stony impact, I feel that I have learned enough charity to offer myself as "first aid to the injured."

PRESENT DISHARMONY.

The first act of a musical performer is to tune his instrument. When a number of instruments are to be played together, they are tuned to each other from a fundamental note; failure to do so makes an inharmonious and discordant performance, no matter how fine the instruments nor how expert the players. The dental educational bodies of this country are expert players, performing on superb instruments well tuned, but not tuned to each other. The result is a garble of disharmony in which the piteous struggle to reconcile B flat and C sharp creates such a din that everyone finds himself more often in a condition to *be* flat than to *see* sharp. To continue the allegory, it can be said that many are trying to play so fast that we find them a few bars ahead of the rest, in a hopeless state of "innocuous desuetude."

THE DENTAL COLLEGES' STANDARD OF REQUIREMENTS AND ITS INADEQUACY.

The three distinctive educational bodies known as the colleges, the examining boards, and the profession at large as expressed by dental societies, are each full of faults, which they are clanging with bass-drum and cymbal effect, thereby drowning the soft *sympathetic* notes of their *virtuous* strings. The result of the condition is that, although we all love music, we are doing everything not to get it. The dental colleges, through their Faculties Association, originally issued the manifesto that they were the judges of who is qualified to begin the study of dentistry and what should qualify such persons to enter upon its practice. Everybody was satisfied, and accepted the manifesto as law. Did the colleges tune up to the fundamental note? I am afraid not. From time to time, through suasion and threat the pitch was raised, but this was a manifesto not made, perhaps suggested, but rather accepted, by the colleges. Did the colleges tune up to these varying pitches? I am afraid not. There were some half-hearted strains at the strings, but the pitch was wofully flat, and discordant music resulted. I still contend that the colleges are the best judges of the material of which they can make dentists, and a sense of justice forces me to maintain equally and positively that, having issued a manifesto as to the competence of their judgeship, they should have stood flat-footed upon it. When they failed to do so, they lost their prestige. The loss of this prestige by the colleges is not beneficial either to them or to the dental profession generally, for the labor necessary to secure a diploma should be clothed with dignity and significance, which being denied, reflects discredit, from the student body, both upon the college and those who deny such prestige to the degree. The colleges might have regained their prestige if after accepting the new manifesto, they had lived up to it, or, having rejected it, had fought their battle for what they thought was right. Had they lost, defeat would have been far preferable to half-hearted and imperfect acquiescence, which aroused only suspicion and distrust. The insincerity of the colleges in complying with the preliminary requirements which they had promulgated in large part, or had acquiesced in, may carry some apology from the experience gained in trying to comply with them, and finding in many cases that such requirements were either premature, impracticable, or unjust to students and conditions—which conditions could have only been understood by those who were engaged in educating students for practice in the profession. Much to the credit of the colleges there has been very little *tenable* criticism from any source that has cast discredit on dental education *per se,* although some flings have been made about employing young teachers just out of college, when experience shows that they, above all, are better able to teach because of their more recent and familiar contact with the steps of the profession which older teachers have long since forgotten. It has not been the seed or the fruit, but the soil which was being cultivated that has been brought into question as being productive of high-class professional men. It might be said in explanation of this statement that the unprejudiced part of the profession has been forced to realize that the fruit was divided into first, second, and third class, and that there are consumers for each class. Communities that could not support a first-class man are perfectly satisfied with a second- or third-class man, and would have otherwise to do without any, much to their inconvenience and detriment.

The justice of the 15-unit minimum basis I will neither disclaim nor confirm, but content myself with discussing its features. If colleges require it, or are forced to do so, I contend that they should be permitted to administer it with discretion. All diplomas from an accredited high school do not express an equation. There is 30 per cent. difference between the highest and the lowest, ranging from the student that passes at 70 per cent. and the one that passes at 100 per cent. or thereabout. The same holds good if units are substituted for the diploma. The result is that under this system all students admitted to our dental colleges are not equal, and will be more *unequal* at graduation. This system, furthermore, puts a premium on opportunity, and opportunity is not a common possession. It is more likely to be the property of the rich, and aristocracy of wealth I am unwilling to bow to, unless it be wealth of mental attainment. If a 100 per cent. accredited high-school diploma represents 15 units, then a 70 per cent. diploma represents only 10½ units. A perfect two-year high-school student will have acquired 7½ units, which is only three units less than the record of the man who is admitted unconditioned with a 70 per cent. diploma, yet the conditioned man must make up 7½ units or discontinue his dental studies. Is this equity and justice? Many apt and diligent students are compelled to quit high school for lack of opportunity; then the opportunity comes, and they are denied the privilege of studying their chosen profession, although mentally well able to acquire the requisite number of units by the time that they receive their dental diplomas. As pertains to these ideas, I think that the dental colleges should be allowed to exercise discretion. It also brings into the foreground the potency of the "equivalent," a word which has been much abused, perhaps, but which cannot be eliminated in the face of justice and superior mental caliber. The blame for not exercising this discretion rests largely on the colleges themselves, because they are not practicing what they would like to exact from others in forcing students to make up their literary deficiencies before they enter the junior class. The colleges claim that only their product and not the raw material should be tested for certificates of practice, but they do not apply the same test to their candidates for diplomas. If they did, students would be given up to the time of graduation to make up their preliminary units as required by the colleges or the state laws. Were this the practice, a premium would be placed on mental capacity, and not on opportunity alone. Many students are bright enough to acquire all the dental studies and a large percentage of so-called preliminary units at the same time, thereby having all the preliminary as well as the dental units by the time they are called upon to use them.

DENTAL EXAMINING BOARDS AND THEIR SHORTCOMINGS.

If the dental colleges are guilty of insincerity, faults, and inconsistencies, the examining boards are no less free from the same undesirable qualities. This applies in many cases to the board member, as well as to the laws as passed or defectively administered.

The dental laws are enacted by the people, and for their protection. The people do not care how many dentists there are; they are only concerned about their quality. If we curtail the number, we create an inequality between the supply and the demand, and the people have to pay the bill by an increase in the price of services. The people are slow to awaken, but when they do, how long will they continue to make dental laws for such an end? and how long will they permit present laws to such an end to exist? The answer is too plain. We are educating the people more now than ever in the needs of dentistry, and they will demand that we give them true exponents of the profession to take care of their needs. The *defective* graduates are not the ones that should be feared by the people. These will quickly recover, or be consumed by the immutable law of the survival of the fittest. It is the *effective* graduate who, to the unwary and unsuspecting, presents a gilded front and an enticing entrance to his office, while in the palatial interior the hopeless victim to false diagnosis and advice of a pecuniary significance gazes from the operating chair upon walls hung with a high-school diploma, and a dental degree, and a highly ornamental state-board certificate. With such a picture as this before him—and there are many—any self-respecting and law-abiding dentist must often address the painful question to himself: Are the present dental laws a success, and do they protect the people? And the answer must be a logical, No.

The examiners should be legalized to examine only the college product in its finished state. This applies to the dental units, and to a simple verification of the preliminary units as a precaution to insure that the colleges comply with their catalog announcements. I think that all states should make or re-arrange their laws to cover completely such a procedure. If the colleges agree to this, and they should, no aspersions on their honesty could be implied, but such a verification would entirely remove any feeling of distrust, and restore that confidence between the two bodies which has so long been absent. Neither a person's nor a corporation's integrity suffers from investigation and verification of their acts.

Competence in others cannot be judged by the incompetent. The call of justice demands that anyone on trial shall be tried by his peers. The examiner should be as clever as the expectancy of the examined. A shoemaker or a blacksmith *per se* might examine correctly my physical properties, but I should be very incredulous of such men's ability to judge my dental and educational units from the standpoint of their technical knowledge of making shoes for man or beast. No dental examiner should be appointed to such office until he has qualified with at least a minimum of what he expects to find anchored in the brain and fingers of a dental graduate. Without such qualifications he becomes, when endowed with authority, an inquisitor, not an examiner. When we have *examiners* on our dental boards I am willing to be trustful, but apprehension and ridicule vie with each other, dependent on the degree of authority, when inquisitors sit in judgment on our college products. This is the viewpoint of our great student body, and their position in this respect, I think, is impregnable. Executive capacity and worthiness of authority are tested by credentials and examinations in other legislative departments, and there is every reason why our dental examiners should be submitted to the same test instead of to the test of political preferment. I believe that every dental law should contain a clause to compel each examiner to qualify both professionally and preliminarily before accepting his commission; it would insure justice and inspire confidence in the prescribed authority of each examining board. The authority of examining boards over the internal affairs of colleges as pertains to equipment and teachers is a waste of energy and expense. There is a higher power that works through the indisputable laws of the survival of the fittest that will quickly destroy any dental school with inferior teachers and equipment. It is a blessing that the power of wealth and endowment and the power of education are not commensurable. If it were so, many of us would be poor indeed, and education would be at a standstill. The virtue of a dental school cannot be measured by the size of its endowment nor by the number of its students. A healthy midget may triumph over a sickly giant, and the worthy product is all the public want.

The colleges and the examiners should work in harmony. What difference does it make to the public, whom you are supposed to be protecting, when or how education is attained, as long as it is attained prior to the time of using it? The college educators are the best judges of the material that goes to make their product, and if they use material out of which they cannot produce the finished product, they can never "get by" with it, because the examiners need not let them. Such an arrangement would secure high-class men for the profession, and would give the student of ability the chance that had been lost by the lack of opportunity. The colleges would have a larger field in which to exercise discretion, as it would be "up to them" to select good material, giving the student the justice of being judged by his ability instead of by the length of time-sentence to be served.

THE DENTAL PROFESSION'S UNFAIR ATTITUDE TOWARD DENTAL SCHOOLS.

The profession at large, being the third educational body, must come in for a large share of criticism, since by it were created the colleges, the examining boards, and the dental laws which they administer. The profession has taken itself too seriously; the individual members too often become competitors instead of co-operators. Even the commercial bodies of the country are discarding the old idea of competition, and adopting and practicing co-operation as being best for the individual as well as the masses. I am weary and soul-tired of the wholesale condemnation of colleges as practiced by the profession at large. Students want colleges and need them. While in them the student body co-operates, but when they once have received their diplomas, they assume the fierce and narrow-minded attitude of competition, damning colleges as a whole and promulgating theories for curtailing the quantity of their product. Such an attitude is manifest on every side, and if not exhibited in boisterous tirades and false accusations, there is a speak-easy vein in the atmosphere of dental deliberations that forces the conclusion on the college man that he is not wanted or is a drug on the market. Dental colleges bear the same relation to the profession at large that primary schools bear to the high schools and universities. Dental schools are intended to instruct in the discovered and well-established principles of the profession. Since these principles involve so many studies, it is impossible to make experts in any one of them, yet sets of questions are often submitted to our raw graduates that would do credit to the expert if he answered them after having had access to reference books. Dental colleges should not be expected to be research bureaus. They are busy enough when they create the professional dental surgeon. When their students pursue such studies as anatomy, physiology, and chemistry, it is done with a view to making these studies parts of the whole, and not making professional anatomists, physiologists, and chemists. There is a large field for the profession at large to establish research work and advance the principles of hygiene and prophylaxis, and there is a large unpaid debt that we owe our teachers which we can best pay by doing something that will reflect credit upon ourselves. By doing something ourselves, we increase the usefulness of dental schools that have to teach that something to compete successfully with progress. Dental schools can best shine by reflected light, and we are the reflectors.

MORE CO-OPERATION AND LESS COMPETITION WANTED.

If war is hell, then civil strife is the redistilled quintessence of it. Each educational body should attend to its own business. If they do so, they will find themselves too busy to criticize each other. There are bound to be failures, many failures, but the number is no greater in professional than in commercial economics, and we know that the commercial failures run by far into the highest percentage. I realize that it is difficult to reason with anyone who carries an empty market basket and a hungry stomach, but such individuals are usually competitors and not co-operators. I honestly and earnestly hope that the time is at hand when one may walk abroad twanging the dominant note among his fellow laborers, cherished and respected, and not shunned as if he had stolen something or as if suffering with some contagious disease, because he happens to be guilty of the atrocious crime of being a college man, an examiner, or a dentist.

UNRESTRICTED RECIPROCITY DEMANDED.

As a profession, we have too much to do. We must fight, not each other, but for each other. Accoutered in our uniforms and shining armor and cemented by harmony, we can march to renewed respectability, into the hearts and the very coffers of a suffering public. Instead of expecting alms, we can demand endowments if we but show the public that we are not preying on its misfortunes, but trying to prevent them. We need a national law or an *unrestricted* interchange of licenses. Some of our brethren of the North, in freezing snows and icy blasts, are longing for the balmy air and orange blossoms of the South, yet cannot seek them for fear of the big stick in the hands of some examining board that will prevent them from plying their vocation for a livelihood. Our brethren, too, of the South, worn by labor and care, who might be restored to usefulness by the invigorating air of the North, refuse to come and dwell among us, lest by the same cause they be placed in cold storage.

"MORE PLAY" RECOMMENDED FOR THE INDIVIDUAL PRACTITIONER.

A little educational harmony in the individual dentist would be appreciated by those who are trying to uphold professional dignity. The closeness of application—and necessarily the nervous strain—has a tendency to make of dentistry a somewhat hysterical profession. Seeing things far ahead that never will exist, and combating prospective conditions that never will arrive, has been the labor lost of many an overworked dentist attending our annual meetings, when his only mission should have been the seeking of rest and recreation. Penned up in our little offices where we continuously wield absolutism over our suffering clients, we not only become autocrats, but must necssarily absorb some of the morbid conditions of our environment. Autocracy and morbidity are two very bad lenses through which to view reforms. When we begin to get too strenuous in our criticisms, and alarming views present themselves to us, it is not necessarily time to grab the big stick, and smite some fearful adversary. The fishing rod and the reflections from some placid stream will effectually chase away the bogey man, and relieve the necessity for a murderous assault.

SUMMARY OF SUGGESTIONS OFFERED.

As a general summary to the foregoing discourse, I have the following propositions to offer: Laws to regulate dental practice should not traduce the dignity and significance of the dental degree. They should place their administration in the hands of those best prepared for justice and proficiency, freed from bias and prejudice. They should protect the college, the dentist, and the people from crooked and unfair practices. They should provide for graded certificates of practice, a feature that would give all communities at least a chance to have a dentist; and above all, laws to regulate dental practice should give universal suffrage to all of its practitioners, regardless of state lines. All laws should be protective, not exclusive.

Criticism and not censure has been my object, that we may secure harmony at any price. If this paper is discussed, I hope that it will be along these lines, feeling confident that, if he that has not sinned throws the first stone, there will be no stones thrown.

[See also *Discussion,* as reported under "Proceedings of Societies," this issue.]

THE EVOLUTION OF OCCLUSION, WITH SPECIAL REFERENCE TO THAT OF MAN.*

By RAYMOND C. OSBURN, Ph.D., Columbia University, New York, N. Y.

(Read before the Pennsylvania State Dental Society, at its annual meeting, Philadelphia, Pa., June 24, 1913.)

THE attempt to discover the reasons for existing conditions in any field of work forms one of the most important parts of scientific investigation. Along medical and surgical lines (of which dentistry forms a special part) advances are made chiefly by first discovering what are the normal conditions, and what things make for their normal development and continuation, in order to know what is abnormal, what agents produce abnormalities, and what steps may rightly be taken to correct untoward conditions and their effects.

Collaborating in this work on the human body for centuries, we have had the physician, the surgeon, and the student of anatomy; more recently the physiologist and pathologist, and still later the biochemist, the bacteriologist, the student of heredity, and the experimentalist, each adding his quota of in-

* This lecture was illustrated by about sixty lantern slides, which, for obvious reasons, cannot be reproduced here.

formation to increase the sum total of knowledge of the human frame. For it is evident that the proper development of man and the correction of abnormalities and diseases, together with the prevention of conditions that produce them, are paramount to everything else, from the standpoint both of the individual and that of the community, and no possible opening for attacking these questions should be neglected.

It is true that until recent years the great importance of the teeth, and of the mouth conditions generally, for the maintenance of health has been largely overlooked, but within the past few decades there has been a constantly increasing number of men interested in the normal and pathological conditions of the mouth and teeth. Within this time the human masticatory apparatus has been considered from nearly every point of view. Not, as we must all admit, to our entire satisfaction, for still "doctors disagree," and if not in as many points as formerly, there is yet far too great a lack of unanimity on many subjects. Until we have really come to a fuller agreement in all essential matters, no one who is interested in these questions can afford to withold his energies from the attempt to discover the ultimate truth regarding them.

THEORIES CONCERNING THE ORIGIN, ADAPTATION, EVOLUTION, AND FUNCTIONS OF THE TEETH.

There has been an abundance of theories concerning the origin, adaptation, evolution, and functions of the teeth; many of them were formulated here in Philadelphia, especially in the days of Leidy, Ryder, and Cope.

One of the most important of all dental theories had its origin here, viz, that concerning the "mechanical genesis of tooth forms," worked out in the eighties by Professors Cope and Ryder. In numerous papers these two scientists showed how in various groups of mammals the teeth are adaptively changed according to the character of the food and the movements of the jaws.

While this work dealt only with the broader aspects of the modeling of the tooth crown as a whole, it opened the way for a further and more refined study of the "mutual mechanical relations," as the subject was then called, of the individual teeth. H. F. Osborn, in his "Evolution of the Mammalian Molar Teeth," has laid great stress on the adaptive changes of the individual teeth, showing how, by cusps, styles, and lophs, the tooth crown is molded to the form best adapted to particular foods and to special methods of handling them. These principles have been of the greatest possible service not only in comparative odontology, but also in mammalian paleontology, in tracing the relationships of ancient and modern mammals.

The expression of "mutual mechanical relations" is only another term for what the dentist and orthodontist have come to know as "occlusion," and occlusion forms the basis of all restorative processes in dentistry and orthodontia. So important is this question that to my mind no one should attempt the restoration of malposed teeth to their correct position in the dental series without a full knowledge of the exact mechanical relations of the individual teeth to each other in the occlusal planes, cusps, and ridges. This knowledge should extend to the relations between teeth of the same and of opposing series, and to the whole dental arch as related to the type of dentition of the individual.

THE EVOLUTION OF OCCLUSION IN HIGHER ANIMALS.

The existing types of occlusion in higher animals have appeared as a result of long and tedious processes of evolution. Ever since the origin of the "gnathostome," or jawed, vertebrates, away back in the Silurian period, Nature has had always before her the problems of occlusion. In many cases, as we can readily see, she has solved them admirably, but again, judging by the evidence of the fossils, many a noble group of animals has passed out of existence because of inability to adapt the teeth and the jaw movements to the food at hand. Sometimes the teeth have been wondrously modified in the process of adaptation to some particular kind of food or the method of handling it, as in the cat, the muskrat, the horse, and the elephant; and again parts or even the whole of the dental series have been dropped out in response to food conditions, as witness the turtle, the bird, certain of the ant-eaters, the whalebone whales, the elephants, the manatees, etc.

In discussing the evolution of occlusion, the time at my disposal will permit me only to allude in the briefest manner to many phases of the subject.

OCCLUSION IN THE FISHES, AMPHIBIANS, AND REPTILES.

The most primitive conditions of occlusion begin with the fishes, where also we find the simplest forms of teeth and the simplest types of dentition. These are found in those sharks which have teeth arranged in the same manner as the scales or denticles of the skin, with which they are homologous, and the occlusion in such forms is merely the apposition of tooth-bearing surfaces.

The fishes, amphibians, and reptiles are capable of making only the vertical or direct up-and-down movement of the jaws, yet they have evolved numerous types of specialized teeth with many cases of occlusion of individual teeth. Perhaps it may occur to you that Ryder made too much of the jaw movements in his theory of the mechanical origin of the teeth. Yet it must be remembered that he was dealing especially with the origin of the crown pattern in the complex type of tooth, and such teeth occur only in mammals—possibly because they alone have been able to free the suspension of the jaw to the extent that other movements than vertical are possible.

The next higher mode of occlusion above the mere apposition of surfaces is that of the occlusion of rows of teeth. *Lamna,* one of the sharks, presents a very simple case of such linear occlusion in which lines of teeth are opposed. In *Squalus,* the common horned-dogfish, we see this carried to its logical conclusion in the formation of a very efficient cutting edge formed by each row of teeth as it comes into a functional position on the jaw.

But some of the sharks crush their food instead of cutting it, and this leads adaptively to a different type of occlusion. The Port Jackson shark, *Heterodontus,* has some specialized teeth for crushing. In some of the rays we find that a complete and even pavement of hexagonal teeth is formed. The next step leads to a fusion of the central blocks of the pavement (*Myliobatis*), and this finally to a complete fusion of the transverse series of teeth (*Æteobatis*).

In the bony fishes we find a very generalized condition in the pike, with patches of teeth opposing each other in the loosest form of general occlusion. The gar-pike has a linear occlusion in a nearly perfect raptorial dentition, while the tautog, also with linear occlusion, has teeth adapted for crushing the shells of mollusks and barnacles. The file-fish, *Alutera,* has an excellent incisorial apparatus, and here the occlusion is worthy of special mention, since a single row of teeth in the lower jaw is opposed to two, which nevertheless form but a single cutting edge, in the upper jaw. It will be noticed that the teeth are reduced in number as they become more specialized.

A still higher specialization is found in the teeth of the swell-fish or puffer, *Spheroides,* which are exceedingly powerful and trenchant and which are reduced to a single tooth on each side of the jaw. This process reaches its natural climax in the box-fish, *Diodon,* which has but a single broad tooth occupying the whole margin of the jaw.

I shall not allude to the teeth of the amphibians and reptiles generally, since in them we find little or no advance in the matter of occlusion—as they all, with perhaps a single exception, have only vertical jaw movement.

OCCLUSION IN THE REPTILE GROUP OF CYNODONTIA.

But among the reptiles one fossil group is of special importance to us. I refer to the group known as the *Cynodontia, Theriodontia,* or *Therapsida,* from which the mammals took their origin. Beginning with this group and extending up to the forms which can first be recognized positively as mammals, we find a series of changes taking place in the dental apparatus which are of the utmost importance. Here the complex lower jaw of the reptile becomes reduced to the dentary, so that the lower jaw is henceforth a single bone; the reptilian mode of suspension of the jaw, by means of a quadrate bone, is lost, and the mandible is thereafter attached directly to the temporal bone of the skull. Along with these changes occur certain very remarkable modifications in the dentition.

Heterodonty of the mammalian type is established, so that we distinguish incisors, canines, premolars, and molars; diphodonty appears, so that henceforth there are two sets of teeth instead of an endless succession; the teeth of the molar-premolar series begin to have complicated crowns and roots and closed pulp cavities, and they are implanted, by gomphosis, in separate sockets; the number of teeth in the permanent series approximates that typical of mammals, and we begin to find an interlocking of the teeth in a simple type of mammalian occlusion.

EFFECT OF SPECIALIZED JAW MOVEMENT IN MAMMALS UPON OCCLUSION OF THEIR TEETH.

The earliest mammals arrived on the scene of action with this wonderful endowment, and also, what is at least of equal importance, they were possessed of a plasticity that gave them the greatest capacity for evolution along a variety of lines. Apparently, the attachment of the jaw directly to the skull has made it possible to vary from the primitive vertical or up-and-down motion, to permit of lateral or transverse and of fore-and-aft movements as well. The teeth have been able to adapt themselves to a purely raptorial use, as in the dolphin and sperm whale; to a cutting and crushing function, as in insectivora, to a carnassial or flesh-cutting function as in the carnivora; to the crushing molar of the human; to the highly complicated grinding molar of the horse or elephant, etc.

It may be well to follow out the specialized types of jaw movement in the mammals, and see what is the effect of the occlusal forces upon the teeth.

All mammals have a vertical jaw movement by which the stress of muscular action is brought to bear on the food. In many species this form of movement alone is present, and in the most highly specialized cases the form of the teeth or the character of the jaw articulation is such as to positively prohibit movement in any other direction. Depending upon the character of the food under the vertical stress alone, the teeth may be simple and pointed, as in the porpoise, for a purely raptorial function in catching and holding the slippery prey; they may be simple and truncate, as in the walrus, in which they are used for crushing the shells of mollusca; or they may be molded into cutting edges, the lower shearing inside of the upper, as in the highly specialized true carnivora, in which the vertical shearing force is used for cutting up the food (cat). Probably all of these animals have been derived from more primitive forms in which the teeth were more complicated. Thus, by the examination of such forms, we can determine what happens to a tooth when it is subjected to stress in the vertical plane only.

In the majority of the ungulates we find that lateral movement has been specialized to a high degree of efficiency in addition to the vertical. The special adaptation here is for the purpose of triturating a hard and comparatively innutritious type of food. In response to the sidewise motion we find that the tooth crowns have become very complex and the enamel elaborately folded to produce longitudinal ridges with the softer dentin and cementum between, so that in the swing of the mandible from without inward the food is caught between the ridges and finely cut. The cow and horse exhibit the effects of this lateral movement upon the tooth crown to a high degree. All the complicated ungulate teeth, as far as we have been able to trace them, have been derived from simpler teeth, and thus we are enabled to see the result of lateral stress upon the conformation of the tooth crown.

The elephants have a fore-and-aft motion of the mandible in mastication, in addition to the vertical, and the teeth are complicated with transverse ridges and grooves to an astonishing degree. Yet the fossil ancestors of this group had much simpler teeth, and once more the effect of movement in a particular direction is clearly shown.

The rodents move the jaws, when masticating the food, in a sliding movement inward and backward, and here also we see the same principle of response to the character of the food and the direction of the stroke (muskrat).

EVOLUTION OF THE HUMAN DENTITION.

Now let us see what application of these principles, if any, can be made to the human dentition. In other words, Has the human tooth developed in response to one or more of the forces which, as we have already seen, appear to be responsible for the condition of the teeth as observed in lower animals?

Since man is a product of evolution, we naturally expect an affirmative answer, but the fact alone does not satisfy our curiosity, and we inquire further how it has come to pass. The answer is necessarily somewhat complicated.

The teeth of man are not highly specialized, like those of the cat or the horse, to a particular form of food. The natural food of man is certainly as much mixed as that of any other mammal—perhaps more so. If we may judge by the diet of other recent primates and by the character of the teeth of fossil ancestral primates, we may say that the group as a whole has always been omnivorous.

Mobility of the human mandible in all directions. The human mandible is extremely mobile, perhaps more so than that of any other animal, since it can be moved in all directions. The conformation of the articulation and the arrangement of the muscles are such that, from a position of rest, the jaw can be moved slightly backward, or shoved far forward; it can be moved widely in a transverse direction; or any combination of the lateral and longitudinal movements may be made. Not only do individuals vary in customary use of the jaw in chewing, according to habit, but the habit of the individual may be changed by some circumstance, such as the soreness or loss of a tooth; and moreover, the individual may vary the direction of the movement unconsciously a number of times during the course of a single meal. A little observation of a person chewing gum will illustrate, better than I can show in words, how, as the quid is shifted about the mouth, the motion of the jaw is changed and the masticatory force is applied in different directions. Observation of apes and monkeys will reveal that they also vary the movements of the jaw. The teeth and the character of the condyle in fossil primates, as far as we know them, indicate that they also were capable of making similiar varied movements.

THE MOLAR CUSPS IN MAN.

Since man is omnivorous and his jaw movements so varied we should naturally expect the crowns of the molars to be so formed as to permit all these motions to take place readily. The arrangement is that of a squared tooth crown with low cusps of nearly equal height (bunodont type) arranged in a very definite quadrate position. This type runs all through the primate series, though in many of them certain of the cusps are higher. This arrangement of the cusps has not always existed, however, nor are all the cusps equally old. Moreover, the upper and lower molars have arrived at their present condition by different methods of adaptation.

The most ancient feature of the human, or, for that matter, of the mammalian occlusion, is found in the alternate or staggered arrangement of the teeth, each lower molar biting in front and inside of its opposing upper molar. This relation, borrowed from ancestral reptiles, has been retained through all the ages.

Beginning with fossil mammals ancestral to the primates, we find a tritubercular or triangular type of molar essentially similar in the upper and lower series, but reversed in position so that the upper tooth crown possessed one lingual and two buccal cusps, while the crown of the lower molar had one buccal and two lingual cusps. The story of the adaptation in the upper and lower series is different from this point onward, so we must treat them separately.

The upper molar has retained these three primitive cusps—the protocone (mesio-lingual), paracone (mesio-buccal), and metacone (disto-buccal), and has added a fourth cusp (disto-lingual) to make the quadrangle. This fourth cusp, known as the hypocone, is developed from the cingulum or girdle of the tooth just behind the protocone on the lingual side of the upper molar. At the same time the tooth became squared up. The hypocone is therefore much younger than the other cusps of the upper molar, and it is still much more variable in size and form than the other and older cusps. Its nature as a cusp of the cingulum is often shown by the fact that frequently it partly surrounds the bases of the adjoining cusps. These four cusps make up the occlusal surface of the fully developed upper molar. Others, such as the "fifth" (*tuberculus anomalus*) and similar stylar cusps may appear on the cingulum, but as a rule these have no relation to the occlusion. The "fifth cusp" rarely is large enough to be functional, in which case it overlaps the lingual cusp of the opposing molar.

This "fifth cusp" and any other anomalous tubercles are neomorphs—that is, they have no predecessors in any of the primates. With the exception of the "fifth cusp" on the upper first molar and the upper deciduous molar they are very erratic in their distribution. Their explanation is in doubt, but since they occur only in the human, in which the jaw, as compared with that of other primates, has undergone a shortening process, it is barely possible that the appearance of these anomalous cusps is the expression of a compensatory action in the attempt to increase the breadth of the molar surface, which has lost something in length by the process of abbreviation.

The quadrangular form of the lower molar has also been derived from the original tritubercular tooth, but by a different process. Of the three original cusps only two remain, the mesio-lingual cusp of the triangle (paracone) having been gradually suppressed at the same time the fourth cusp was added to the upper molar. All of the hinder portion of the tooth has developed from the cingulum, and this bears two larger cusps, buccal and lingual, the hypoconid and entoconid, with the smaller hypoconulid, sometimes improperly called the "fifth" cusp, between them. Sometimes another (sixth) cusp is present, the entoconulid. It thus happens that the lingual cusps of the upper molars and the buccal cusps of the lowers are similar in origin, while the buccal cusps of the upper and the lingual cusps of the lower molars are different in origin. Yet, notwithstanding this loss, addition, and shifting of cusps, the original primitive feature of occlusion has not been interfered with, and the lowers still bite one cusp farther forward than the uppers, as they always have done.

The change from a triangular to a quadrangular form makes a more effective molar surface, since it covers the ground more fully and adds another cusp for holding and triturating the food. Since the primate mandible, and especially that of man, is movable in any direction, it is necessary that the cusps of the teeth should be so shaped and arranged as to permit these various movements without any interference. For this reason the cusps are low and of nearly equal height; they have a rounded or semi-pyramidal outline, and are arranged so that their points form the corners of a quadrangle. The connecting ridges are low and the intervening valleys shallow. No other plan than this would permit of such variety of motion, except that of a smooth crown, which would be of no use in grinding.

The relation of the cusps of opposing teeth is constant, and is of a very ancient order. The oldest date back to the beginning of the trituberculates, from which the primates, as well as probably all other existing orders of mammals, have originated; and even the youngest date back to the early primates of the lower Eocene period—a matter of some four million years, according to Walcott. In all this lapse of time neither the general features of the occlusion, nor the number, nor yet the arrangement of the cusps, has suffered any material change in the primate series leading up to man. If efficiency may be judged by stability, consider how perfect must be the dental arrangement which has persisted almost unchanged through years that can only be measured by the millions! And this, too, in a system which is generally recognized by comparative anatomists as one of unusual plasticity.

The plasticity of the primate and human tooth is probably not less than that of other mammals. This is perhaps more readily seen in cases of brachycephaly and dolichocephaly—short-jawed and long-jawed types. The related apes *Colobus* and *Cynocephalus* have widely different skull forms. The teeth of the latter are much longer mesio-distally than those of the former, yet the pattern is the same and the occlusion identical. It is as though a sculptor were to take two identical wet clay forms and draw one out and compress the other to make them fit different spaces.

PRACTICAL SIGNIFICANCE OF OCCLUSION TO DENTIST AND ORTHODONTIST.

In the races of man we have similar cases, though not quite so marked. There are brachycephalic races and individuals, dolichocephalic races and individuals, and all sorts of intermediates, and the teeth are exactly adapted by nature to the type of the individual as a part of his constitutional inheritance. It behooves the dentist and the orthodontist to consider this phase of the question with the greatest care.

The foundations of the study of occlusion have been soundly laid, as a result of the labors of numerous scientists. To be sure, differences of opinion exist, even at present, with regard to the origin of certain of the primitive cusps, but the importance of the interlocking of the cusps in their mechanical relations, which we know as the occlusion of the teeth, is generally conceded. However, the value of this mechanical relation to the individual, which is so clear to him who has investigated the subject, is often slighted by the careless and overlooked by the ignorant.

Because frequent cases of malocclusion appear in the human, and often do not seem to interfere greatly with health, some dentists have been inclined to make light of the whole subject. But nature has adapted a particular arrangement of the teeth to the needs of man as she has to every other vertebrate animal. If anyone doubts the importance of occlusion, let him investigate the subject in wild animals, in which very frequently the lack of proper occlusion is directly responsible for death.

Civilized man, to be sure, is able to offset some of the deleterious effects, by cooking and mechanically grinding his food; but even so he cannot entirely escape. Numerous cases of nervous and other troubles, some of them at first quite puzzling, have already been traced to imperfections of the dentition, and who can say how far the evil effects may extend in the human system? The animal organism is so nicely balanced that any untoward condition, though its first effects may seem unimportant or even be unrecognizable, may in the end, either singly or combined with others, produce most baleful results.

Defects in occlusion may appear harmless, but such abnormalities are insidious because they work all the time. The dentist, therefore, should make himself familiar with every detail of the human occlusion, should study it in every type, and especially should take careful account of it in each individual, in order that operative work of whatever character shall do no injury to this intricate mechanical system, and that restorative work of whatever character may conform as closely as possible to the particular phase of occlusion with which nature has endowed each individual of the human species.

PHYSIOLOGY OF NITROUS OXID AND OXYGEN ANALGESIA AND ANESTHESIA.

By CARL G. PARSONS, M.D., Denver, Col.

(Read before Section II of the National Dental Association, at its annual meeting, Kansas City, Mo., July 8, 1913.)

AT the present time there are two main theories as to the nature of narcosis. Meyer and Overton, on the one hand, contend that a loose physico-chemical combination of the fatty constituents of the cells and the anesthetic causes an inhibition of cellular chemism. Verworn, on the other hand, claims that—"The factor which produces the characteristic symptom-complex of narcosis is, under all circumstances, the suppression of the power to carry on oxidations—an acute asphyxia of the cells." The theory of Meyer and Overton would seem to apply to anesthesia produced by alcohol-derived drugs, and that of Verworn possibly, to some extent, to gas anesthesia.

THE SPECIFIC ANESTHETIC ACTION OF NITROUS OXID.

Nitrous oxid possesses a specific anesthetic action, viz, a temporary non-toxic molecular change in the brain-cells, proved by the following reasons, most of which are mine: The early induction of analgesia when nitrous oxid is inhaled in the pure state, before cyanosis appears; the fact that when combined with the proper percentages of oxygen, with the patient showing even an over-pink color, anesthesia is profound and satisfactory; the fact that characteristic symptoms of anoxemia are not present during a correct gas-oxygen anesthesia; that, if anesthesia were due to cellular asphyxiation, pure nitrogen combined with oxygen would give results equally as good as nitrous oxid and oxygen, but if enough oxygen is combined with the nitrogen to give the patient a pink color, no anesthetic results are obtained (Teter); if an anoxemic nitrous oxid and oxygen narcosis is conducted for any length of time, an asphyxial acidosis, due to suboxidation, will occur in a large number of cases, but with a pink gas-oxygen anesthesia, the above does not obtain. As stated by Teter, when cyanosis does occur with nitrous oxid and oxygen, it is concomitant, and is usually seen during early anesthetization, or when the air-way is obstructed.

Cellular function is almost entirely suspended, but more so by alcohol-derived narcotics because of greater cell destruction, yet afferent—centripetal—impulses are blocked very much more by gas-oxygen anesthesia, thus preventing shock. There is a difference between undiluted nitrous oxid and gas combined with oxygen. The former, when a few breaths are inhaled, soon produces asphyxial symptoms; there is marked venous engorgement; the work of the heart is increased, and headache often follows the administration.

THE ACTION OF OXYGEN.

Nitrous oxid given with varying percentages of pure oxygen produces a scientific narcosis by harmonizing with the law of anesthetic accommodation, and thereby gives a more tranquil and safer anesthesia. In regard to oxygen—"It is not an ordinary pharmaceutic substance endowed with a special therapeutic virtue, but it is a vivifying element by which organic metamorphosis, the *circulus vitalis,* is possible." (Demarquay.)

It is said that pure oxygen possesses analgesic properties when inhaled. This is quite true, and further, all respirable gases produce varying degrees of analgesia. Rapid breathing of atmospheric air (Bonwill method) will produce analgesia. By means of the oxygen control, nitrous oxid can be given safely by skilled anesthetists to moribund patients. The inhalation of pure oxygen is pleasant and exhilarating; there is a sense of warmth felt in the entire body, tingling occurs, and perspiration is produced. Acapnia is prevented by gas-oxygen anesthesia. Acapnia means deficient carbon dioxid in the body; it is produced clinically by pain, ether, excitement, sorrow, fear, and rapid artificial respiration, all of which cause excessive respiration—hyperpnœa—with a consequent elimination of carbon dioxid.

THE VALUE OF NITROUS OXID IN ANOCI-ASSOCIATION.

The valuable researches of Crile in regard to the principle of anoci-association places gas-oxygen in its proper sphere in that respect. Anoci-association simply means doing away with harmful or nocuous associations in the patient during a surgical operation. It is accomplished by having the patient in a tranquil frame of mind before the operation; by the preliminary use of narcotic drugs; by peripheral nerve blocking; and by the use of gas-oxygen, and small amounts of ether, if necessary. Crile says—"Anoci-association may further be promoted by the use of pleasant nitrous oxid instead of the irritating, suffocating ether; provided only that the anesthetist is an expert in this anesthetic."

THE QUESTION OF SHOCK.

Considerable contention has arisen over the subject of so-called primary shock. Shock, in general, means depression, and the surgical pathology is varied. Exhaustion of the vaso-constrictor center, the result of injury, is one condition present in shock. Henderson claims that acapnia is the primary cause of shock. Many persons speak of primary shock when in fact the real condition is reflex inhibition—commonly cardiac. This dangerous phenomenon is usually seen during incomplete chloroformization. Whether or not vagus inhibition occurs during gas-oxygen analgesia or anesthesia is a question. It probably does not, because nitrous oxid and oxygen has a specific property of blocking afferent nerve impulses from the very beginning of the inhalation of the gases. At any rate, personal experience, and the fact that no such condition has been reported, would tend to bear out the above statement.

REFLEXES DURING NITROUS OXID AND OXYGEN ANALGESIA AND ANESTHESIA

The reflexes during gas-oxygen analgesia and anesthesia are more active in the various stages of narcosis than when ether or chloroform is the anesthetic used. Nitrous oxid is not a toxic nor depressing drug, like the latter, consequently there is more muscular tonicity and more active reflexes. The special reflexes made use of during gas anesthesia are the conjunctival (lid reflex), tarso-corneal reflex (Parson's reflex, produced by pressing the margin of the superior tarsal plate against the cornea, directly over the pupil, producing reflexly an inward retraction of the lower lid), and the pupillary reflexes, including reaction to light and marginal motility, and the crossed concomitant. The degree of anesthesia depends upon the comparative activity of the reflex, viz, the less active the reaction, the deeper the narcosis.

Much more could and will be written about the physiology of this important gas, but this article is only intended to bring out a few points of practical importance.

CROWN AND BRIDGE WORK, PAST AND PRESENT.

By J. L. HOWELL, D.D.S., Denver, Col.

(Read before Section I of the National Dental Association, at its annual meeting, Kansas City, Mo., July 8, 1913.)

THE ideals of yesterday are the realizations of today, and the ideals of today must, and will, be realizations of the great tomorrow.

We are standing upon the threshold of a new epoch in dentistry, with its apostles of new and progressive thought, who have the power to catch and hold the attention of the money-mad public —Dr. Evans teaching and preaching and driving an unthinking public to give more thought and attention to oral hygiene and general sanitation, while that valiant and renowned philanthropist, Mr. Horace Fletcher, the layman and the apostle of right living, by teaching us the value of proper foods and how to masticate them, has done our profession a great and lasting good indirectly by teaching the general public the necessity for good dentistry, that good digestion and good health may follow. Such men as these have helped to start the general public to "thinking dentistry."

HIGHER STANDARDS OF DENTISTRY IMMINENT.

At this time let me sound the warning that owing to this oral hygiene and oral prophylaxis education which the public is receiving today, the people tomorrow will ask and demand of us a better and more prophylactic dental service, demand that the dentist be an oral surgeon, an artist, and a mechanic all in one, and that he be able to "stand to and deliver the goods."

And when that tomorrow arrives the dentists will have discarded the practice of inserting the ill-fitting crown with its projecting band and the unfinished filling with its overhanging ledge and unpolished wall. He will have discarded the old idea of non-devitalization of the pulp in crowning; the "no cure" idea for pyorrhea alveolaris, the "too young" idea for the regulating of children's teeth, and the practice of promiscuous extraction in orthodontia, as well as many other ideas and practices that are prevalent today, but which are fatal to good dentistry. In that junk-heap of discarded methods and ideas will be found the old, filthy, microbe-breeding stationary bridge. Instead, we shall see the dentist who takes pride in his work, loves his profession, and is ambitious to *best* serve his patients, making and placing the removable prophylactic molar and bicuspid bridge, a removable bridge, more simple and easy of construction than any we have now. This, I hope and feel sure, will be perfected in the next few years.

I wish to call special attention to the fact that now all of our time and skill is spent in trying to duplicate nature in her best and loveliest design, in restoring the usefulness and esthetic beauty of diseased, broken-down, and lost teeth. And to that usefulness and beauty the dentist of tomorrow is going to add prophylaxis as his standard of requirement.

A dentist cannot possibly serve his patients well unless he understands the underlying principles of crown and bridge work and puts these principles into practice. The dentist who falls a victim to the temptation of taking short cuts in order to hurry his work—and it is difficult sometimes to withstand that temptation—will fail to achieve the best results for his *clientèle.*

PREPARATION OF TOOTH FOR A CROWN.

I dare to assert that there is not a dentist who has not heard, time and time again, in his college course a description of how to prepare and crown a tooth, yet for the benefit of those who may have forgotten, I will hurriedly call attention to the essential requirements that are necessary in preparing a tooth for a crown. The first requirement, of course, is devitalization and filling of the canals; the second requirement is adjusting of the band; the third requirement is contour of the band; the fourth requirement is contact and occlusion; and, in crowns for any of the anterior teeth, we will add a fifth essential requirement that must be considered from an esthetic standpoint—and that is, form and color.

DEVITALIZATION DEMANDED.

There was a time when the majority of the dental profession thought it a crime to destroy the pulp of a tooth for crowning purposes, and even today some so-called good dentists are of that opinion. But to me—and I believe that I am backed in my opinion by the very best men in our profession—it seems a blundering mistake if one fails to remove the pulp and to fill the canals to the very apex before the crowning of a tooth. It is sometimes necessary to cut the crown almost entirely away in order to get access to the crooked and irregular canals. In such cases it is advisable to have an X ray made, which I find a great help in speeding my work, with a certainty of success. I feel that it is imperative, before setting a bridge, to have a skiagraph made, to make sure that the canals are filled to the apex.

REMOVAL OF ALL ENAMEL.

The second step in the process of making a crown, after filling the root-canals, is to remove every vestige of enamel from the root, using carborundum stones, sandpaper disks, and enamel cleavers, as the aim is to build a crown that will duplicate the original, natural enamel crown. After the enamel has been entirely removed from the tooth, the greatest circumference of the tooth will be found to be about one-sixteenth of an inch under the gingiva, or at the line of contact between the enamel and the cementum. From this line toward the occlusal surface or edge, the diameter of the dentin diminishes, and the enamel increases in thickness.

DOUBLE BANDS SUGGESTED.

The fitting of bands for molars so as to get a proper fit and to keep it while contouring the bands for excessively bell-shaped teeth, is one of the two original ideas I have to present in this paper—that is, they are original as far as I know.

The great trouble I had up until a few years ago was to get the band to fit and at the same time have the proper contour at the gingival margin. As a rule, it had the reverse contour; that is, it fitted and paralleled the dentin of the tooth, but did not protect the delicate membrane of the gingiva because it did not have the proper contour, and if I gave it the proper contour it was too uncertain in putting on and off. But after repairing a poorly fitting but well-made bridge by removing the enamel from the abutment teeth and making a narrow band for the abutment roots, contouring the gingival portion of the bridge abutment crowns, forcing the bridge crowns down over the new band that I had made for the abutments, I found that I had a beautifully contoured and well-fitting bridge, and after soldering and polishing I was so well pleased with the fit and contour of the crowns that I have used that method for fitting and contouring all gold crowns I have made since then.

ADJUSTMENT BAND.

The technique is as follows: The first band, which we will call the inner or adjustment band, should not be over one-fourth of an inch in width, unless the festooning of the gingiva is decidedly marked, and should be cut from 30-gage plate. The band is to be a trifle short of the measurement of the tooth under the gingiva. In taking the measurement, I use the Hollingsworth copper strips, as they can be forced up under the gingiva better than wire or waxed floss. One end of the band is filed to a knife-edge thinness, the other end is lapped over, with the knife-edge end on the inside, and the band is soldered with a very small amount of 22-karat solder. This band is then forced over the prepared root down to the gingiva with a sharp instrument, and the gingival line is marked upon the band, mesially, distally, buccally, and lingually. The band is removed and trimmed as marked, is replaced on the tooth, forced down over the tooth until it extends under the gingiva a little less than about one-sixteenth of an inch, and then burnished to the walls of the tooth. If this has been done properly, the band will be greater in circumference under the gingiva than at the occlusal end—in other words, it will be slightly cone-shaped. Then, with a sharp instrument, the gingival line is marked on the band, an impression is taken, the band is removed from the tooth, placed in the impression, and a model is run and finished in the laboratory. As I said in the beginning, the second essential principle to be considered in making a crown is to fit the adjustment of the band, and now we have the adjustment band on the plaster model.

CONTOUR BAND.

The third requirement that is absolutely necessary to be considered in the making of a perfectly serviceable crown is contour. It is as essential that a crown should have a perfect contour as that it should have a perfect adjustment at the gingival margin. The first is necessary to prevent irritation to the gingiva, the second to prevent the food from crowding down upon the gingiva and starting an irritation that so often leads to that dreaded disease, pyorrhea alveolaris.

To obtain a good and sure contour, a measurement of the band on the model is taken at the gingival line, and the band width is cut so as to bring the band buccally and palatally to one-thirty-second of an inch of the cusps of the occluding teeth. This band we will call the outer or contour band. It should be cut so that it will have a greater circumference at the occlusal edge than at the gingival, that is, in large bell-shaped molars. One end is filed, lapped and soldered as was done with the inner or adjustment band, using a small amount of 22-karat solder. The contour band is returned to the model and contoured as desired, using spreading and contouring pliers for the purpose, so that the band assumes the proper curves and angles labially and lingually, also insuring perfect approximal contact. The rest of the crown can be finished after any favored method, either by carving the cusps in casting wax, casting and soldering the cast cusps to the band, or by carving the cusps in a metallic carving compound and swaging them in 32- or 34-gage pure gold plate, using a coat swager with soft rubber between the gold plate and the plunger. The cusps are flowed flush with 22-karat solder, or with 22-karat gold, or coin gold, and soldered to the band with 18-karat solder. The crown is then polished, feather-edged at its cervical margin, gold-plated, and well burnished.

All crowns and bridges should be gold-plated before being cemented into place, except the split posts, tubes, and telescope parts in removable bridge work, to prevent unsightly oxidizing of the soldered parts as well as to cover up the cadmium in the solder, which some authorities claim to be poisonous to the system.

By following the method described, a crown is obtained that will always go to place without any danger of the band stretching and going too far down under the gum and impinging upon the gingiva, thereby starting future trouble for both patient and dentist. Such a crown will hold without risk of breaking or tearing, and will bear the greatest amount of stress and strain when used for abutments in Morgan, Roach, or Gilmore bridge and plate attachments.

There is a great variety of factory-made or "ready to set" crowns on the market for the anterior teeth, and I am sorry to say that they seem to be most universally used. But for fear of exhausting your patience, and out of charity, we will refrain from commenting upon their use.

I have never become a convert to the theory that a cast adaptation crown is as satisfactory as the banded Richmond crown or the banded baked porcelain crown. For insuring the greatest efficiency in anterior crowns, no crown made with cast adaptations is equal to the crown made with the band, cap, and post. While the bands are difficult to fit and take more time, perseverance, and skill, yet in the end it pays to employ this crown, owing to the protection offered to the root against fracture and against the micro-organisms of the mouth.

FITTING BANDS FOR A RICHMOND CROWN.

The many failures with the Richmond crown are due to the fact that the proper technique of fitting the band is not followed. Teeth, as before stated, as a rule are slightly conical in shape when the enamel is removed. Therefore, in order to obtain a band that will have the same contour as the enamel portion that extended under the gingiva, we have to be very careful and painstaking in our technique. I do not believe that there is any branch in dentistry where a man's skill and patience are so severely taxed as in the making and fitting of a Richmond crown. The technique of making and fitting a Richmond band is as follows:

The tooth is ground to within $\frac{1}{8}$ of an inch of the gingiva labially, and not nearly so close palatally, the measurement taken, a band is cut a little short of the measurement, fitted to the tooth, and festooned so that it will go up under the gingiva less than one-thirty-second of an inch. The band is then removed and feather-edged with a file and burnisher, making sure that it is festooned sufficiently mesially and distally. Then it is replaced on the tooth and forced down so that it will stretch enough to extend under the gingiva a little less than one-sixteenth of an inch, at the same time becoming slightly conical in shape. While the band is on the tooth, the labial portions of the tooth and band are ground with a round carborundum wheel even with the gingiva; then, with a homemade instrument that is bent and ground so that it takes on the curve or festoon of the buccal portion of the gum and is so made that it will fit the neck of the tooth, the gum is held down and out of the way so that the carborundum wheel will not lacerate it. The band and tooth should not be ground down over one-sixty-fourth to one-thirty-second of an inch below the gum line. Before removing the band, a piece of pure gold plate, well annealed, and a trifle larger than the occlusal surface of the tooth, is burnished over the end of the tooth and band, the band is slipped off, the piece of pure gold is re-annealed, fitted closely to the band, and soldered. The cap thus obtained is replaced on the tooth, an impression is taken, and the crown is finished in the laboratory. As I said before, in my opinion the shortcoming of the Richmond crown lies in the lack of *adjustment* and *contour* of the band. Therefore, after running a model and placing it on an articulator, a facing is ground to fit the cap with a perfect joint, and backed with pure gold or platinum foil, or both, as the case may demand. In about fifty per cent. of cases I find that it is necessary to use both platinum foil and gold plate, 36-gage, in backing facings, using the platinum foil to back the occlusal or cutting half, to give the facing its natural bluish tinge, while the gold is necessary to give a yellowish tinge to the gingival third.

For contouring the band, the facing is waxed to the cap, allowing the facing to stand out over the edge of the band from about one-third to one-half of the width of the band labially. Upon removing the appliance from the model, a V-shaped space will be noted between the labio-cervical margin of the facing and the band. This V-shaped space is filled with very narrow strips of pure gold cut from 34-gage gold plate, and so narrow that it practically becomes gold wire; this is covered with Parr's hard wax flux, invested, and soldered. The solder will follow the pure gold strips and a band perfectly contoured labially, mesially, and distally is obtained. Before taking the crown from the investment, two pieces of 30-gage gold plate are placed upon the palatal portion of the band so that there will be plenty of gold on the band to give the crown, when finished, the proper contour on the palatal margin, as well as to impart to it the additional strength needed for the prevention of root fracture.

REMOVABLE VS. STATIONARY BRIDGES.

Practitioners today seem to make too many stationary bridges and too few removable or prophylactic bridges. The one great fault we find with the stationary molar and bicuspid bridge is the filthy, germ-breeding, odoriferous existence it leads. Only in rare instances do we find a mouth with long slender teeth on which a serviceable prophylactic stationary bridge can be placed. How often do we find cases in which the conscientious dentist, in his anxious dilemma, has compromised and put in a half-serviceable, half-sanitary, stationary bridge, making the molars only one-half to two-thirds as wide as they should be, and calling this a sanitary bridge—and "letting it go at that"—because that seemed to be the best he knew.

The one permanent or stationary bridge that is being used extensively and is commendable, in that it is artistic, serviceable, and comparatively sanitary, is the cast inlay abutment bridge used for canines and centrals, also for bicuspids and molars where there has been considerable absorption from pyorrhea. One reason why I think we like this type of bridge is because all of us can make a more perfect inlay in less time than it takes to remove the enamel from a central incisor and fit a band properly. In this, however, as in every other branch of dentistry, there are bound to be a great many failures by men who are honest and sincere, yet who have not a sufficiently mechanical turn of mind to know or properly judge where such bridges are indicated, how much stress and strain will be brought to bear upon such a bridge, and how much it will stand.

TECHNIQUE OF MAKING INLAY ABUTMENTS.

As to the technique of making an abutment inlay, it is important to have the inlay cover the whole of the occlusal surface of the tooth if the abutment is a bicuspid or canine, thus preventing fracture of the tooth. The cast gold inlay alone must not be depended on for strength, but an iridio-platinum wire must be used for a post, which is set deeply into the canal and bent at right angles so that it will not interfere with the articulation of the occluding teeth. The cavity is filled with inlay wax, so as to cover the iridio-platinum post. The inlays are cast and replaced in the cavities, an impression is taken, models are made, and the bridge is finished in the usual way, excepting the soldering process. It is necessary to invest and solder twice in making a cast inlay abutment bridge, on account of the contraction of the solder when changing from the molten to the solid state, while in making a crown abutment bridge it is only necessary to solder once.

I am especially partial to the removable bridge, using the Peeso removable attachments. These abutment attachments are the telescope crown and the split pin and tube, which are used for the lower bicuspid and molars separately and in combination. The telescope crown is what the name implies, viz, the telescoping of one crown over another with such fine adjustment that the capillary attraction holds them together rather than mechanical friction.

The split pin and tube are used in conjunction with the telescope crown, also for the anterior teeth when we use porcelain facings.

The most satisfactorily artistic as well as prophylactic bridge is the removable bridge having as attachments the split pin, tube, and cast inlay abutments.

CORRESPONDENCE.

MUSIC AS AN AID IN N_2O+O ANALGESIA, AND IN DENTAL OPERATIONS IN GENERAL.

To the Editor of the Dental Cosmos:

Sir,—Few of us, I think, fully realize how important a part mental suggestion plays in the practice of dentistry in general, to say nothing of its influence in the successful use of nitrous oxid and oxygen for analgesia and even for anesthesia.

When one pauses to think of all that is being accomplished by those who are using this agent, he wonders, at first, why its use is not far more general. It seems to the writer that the explanation lies in the fact that it is impossible to obtain the best results unless the subject be taken up more thoroughly than is possible in the time which most busy practitioners are willing to take for it. The mere installation of an apparatus and reading of accompanying directions is not enough to pave the way to success in this work. It must be undertaken in a thoroughly scientific manner; if this be done it will well repay any dentist, who is at all fitted to do the work, for all the time and effort he puts into it, by enabling him to do better work in less time and without inflicting any pain in connection with his operations.

Having used the nitrous oxid-oxygen combination with the most gratifying results for about two years, it has occurred to me that other readers of the Cosmos who are interested in the subject might also be interested in an experiment which I have been carrying on for the past three months in connection with this branch of the work and which has seemed to add considerably to the value of the procedure. This experiment consisted, first, in the installation in my operating room of one of the modern graphophones. Now, as the patient is being carried under the influence of the gases, I find that in the majority of cases their attention is fixed on the music. This is continued throughout the operation, if it is cavity preparation or anything which can be done during analgesia, or until the patient is unconscious, if it be a case for anesthesia. In either instance, if the subject's mind be properly directed by mental suggestion, the result is most gratifying. It gives the patient something to think of besides the impending operation, and altogether the plan proves to be a most beneficial adjunct to the nitrous oxid-oxygen method.

Also, in many cases of nervous patients and children, in which, inasmuch as there will be no actual pain inflicted in operating, it is not considered necessary to use the gases, I find that the music helps considerably to divert the patient's mind.

This is not a theory, but a procedure which has proved of inestimable value to me in practice, and I offer it to the "other fellows" through you, in the hope that some of them may be able to help their patients to overcome the dread of the dental chair, as I have been able to help mine.

The day has come when good dental operations do not necessarily mean the infliction of almost unbearable pain.

J. Neales.

Providence, R. I.

PROCEEDINGS OF SOCIETIES.

NATIONAL DENTAL ASSOCIATION.

Seventeenth Annual Meeting, held at Kansas City, Mo., July 8 to 11, 1913.

(Continued.)

SECTION I: Prosthetic Dentistry, Crown and Bridge Work, Orthodontia, Metallurgy, Chemistry, and Allied Subjects.

Chairman—HARRY E. KELSEY, Baltimore, Md.
Vice-chairman—FRANK T. TAYLOR, Boston, Mass.
Secretary—J. H. WALLACE, Omaha, Neb.

(Continued from page 1164.)

THURSDAY—*Second Session.*

The second meeting of Section I was called to order on Thursday evening at 8 o'clock by the chairman, Dr. Harry E. Kelsey, Baltimore, Md.

The first order of business as announced by the chairman was the reading of a paper by Dr. J. L. HOWELL, Denver, Colo., entitled "Crown and Bridge Work, Past and Present."

[This paper is printed in full at page 1245 of the present issue of the COSMOS.]

Discussion.

Dr. M. E. VANCE, Omaha, Neb. The essayist of the evening has given us a dissertation on the ideal in crown and bridge work, but how many of us follow that ideal? There is no need of my enlarging or commenting upon the essentials for successful crown and bridge work which the essayist has outlined, but I wish to urge greater adherence to these essentials. All that Dr. Howell may say of better crown and bridge work will not benefit us unless we put his suggestions into practice. Many practitioners attend dental meetings and witness clinics and demonstrations of how best to prepare teeth for the insertion of crowns and bridges, and yet they continue to do the work in the same manner as before, which I am sure is not proving satisfactory to themselves or their patients. This is a rather severe commentary on the dental profession, which claims advancement and progress. Yet how many mouths contain dental work which makes us almost blush for shame!

It has been my pleasure since coming to Kansas City to know Dr. Howell personally, and to discuss with him in detail the manner in which he constructs bridge work. I question whether any of you could follow the essayist's short description sufficiently well to be able to construct this work in the way he does. I have received a great deal of benefit in this direction from a study-club to which I belong, where we spend two or three days in going over some special class of work. For instance, at one meeting we study amalgam fillings, at another the construction of crown and bridge work, and at another plate work. Some fifteen or twenty of us get together, discuss these subjects and do the actual work in the mouths of patients provided for us. In this club there are a number of competent demonstrators.

When in college we were supposed to work in an ideal way, but most of us were hardly able to do what we would today consider ideal in any line of work when we were students.

I wish to say a word about the porcelain crowns—such as the Logan, the Twentieth Century, or the Davis crown—the application of which Dr. Howell does not favor, preferring the Richmond crown to all these. With the Logan crown or the Twentieth Century crown I have been very successful in reproducing the natural tooth. I rarely construct a Richmond crown, because I feel that it is almost impossible to overcome the irritation around the gingival margin. I had the pleasure of seeing this afternoon some beautifully constructed Richmond crowns made by Dr. Howell, but the great amount of irritation which I have seen from time to time, due to poorly constructed bands of Richmond crowns, has led me to feel that the great majority of dentists are either not capable or not willing to properly construct such a piece of work. Unfortunately, I have seen a great deal of porcelain crown work which is neither creditable to the operator nor the dental profession. But with proper care and technique, and if a man has any ability at all, it seems to me that he can adjust a porcelain crown to the root of a tooth and make a margin that is far better at the gum than a gold band. Moreover, the color change produced by gold or platinum in the facing is nearly always detrimental. I do not think it is possible to obtain as good color in a Richmond crown that is backed with gold as in an all-porcelain crown. The contour of the crowns that are on the market today will fill the needs of almost every case. To be sure, there are difficult and almost impossible cases which it seems impossible to remedy with anything, but in the great majority of cases I think the porcelain crowns we buy are far better than the Richmond crown. The majority of dentists, in my opinion, are not able to bake porcelain crowns that are equal to those of the manufacturers.

In the preparation of the roots for crown work, the enamel cleavers for the four corners of the tooth, if I may so express it, are very essential. The four sides of the tooth can be ground off with stones of different kinds, but the four corners of the tooth are too often neglected, and if these corners are left untrimmed, a band extending under the gum is sure to cause pyorrhea alveolaris sooner or later.

I wish to say a word in behalf of the cast abutment for bridge work. It seems to me that the saving of tooth structure which we are able to accomplish today with the cast inlay as an abutment argues well for its employment. In years gone by we had to make either porcelain or gold crowns for these abutments, but today we can extirpate the pulps and save practically the entire labial surfaces of bicuspids and canines, if we employ the cast inlay.

Fixed bridge work has been unsuccessful because we have tried to make crowns over teeth without first paralleling the walls of the two abutment teeth.

Dr. J. K. Will, Bonner Springs, Kans. In regard to the Richmond crown, the last speaker said that we cannot obtain the proper color. But, if the gold is held behind the facing and allowance is made for the changes of the shade, the shade will be exact.

In grinding Logan or Twentieth Century crowns I find that by using articulating paper I can obtain perfect adaptation to the roots.

As to the questions of paralleling the abutments for bridges, we can usually get the bridge in place, even if the abutment teeth diverge somewhat.

Dr. J. H. Blachly, Manhattan, Kans. I would like to say a word in regard to the cast joint. If a patient presents a badly broken-down joint which it is impossible to correct by means of the Richmond crown, a solid crown can be obtained by the careful use of the cast joint between the porcelain and the root, especially if we use a detached post, thus getting a result that is esthetic in appearance and will be of great service to the patient.

Dr. J. V. Boswell, Springfield, Mo. Several years ago I favored the use of the banded crown, but have come to the conclusion that a properly inserted all-porcelain crown is the acme of perfection. The trouble encountered with non-banded crowns in a great many instances is due to the careless way in which they are set. In the Logan crown, for instance, we recognize that the pin is rather too soft, but it has the advantage of being made of a noble metal, and unless the root-canal has been unduly enlarged, it will stand in most cases. My method of setting the Logan crown consists in using the Ivory No. 9 clamp and, with a rubber dam on the root, grinding down the stub as desired. In this way I can almost perfectly fit the joint. One great trouble in setting a Logan crown, or any all-porcelain crown, is that we leave the back of the root too low. Of course it is necessary to cut the labial portion high enough to hide the joint; the joint should not be left exposed behind, but the face of the root should be given a slant, which will offer resistance to any force that is brought to bear upon the crown. That is, the face of the root and the base of the crown should be shaped and fitted at as nearly a right angle to the direction of stress as possible. Then the stress will tend to force the crown toward the root, instead of away from it. If a clamp and the rubber dam are used, the field of operation is clearly visible, and the operator can see what he is doing. I do not believe it is possible to have an anterior banded crown remain in the mouth any length of time without producing an untoward condition of the gum. In bridge work, of course, we are almost compelled to use banded crowns if we want permanence, and we have to choose the lesser of two evils. If the abutment teeth are converging, I do not believe in placing a removable bridge of the type described, for an ordinary fixed bridge can be made and placed in most of these cases, if the abutments are properly prepared.

Dr. N. C. Christensen, Omaha, Neb. With regard to the banded crown, I do not think it necessary to allow the band to extend up to the alveolar process, if the root is properly prepared, and this I consider a very necessary feature for the success of the crown. In some cases which I have observed, the root had been crushed and the mesial portion pushed off, presenting a condition which is very difficult to repair. A band properly prepared with good judgment is, in my opinion, a good appliance in such complicated cases.

The color of a Richmond crown can be preserved for many years, if the gold is properly swaged against the facing so that no moisture can get in. I have several patients in whom such crowns have been standing as long as eight and nine years. If necessary, the color can be modified by using platinum. It is desirable that the manufacturers supply us with teeth of natural color, which can be changed to a deeper shade by proper backing.

Dr. W. S. Zeile, Sydney, Australia. I am making removable crown and bridge work successfully, and am glad to see that in the seven years, since I was last in this country, the methods have not been changed in any particular detail. I find that the split pin is of very little value for the purpose for which the essayist uses it, and I would like to ask how he spreads the pin in the center without disturbing its fit, and without spreading the end of the pin that first fits into the tube?

Dr. F. H. Skinner, Chicago, Ill. For hygienic reasons, I believe, we must avoid large fixed bridges. The method which Dr. Howell has described this evening is one of the most perfect methods of removable bridge work that we have, but I think it has a few objections. Dr. Howell, you introduce a tube into the root-canal and run a split pin into the tube, do you not?

Dr. Howell. Yes.

Dr. Skinner. I think the objection to this procedure is the trouble encountered in enlarging the root-canal in most teeth to accommodate a split pin and tube without weakening the root. For this reason I have, for some time, soldered to the abutment a nut or tube threaded on the inside, and screwed a split pin into this tube, allowing a platinum tube to go over the pin, and building the crown around the tube. I prefer the use of split pins to telescoped crowns for the attachment of removable bridge work, for they can be tightened if necessary, and better cosmetic results can be obtained; also, if one side of the split pin should break off, the pin can be unscrewed and replaced without any trouble.

Banded crown abutments add strength to the roots and form firmer attachments, but unless the root is very conscientiously prepared, the band accurately fitted, and the crown contoured so as to protect the soft tissue, irritation will result.

Dr. J. F. Wallace, Canton, Mo. From the discussion it seems that we have no fixed rules for making a crown or bridge. The conditions under which we must do the operation, and under which the crown or bridge must stay, must be taken into consideration, if the appliance is to be a success. A crown or bridge that may be a success in one instance may probably be a total failure in another instance, and it is the operator's duty to study the conditions to which the appliances must be adapted, and under which they must remain in the mouth. We cannot possibly be successful if we confine ourselves to any particular form of construction of artificial substitutes. The banded crown may be ideal in one case, but an absolute failure in another. The audience seems averse to the banded crown, but there are cases in which it is fully indicated. Someone mentioned the case of a badly decayed or crushed root, and suggested that, in order to remedy this, a band must be made to extend beyond the decayed margin. In such a case a cast matrix between the root and the crown is indicated. After all, the operator's gumption in studying conditions and reaching conclusions is the most important factor.

Dr. M. T. O'Neill, Vienna, Austria. Dr. Bryan of Basel, Switzerland, has devised a very satisfactory method of removable bridge work, which consists in attaching the bridge to its abutments by the use of a screw. This method has been described in dental journals several times. It is especially adapted to teeth in which we have to restore a certain portion with porcelain. The bridge can be easily removed and cleansed, and, if the porcelain breaks, a great variety of facings are available for repairing it.

The essayist's description of his bridge work is very instructive. The split pin, on which several of the speakers have been commenting, I have seen in a great number of cases, but have found very few in which the elasticity of the material will last over a few months,

As to the banded crown, I think that the majority of dentists do not use enough pains in fitting the band. We must not forget that, if we allow the band to encroach on the tissues, inflammation will ensue. Probably the only way to avoid this is to be sure that the circumference of the band is not larger than the original circumference of the tooth. It takes a great deal of pains to do this work, but, if properly executed, it will repay us in the end.

A Member. I have been waiting to hear something said about the essayist's method of contouring the band so as to restore the contour of the enamel that has been removed. In a banded crown, that is, I believe, one of the most important features, next to the fitting of the band on the root. We should aim to fit the band to the root as we fit a hoop to a barrel—in contact everywhere. I do not, however, believe that it is absolutely necessary to use a band to prevent the splitting of the root, especially in the six anterior teeth. In these cases, I firmly believe, the porcelain crown with the cast base is the most suitable. This crown will produce less irritation of the gum tissue than a banded crown, no matter how carefully the band is fitted. In order to prevent the root from splitting it is necessary to put the strain on the lingual side of the root. This can be accomplished by cutting a square in the lingual side and making the casting so that it fits well into this square. Any force exerted on the lingual surface of the crown will then be thrown to the lingual surface, and splitting of the root is prevented much more successfully than by any band.

Dr. Howell (closing the discussion). I wish to thank the audience for the consideration, criticism, and extended discussion accorded to my paper. It always seems remarkable to me how much success so many operators obtain from different methods. Each operator obtains better results with his own favorite method than with any other, according to the law of the personal equation. I am partial to the Richmond crown, because in my hands it has given so much satisfaction. I have been trying to learn other methods, in order to obtain results with the least expenditure of labor. I have been trying the method of casting the joint, but have never yet been able to make a joint without a cleft, and such a joint cannot be kept absolutely prophylactic. I intended to bring with me a three-teeth bridge that I inserted nine years ago, using banded Richmond crowns as abutments, for a patient who since that time has been all over the world. When this bridge was inserted he had four natural teeth left on that side, and was wearing a partial plate. During his absence he lost a central and a lateral incisor and canine, and when, on returning to Denver, he came to me he had only a right lateral and central and two right molars left, which were so loose from pyorrhea that they could almost be removed with the fingers. I remembered having made a note when I inserted the bridge that the two abutment teeth were affected with pyorrhea, as much as the other teeth left in the mouth. Yet after nine years these two abutment teeth with banded contoured Richmond crowns were absolutely solid, although the natural teeth had either been lost by pyorrhea or were hopelessly loose. The patient insisted on having the bridge removed and a full gold plate made. I had intended to show the bridge and the extracted teeth here, in order to demonstrate what a great amount of tartar had accumulated on the four teeth which I extracted and what a small amount on the teeth that had been crowned.

If one can get better results by using the cast gold base, as my friends claim, he should use it by all means, but personally I have never been able to obtain a perfectly fitting cast base for a Logan crown, even if I use articulating paper. Moreover, it takes three times as long to get a perfect adaptation as to make a perfectly fitting band and contour by the method described. The great fault of the Logan crown is not so much getting this joint here [indicating], as in the mesial, lingual, buccal, or palatal joints, because there is always some little overhanging ledge there, which holds food and starts inflammation.

It is true that in many cases the Richmond crown is a failure, but this is not due to the system, but to the mechanism of the finger-tips and to lack of skill on the part of the operator. After twelve years of practice I find this to be the only system that will universally answer all the requirements, if applied properly. It takes a great deal of time to get good results, however, and many practitioners are inclined to take short cuts. I have seen fifty or more fractured roots on which unbanded crowns had been used, and I object to that form of crown on account of this risk of fracture as well as for prophylactic reasons.

The correct color can be readily obtained, if a facing of suitable shade is selected, and platinum and gold is used for the backing. As a rule I can get as perfect color as with a Logan crown, although I am partial to the Logan crown as far as artistic effect is concerned; but we cannot sacrifice durability to esthetic appearance, although our crowns must be as nearly esthetic as possible.

One of the speakers said that it was impossible to fit a band and not produce irritation of the gum. I wish I could show some of the cases in which I have used the Richmond banded crown. I have had, of course, failures in some Richmond crowns. I have had to remove one or two such crowns when gingivitis was present, and made a banded porcelain crown, allowing the porcelain to extend down over the band, thus providing a heavy band of porcelain, which is, I admit, unsightly when out of the mouth, but when set will allow the gum to remain in a healthy condition. I have inserted many of these crowns in cases where there seems to be some idiosyncrasy of the gum tissue against tolerating gold even when properly burnished.

Dr. Zeile wants to know how the pin is spread. There are two ways of doing this. If the pin is ground off to this point [indicating], and opened with a fine instrument, it will split in this manner [indicating].

Another method is as follows: I do not grind off this little flare [demonstrating], but leave this end of the wire bent and only cut about one-half. In the cases where I have used this method I have had only one bridge come off owing to a spread pin. There seems apparently no wear and tear on these abutments in five and a half years. It seems they hold by capillary attraction. In other words, a certain amount of moisture present does not allow the pieces to come together, and yet there is a better and tighter fit if such moisture is present. The best way is not to grind the pin off here [indicating], but to make the split from here to here [indicating] obtaining the spread from here to here [indicating], rather than at the end.

Section I then adjourned.

SECTION II: Operative Dentistry, Nomenclature, Literature, Dental Education, and Allied Subjects.

Chairman—J. R. Callahan, Cincinnati, Ohio.
Vice-chairman—Joseph D. Eby, Atlanta, Ga.
Secretary—J. P. Marshall, St. Louis, Mo.

Tuesday—*First Session.*

The first session of Section II was called to order on Tuesday afternoon, July 9, 1913, at 2.30 o'clock, by the chairman of the section, Dr. J. R. Callahan.

The Chairman announced as the first order of business for Section II the reading of a paper by Dr. G. S. Junkerman, Cincinnati, Ohio, entitled "Dental Educational Harmony."

[This paper is printed in full at page 1231 of the present issue of the Cosmos.]

Discussion.

Dr. Henry W. Morgan, Nashville, Tenn. The paper to which we have had the pleasure of listening has been very carefully read several times by me, and I feel quite confident that I but re-echo the sentiment that fills the hearts of all present when I say that Dr. Junkerman's conclusions are pretty generally accepted by the profession everywhere—viz, that there should be harmonious co-operation between the profession, the boards of examiners, and school men, and that this would lead to less fear of the adverse criticisms which go forth and poison the minds of the public, doing injury to the profession and still more to the schools. Those who carelessly circulate such reports are lowering themselves in the eyes of the profession as well as in those of the public. This is a plea for harmony; it does not ask for the sacrifice of any principle, but simply for hearty accord and further co-operation, for a full, just and intelligent survey of the problems which are to be solved, and in which each of these bodies we have alluded to have an equal interest.

He who knows the sacrifice that the professional dental educator is called upon to make, and anyone who will follow the history of our dental institutions and but briefly survey them for one moment, knows that they all have the best interests of the profession at heart. We have heard this morning the eloquent address of Dr. Price on the demands that are being made for higher education in the profession of dentistry. How many scientists have we in the dental profession? We cannot hope to make scientists of all our students, but we can impart to them a love of science.

A dental school in order to survive must in the future be a nursery of research. If we do not step in, as Dr. Price has shown us this morning, and assume our part in the responsibility of caring for that branch of preventive medicine which that celebrated surgeon of Chicago said a few weeks ago was the next important domain for the dental profession to occupy, how can we expect to raise any claim for higher professional standing? It rests upon us, and since, as the essayist says, the mouth is the most infected portion of the entire alimentary canal, we shall have to dig deep down into the science that underlies oral conditions, and all schools must become research bureaus.

The *Dental Review* for June published a clipping from the Northwestern University folder enumerating thirty-odd towns that need dentists. No doubt many of you realize that we are not supplying the annual loss of dental practitioners. Unless the colleges are allowed some discretion as to preliminary educational training, and increase the number of graduates, they cannot do justice to the rapidly growing importance of dentistry, and fill the demand for dental services, and soon we shall find ourselves in the embarrassing position depicted by the essayist of this afternoon. What are we going to do? How can we face our legislatures and ask for revised statutes when we know that we are not supplying the demand for dental surgeons?

I do not mean to say that I believe in having no regulations whatever for the entrance of students into dental schools. In the school I have the honor of being connected with, the university entrance committee passes on all credentials measuring up to the requirements of the National Faculties Association, and these in turn are *visé*'d by the state superintendent. I do believe, however, that we shall have to relax somewhat and supply the demand, else our legislatures may take the bridle off, and pandemonium may result.

I wish to congratulate the essayist on the very forcible manner in which he has presented these questions, and to invite careful reading of the paper after it has been published.

Dr. Chas. McDowell, Rapid City, S. D. In discussing the timely and efficient paper by Dr. Junkerman, I will confine my remarks to the third section of the "inharmonious brass band," as he calls it, viz, the profession at large, to which I belong. Incidentally I may smash a drumhead or dent a cornet in the other section. I played in a band as a youngster and after we had learned to harmonize sufficiently, we went out on the prairie back of the depot and practiced marching, and it is in this very respect that this third section, the profession at large, falls down. We are not in step. Vast numbers of the public have no ear for harmony; but if we make a noise, and keep step with it, they are impressed. Our responsibility is great; we should see that colleges are giving the best that can be given, and that they do not put quantity above efficiency. If a certain standard of education be required for admittance, it should be maintained in all colleges. But the spirit of "getting the money" has not been dormant in these institutions. No school should be run as a dividend-paying institution. The state should back up and control this department, and close any schools that are being run for profit.

It should be a shame that a university dental department, with some of the brightest and best teachers in its faculty, should be closed because it did not pay financially, though every teacher devoted his energy to producing efficiency and turning out graduates that passed various state boards with the lowest ratio of failures.

Dr. Junkerman states that "Much to the credit of the colleges, there has been very little tenable criticism from any source, to cast discredit on dental education," and then goes on to throw stones at the examining boards, stating that they are inquisitors, inconsistent, and the product of political preferment. The profession at large also seems to him to be a mighty discordant group. Now, while we have been hit, let us look at the stone-bruise on the colleges, and then all convalesce together. The preliminary mental qualifications for admission to dental colleges have been stated. Does it not occur to you that there should be some method of determining a prospective student's mechanical and constructive ability? I have known students, as you all have, who have studied three years, and four, and have then been given a diploma, although in reality they were so awkward that they could hardly sharpen a pencil. I believe it will hardly be denied that any graduate of a recognized school can pass the mental or written tests in the state board examinations; the failures are in operative and prosthetic technique.

Let us hasten the time when we can have uniformly controlled colleges, with a national law broad enough to recognize that a man capable of performing dental service for a citizen in South Dakota is qualified to do the same for a resident of Boston.

I do not quite agree with the statement in Dr. Junkerman's paper that "The dental laws are enacted by the people for their protection, and that the people do not care how many dentists there are —they are only concerned about the quality.

It is a fact that, if it were not for some of the progressive, public-spirited dentists that drafted protective laws for the people, a good many states would not yet have examining boards. How many states at present meet the expenses and allow salary enough to maintain a board without the practicing dentists themselves contributing to its maintenance by a yearly diploma registration fee? Though this fee is small, it is wrong. The people reap the benefit, and the state should pay the expense and allow salaries besides.

Another statement in the paper to which I call attention, not in criticism, but in fairness to those examining boards that are free from politics, is this: "Executive capacity and worthiness of authority are tested by credentials and examinations in other legislative departments, and there is every reason why our dental examiners should be submitted to the same test, instead of the test of political preferment."

First: Let me ask how many would voluntarily take those examinations for what glory or salary there is in the position?

Second: State board appointments can be removed from politics by each state society, if the society wishes. As an example, we in South Dakota at our annual meeting select two members of our society, whose names are sent to the governor with the request that one of the two fill the vacancy, and so far every governor has respected our choice. I believe every state society is a good judge of who should be upon the state board. Competitive examinations for dental examiners would be a useful innovation, but the board should be a national one.

I am in accord with Dr. Junkerman as to the lack of educational harmony, and with his permission would like to suggest that the public be included in this educational harmony. The profession at large must assume the responsibility of enlightening the public as to what they ought to expect from us, and of showing them what we are doing for the good of humanity. If we will decide on the noise we must make, and then each enlighten the community with which we come in contact, and keep step, we will be doing part of our share in this dental educational harmony.

Dr. Truman W. Brophy, Chicago, Ill. I very much enjoyed the paper read by Dr. Junkerman. Some thoughts, however, were expressed by him that are not in exact accord with my experiences of the past few years, though I have no reason to doubt that he has some justification for his viewpoint. As far as I am able to judge the conditions of today as compared with those which existed a few years ago, great improvements have been made. I am not in sympathy with the opinion of the essayist, and of the last speaker, regarding the spirit of discord in the profession. There is no profession in which there is such a general feeling of good-will and harmony as exists in the dental profession today.

In corroboration of my statement, look for a moment into the history of medical education in this country and review the literature thereon, especially the reports of the committee having in charge the work of medical education in medical colleges. Some of you, perhaps, will be surprised when I state that at Atlantic City as recently as five years ago that committee reported that fifty per cent. of all the medical schools in the United States were so ill-equipped and so deficient in their qualifications for teaching, in faculties, buildings, apparatus, etc., that the very best interests of the public would be subserved if that fifty per cent. of the colleges were to be closed by the government or by some power that might be able to do so.

What have we here? I look about and see before me different bodies of men in the dental profession—absolutely honest, I believe, in their purposes, each one doing all that he can to advance the interests of the profession and to guard the interests of the public. Is it possible for one to name a man on a board, a teacher in a dental college, or a member of the profession, who has not the best interests of the profession at heart? Does anyone believe that these men to whom I have referred are dishonest? Do you not believe that each is doing his very best to elevate the profession and care for the people? Go with me to the cities of our country where men have sacrificed almost everything in caring for poor children in the public schools. Point out, if you can, members of any other profession who have done as much in a philanthropic way—and then talk of general discord. I do not know where there is any general discord.

In Chicago three years ago there were three colleges, and we called our faculties together and organized an association of the colleges of that city, with this object, viz, that we might exchange views, might improve ourselves, so that each and every man engaged in dental educational work in that city might profit in such a way as to be able to do better work. In this association there exists perfect accord, and its members have all been greatly benefited.

I would suggest to the gentlemen who have said that there is discord in the profession, to try to have the members of the board meet the faculty members, sit down to a dinner together and discuss the essence of dental education and the aim of the profession in a general way, and I know that they will be able to exchange views in a way that will prove mutually beneficial to all.

There is another phase of the paper with which I do not agree, and that is the suggestion that some men are engaged in educational work for the money that is in it. You all know that the salaries of dental teachers are not in proportion to the amount of time and sacrifice made in educational work. You also know that every man who takes upon himself the great task of the educator is a financial loser. Teachers generally are inadequately compensated for their services. I therefore do not like to hear the author of a paper declare that certain institutions are managed for financial purposes. For my part I would like to see these institutions endowed in the magnificent manner exemplified by the Forsyth brothers of Boston. I would like to see money advanced in sufficient quantity to equip laboratories, and I cannot speak too enthusiastically regarding the work that is being done here today. I do not know how much money has been raised this morning for the purpose of scientific research, but I am sure that it is a considerable sum, and that all the money will be raised that is necessary to equip laboratories for that good purpose. Then let the boards of examiners, the teachers in the dental schools, and those interested in the progress of the profession, get together and discuss this question in the right spirit and with the determination that there shall be harmony and progress. Then the best interests of the profession will be advanced, and we shall obtain results that no one at the present time is dreaming of.

Nay!—we should not have discord in the dental profession; and we shall not have discord in the dental profession. Harmony must prevail. The magnificent body of men assembled here today must stand as one man, resolved to do the very best possible work to advance its interests. Over the mantelpiece of the Union League Club in Chicago are inscribed these words: "*Welcome to all loyal hearts.* We join ourselves to no party which does not carry the flag and keep step to the music of the Union." Let this apply to us. We should not allow any opportunity to pass to loyally carry the flag and keep step to the music of the profession.

Dr. Junkerman (closing the discussion). I shall have very little to say in closing the discussion.

In reply to Dr. Morgan's comment on the question of research work in dental colleges, I would say that I did not mean my remarks to apply in the sense in which he referred to them. I referred to the need for research work in colleges after the students have obtained the degree of Doctor of Dental Surgery. As far as the universities are concerned, the more they can do the better, but first these men must be educated to the degree.

With regard to harmony in dentistry, I admit what Dr. Brophy has said. We are harmonious, but Dr. Brophy has lived long enough to know that one specked apple may contaminate the whole barrel eventually. There are a lot of things, as Dr. Brophy says, that we should talk over together; and he is quite right in his intimation that the best way of approaching one's fellow man is to invite him to a good dinner. I would like to take out to a good dinner some of these individuals who have a tendency to misunderstand the purposes and intentions of the colleges, and then I could probably convert them. Dr. Brophy says there is harmony in the profession—but *not educational harmony,* say I. That is what I intended to emphasize in the paper. It is only by educational harmony that we can present a solid phalanx and accomplish the results we wish for the public and for ourselves.

Another matter referred to is the money made in dental colleges. I do not see how that is possible. I do not know of any college that declares a dividend; if there is one in this country that does, I am ignorant of it. I agree with Dr. Brophy in the statement that probably no other set of men make such sacrifices as do teachers, and especially dental teachers. It is necessary for them to do so. We become practically "possessed" with the subject of dental teaching. We get into it like the preacher who receives a "call" to preach; we teach because we love to. I know a great many teachers who do a great deal of work for a few dollars of compensation, but they stick to it. Why? Because they love it. Dental teachers have received the call to teach, and nothing could stop them from teaching and preparing the youth for the profession.

The next order of business for Section II, as announced by the Chairman, was a lantern lecture by Dr. Howard R. Raper, Indianapolis, Ind., entitled "The Value of the Radiograph in the Practice of Modern Dentistry."

Dr. Raper's lecture consisted in a *résumé* of the papers on "Dental Radiography" as published in the *Items of Interest* for 1912. The lecture was discussed by Dr. L. E. Custer, Dayton, Ohio; Dr. R. Ottolengui, New York, N. Y., and Dr. Truman W. Brophy, Chicago, Ill.

The section then adjourned until a later session.

Wednesday—*Second Session.*

The second session of Section II was called to order at 2.30 o'clock Wednesday afternoon, July 9th, by the chairman, Dr. J. R. Callahan.

The Chairman announced as the first item on the program for the afternoon session a paper by Carl G. Parsons, M.D., Denver, Colo., entitled "Physiology of Nitrous Oxid and Oxygen Analgesia and Anesthesia."

[This paper is printed in full at page 1243 of the present issue of the Cosmos.]

Discussion.

Dr. J. S. Jackson, Denver, Colo. Dr. Parsons gives a very minute, concise, and scientific treatise on the physiologic action of nitrous oxid and the combination of nitrous oxid and oxygen in analgesia and anesthesia. He records an observation which all anesthetists have noted, viz—"A few breaths of nitrous oxid inhaled soon produce asphyxial symptoms. There is marked venous engorgement; the work of the heart is increased, and headache often follows its administration." This quotation and the entire paper impress me most strongly with the danger involved in the administration of anesthetics, even nitrous oxid, which is claimed by its admirers to be the safest of all anesthetics, though this has not been proved. In their efforts to prove the safety of gas-oxygen anesthesia, they decry the safety of nitrous oxid, with or without air. Perhaps one of the most dangerous symptoms of nitrous-oxid narcosis is blood pressure in all cases; especially is this true in patients advanced in years. If we suppose the blood pressure to be from 20 to 30 mm. of mercury above normal, and if by the administration of nitrous oxid this pressure is raised another 20 or 30 points, rupture of a sclerotic artery might be caused, giving rise to a very serious condition. We are all aware that oxygen is not a panacea for the deleterious effects of nitrous oxid. It may lead in combination with nitrous oxid to more serious and mysterious symptoms than nitrous oxid alone. It seems to be taken for granted that oxygen can be introduced by the lungs as readily as food is carried into the system through the stomach, and that by its administration all the organic operations of the economy can be roused to increased activity, but it has been proved that not more than a certain proportion of oxygen, such as exists in the atmosphere, can be absorbed by the lungs. It should also be remembered that oxygen, when inhaled in large quantities, is so far from being a stimulant that it relaxes and debilitates the system, in fact induces narcotism. Happily the gas-oxygen combination, or any other anesthetic, will not be administered as recklessly as has been done in the past. The administration of ether and chloroform mixed is difficult, because of the difference in the density of the two gases. Perhaps somnoform has given us the idea of a definite anesthetic mixture. With the reasonable safety of nitrous oxid alone, and mixed with a known quantity of oxygen, and a skilled anesthetist who can follow symptoms by intuition, beyond the shadow of a doubt as to when to increase and when to decrease the quantities and proportions, the responsibility of success or failure is left where, perhaps, it properly belongs, viz, to the "man behind the gun," the anesthetist. Very little is known of respiration, and that little seems to be far from right. If a patient is short of breath, or anything is wrong with him that looks like failure of respiration, as much chemically pure oxygen is administered as the pulse will tolerate—when the one substance that might, for a time at least, restore the respiratory centers to normal activity is carbon dioxid!

I think the principle of gas-oxygen anesthesia is faulty, if not wrong. In its administration we diminish the amount of carbon dioxid, nature's respiratory stimulant, and have no means except rebreathing to replace it. Let us get right, therefore; we lack knowledge of the functions of man himself, and not until we understand the respiratory and circulatory system more fully can we hope for an anesthetic that will deaden the sensibilities and yet keep and leave the patient in a normal condition.

Dr. O. Cunningham, Kansas City. We may add two reasons why nitrous oxid is an anesthetic agent independent of oxygen; one is, Anesthesia can be obtained in children by administering from forty to fifty per cent. oxygen with nitrous oxid; another is, If nitrous oxid is breathed for ten or fifteen seconds, the effects are easily felt. One may hold his breath for a minute or longer without getting any analgesic effect. This, together with what Dr. Parsons has said, is fairly conclusive to me that nitrous oxid is a true anesthetic agent.

I believe the administration of nitrous oxid anesthesia has been sadly neglected as regards the proper selection of cases. It is true that many of the cases that take nitrous oxid and oxygen apparently the best, involve the greatest risk. We can divide the cases that present complications into four divisions: First, complications due to obstructions such as adenoids, etc.; then three more divisions in which complications principally arise in connection with respiratory exchange, viz, the exchange of oxygen between the lungs and the blood. As a person develops from adolescence, the lungs keep pace with the body. Early in childhood the body weight is greater in proportion to the lung capacity. This is gradually overcome, but often, after adolescence, an individual takes on additional weight, which interferes with the administration of nitrous oxid through the limitation of oxygen.

Suppose an individual weighs one hundred and fifty pounds at adolescence, then within a few years takes on thirty additional pounds; a true respiratory exchange would add two per cent. oxygen, instead of which four or five per cent. of oxygen should be added. This is probably because there is also a delinquency in the cardiac functions and in other organs of the body, as well as in the lungs.

Another limitation of gas-oxygen anesthesia is in the case of anemia. A person whose hemoglobin amounts to only 50 per cent., will require fully 50 per cent. of oxygen. This proves that the deficiency in hemoglobin limits the oxygen-carrying capacity fully one-half; but if the hemoglobin is 50 per cent., we do not add oxygen in the same proportion. Another limitation is toxemia, which also has to do with the respiratory exchange. If the patient has from thirty-five to forty respirations per minute, he would be getting about double the supply; this would indicate that the toxemia has nothing to do with the hemoglobin limiting the oxygen-carrying capacity. With the hemoglobin about one-half, we would have to use fully 50 per cent. of oxygen.

I believe that the time is coming when a careful selection of cases will be considered in analgesia as well as in prolonged anesthesia with nitrous oxid and oxygen.

In the use of nitrous oxid in dental work, we sometimes desire to secure prolonged anesthesia in some operations, but since analgesia has come into use, one dentist will usually employ nitrous oxid to the stage of complete anesthesia, even if he has only one or two teeth to extract, while another will employ analgesia. When we induce anesthesia for the shortest available period, we really need no oxygen, although oxygen is very good to have at hand, and affords a little longer working period. In analgesia, the amount of air admitted to the mouth supplies all the oxygen needed, as the normal individual requires only about ten per cent. The nitrous oxid administered for this purpose need not be under positive pressure; although, if prolonged anesthesia is desired, an inhaler is needed, and positive pressure. The positive pressure inhaler is to be avoided merely because of the inconvenience of the soft palate pressing against the tongue and in case the tongue drops back, creating an excessive intrapalatal compression.

Dr. Wm. C. Teter, Cleveland, Ohio. Although I am not on the program to discuss this paper, having met Dr. Parsons recently in Cleveland and having expressed my desire to hear his paper on the subject of nitrous oxid and oxygen, I am very glad to take part in the discussion, as the administration and study of this anesthetic is the greatest part of my life-work.

The physiological properties of nitrous oxid and oxygen, I believe, are less definitely known and understood than those of any other anesthetic agent. A number of theories have been advanced. Dr. Crile has written considerably upon the subject, yet I cannot concur in his belief regarding the anesthetic properties of this agent. My knowledge of the subject has not been gained by research work along this line, but is based wholly upon ten years of clinical experience and actual work in major and minor surgery, and in the extraction of teeth. Although in my practice I have not used analgesia for a number of years, I sometimes administer it for other dentists.

Cyanosis is no part of anesthesia. Nitrous oxid is not always responsible for the cyanosis that appears in the initiatory stage of anesthesia. There may be obstructions such as have been spoken of here; the patient may struggle or other complications may arise that produce cyanosis, and oxygen alone is not always indicated for overcoming that condition.

I think cyanosis or the livid color or bluish cast of the complexion will occur almost always in the beginning of the inhalation of nitrous oxid and oxygen in the average person in very good health and with plenty of red blood, but not necessarily in a weak and anemic patient. Cyanosis is due to the crowding of nitrous oxid in the desire to obtain the proper anesthetic tension. It can be overcome if a longer time is consumed in producing anesthetic tension. In ether and chloroform anesthesia a considerable period of time is consumed in obtaining this tension, and more time should be taken when nitrous oxid and oxygen is the anesthetic agent employed.

The asphyxial element at commencing is a hindrance to anesthesia. The more asphyxia, the farther away the patient is getting from real anesthesia. The asphyxial character of nitrous oxid, therefore, is entirely separated from its anesthetic property, and a proper amount of nitrous oxid with oxygen will not cause asphyxia.

In the administration of nitrous oxid and oxygen, we find that the administration of warm gas under positive pressure and its gradual mixture with oxygen are the greatest factors in preventing both cyanosis and asphyxia.

Much has been said about shock resulting from the administration of this anesthetic. In my opinion the administration of nitrous oxid and oxygen produces no shock to the system. It is non-irritating to the respiratory tract and to the lungs, and I do not believe that it has a chemical action upon the cellular tissue. It is a mechanical compound or mixture with molecular action upon the blood corpuscles acting upon the brain centers that produces sleep, not unconsciousness—because unconsciousness is not always anesthesia. When ether or chloroform is used as an anesthetic, I believe that as much shock results from the anesthetic as from the traumatism of the operation. Another factor that tends to inhibit shock in the administration of nitrous oxid and oxygen is the fact that phagocytosis is not affected; the patient retains all the resistance necessary to combat the shock from the operation. In a person of low vitality, if ether is given, the resisting power is considerably reduced, therefore shock is produced by the anesthetic. If, in addition, there is shock from the operation, the patient has less chance of regaining consciousness. I believe, therefore, that in regard to shock, very much is to be said in favor of nitrous oxid.

Dr. Crile of Cleveland has recently written about the use of novocain, which he has been employing in his practice, as an agent which acts upon the periphery of the nerves. This suggestion, I believe, is one of the best that has been made to the surgical profession for a long time. I also believe that by administering nitrous oxid and oxygen, together with the use of this local agent, a careful surgeon can do away with the major part of shock.

The use of carbon dioxid is based largely on theory at the present time. I was in New York City a short time ago and heard Professor Henderson of Yale speak upon this subject. He admitted that there is a great deal of mere theory in connection with it. He has an apparatus consisting of a little motor, which he employs to administer carbon dioxid. He mentioned the case of a boy who had both limbs cut off in a streetcar accident and to whom he administered the carbon dioxid and kept him alive for some time, though he finally succumbed to the shock and loss of blood. Still, the result in this case was quite problematical as to how much the gas contributed to prolonging the boy's life. He stated also that it would not do to administer too large a dose of that gas.

In my anesthetic work, I obtain carbon dioxid in the mixture by the rebreathing method. In a number of experiments conducted at St. Luke's Hospital, and reported by Dr. Chas. K. Teter, the patients were made to breathe back and forth into the bag, and the contents of these bags were saved and analyzed. It was proved that they contained from four to eight and one-half per cent. of carbon dioxid, depending, I think, largely upon the amount of nitrous oxid required to maintain anesthetic tension.

Dr. Jackson spoke of the safety of nitrous oxid and oxygen. In the earlier days of the revival of the use of nitrous oxid in the dental profession, the safety of the administration of this agent was chiefly spoken of. It is a proved fact that it is the safest anesthetic if properly administered. I do not believe, however, that it is the safest anesthetic in major surgery in the hands of the novice. If I were compelled to take an anesthetic and I had the choice between taking nitrous oxid and oxygen administered by an inexperienced man or ether administered by an experienced man, I would prefer the ether. But that does not disprove the fact that nitrous oxid and oxygen is the safest anesthetic which can be employed, if properly administered.

In case of a cessation of breathing, as has been said, oxygen is not always called for. This is a fact, because oxygen cannot be given if nitrous oxid and oxygen anesthesia is being induced, as in all probability the patient, if he has good color, has already too much oxygen, and therefore will hesitate in breathing until he needs more oxygen. In the analgesic stage, the patient can hold his breath a long time; he is not actually holding his breath by any conscious effort, but his system does not demand any more oxygen, and therefore does not take in any more.

Children, as Dr. Cunningham has said, will take a larger percentage of oxygen, in a majority of cases, after anesthesia is induced, though in my tonsil and adenoid work I find that some children as young as two years of age really require more nitrous oxid with more pressure to secure quiet anesthesia than is required by adults. I have frequently resorted to the addition of a small quantity of ether in those cases, simply because in the child the respiration is so fickle that, by the time he has been quieted with nitrous oxid and oxygen, the operator has to be very careful, lest respiration cease or the child be thrown into clonic spasms.

I realize that the essayist's paper and the discussion largely pertains to the administration of nitrous oxid and oxygen in major surgery. I also realize that this is a meeting of dentists, and that there is a wide difference between the administration of this gas in major surgery and its administration in the practice of dentistry. For the benefit of our medical brethren, I want to disabuse their minds of the opinion that it is easier for the dentist to give nitrous oxid and oxygen in his practice than it is in major surgery, because the opposite is true. Prolonged anesthesia for oral operations is seventy-five per cent. more difficult to get and to maintain satisfactorily than when the face inhaler can be used and all air excluded, as for major surgery. In dental operations we have to contend with the air that is breathed through the mouth when the latter is open and the muscles are relaxed. The atmospheric pressure of fifteen pounds to the square inch compels the patient to breathe through the mouth, therefore no effect is obtained from the anesthetic unless the gas is forced, and forcing the gas involves other difficulties.

I do not agree with Dr. Cunningham regarding asphyxia induced by the gas. In the old method of giving nitrous oxid with the common gasometer and face inhaler, the air-valve was opened after the first few inhalations in order to overcome the depressing asphyxial effect. This was not done to produce anesthesia, but for the comfort of the patient. It takes as long or longer to produce nitrous oxid anesthesia in a manner comfortable to the patient, than it does to produce nitrous oxid and oxygen anesthesia with the nasal inhaler. If the patient is watched carefully, and he is not fighting the anesthetic, and oxygen is added gradually, all sense of suffocation or distress on the patient's part can be overcome. It is better, therefore, to administer nitrous oxid and oxygen regardless of the fact that anesthesia can be obtained with nitrous oxid alone. After the operation is begun, and the patient commences to breathe through the mouth, it is necessary to force the gas to the point where it will be taken into the lungs.

In extracting this is easier than in throat work, because in extracting cases sterile sponges can be used to pack the mouth, preventing a certain amount of the air being breathed in that way, and if the mouth be packed solidly enough, the patient can be compelled to breathe or will breathe through the nose. Therefore the gas will not have to be forced.

I never advise the use of the face inhaler to induce anesthesia for extracting teeth. Even if we have only one tooth to extract, we do not know in advance how much suffering the extraction of that one tooth might cause. Some of the most difficult and painful extractions are caused by teeth which may appear as if they would come out easily. I never want to assume the risk of inducing anesthesia thinking that I can remove a tooth in thirty seconds without the patient feeling it, for I may not be able to do it. In all my extracting, therefore, I use the nasal inhaler, so that I may be prepared for any emergencies.

As to analgesia, I believe that fully nine-tenths of our operators are working in the first stage of light anesthesia. It requires very little gas to produce analgesia in the majority of cases. While many operators advocate the use of nitrous oxid and oxygen for analgesia, I would advise the use of a great deal of air, because the capacity of the lungs demands so much volume. With every inhalation and exhalation a certain amount of gas or air is taken into and expelled from the lungs. No great volume of nitrous oxid and oxygen is required to produce analgesia.

I would not depend upon nitrous oxid and air alone, for oxygen has some analgesic properties in addition to being preferable for many other reasons, and I believe it is safer to use nitrous oxid and oxygen at all times instead of nitrous oxid alone.

Dr. R. D. HAMMOND, Winfield, Kans. I would like to inquire as to the advisability of the administration of oxygen after the patient has gotten over the effects of the anesthetic?

A MEMBER. It occasionally happens that the heart stops beating for a moment, but the pulsations will resume after four or five inhalations of nitrous oxid. I would like to have the essayist explain that phenomenon.

Dr. MORGAN. Many times there is a form of hysteria that follows anesthesia; I want the speaker to touch upon that phase.

Dr. W. L. REED, Mexico, Mo. I would like to inquire what is the test by which the essayist may know that he has complete anesthesia. Is it the eye test, or the facial appearance, or the breathing?

Dr. O'BRYON, Lawrence, Kans. I have heard it stated that nitrous oxid and oxygen for analgesia is not dangerous at all. I would like to know if that is true?

Dr. LEE, Greenfield, Mo. Which is the better, to start with pure nitrous oxid, or oxygen, or to start with a little oxygen combined with nitrous oxid?

Dr. H. S. DANIELS, Mexico, Mo. Is it necessary to have an assistant administrator?

Dr. PARSONS (closing the discussion). I had hoped that more questions would be asked about the theory that anesthesia with gas-oxygen is due to anoxemia. I have in my paper given the reasons why nitrous oxid has true and specific anesthetic properties, and have stated that the limitation of oxygen has nothing to do with producing a satisfactory anesthesia. I mentioned the above for a specific purpose, namely, to emphasize the true nature of this valuable drug, so that you may be able to produce better analgesias and anesthesias. Some patients color up quickly under nitrous oxid and oxygen; they seem to be susceptible to nitrous oxid. To overcome this condition and produce a pink color, a greater amount of oxygen is needed. This causes in turn an apnœa, a transient cessation of respiration from an overabundance of oxygen. This fact should be kept in mind, and should occasion no alarm to the administrator.

In regard to the safety of nitrous oxid and oxygen, I will say that in competent hands it is the safest general anesthetic we have, but on account of the small margin between no anesthesia and profound anesthesia, it is a very difficult anesthetic to administer, and, with a tyro, deaths are very likely to occur—indeed, not a few have occurred within the past few years. When analgesia or anesthesia clinics are held, it behooves the spectators to have a profound respect for the gases being used, and not to joke and jolly with the patient during the induction of anesthesia.

The question is often asked why nitrous oxid, the properties of which were discovered in 1842, has only recently attained its present universal use in surgery. Three reasons may be given in answer to this: First, a better understanding of the physiological action of gas and oxygen; second, perfection of apparatus, and third, specialization of practitioners in anesthetics and their administration.

My paper was short, it being intended only to bring out a few important physiological points. I did not touch on the subject of rebreathing, but I might say that rebreathing, to a certain extent, and at proper times during anesthesia—when apnœa or acapnia occurs, for instance—is allowable and of advantage, if the administrator possesses a profound knowledge of the physiology of respiration.

The heart may stop momentarily after a few inhalations of pure nitrous oxid, probably due to vagus stimulation, or perhaps to a sudden dilatation of the right heart. However, I have never observed this condition, because I always induce anesthesia slowly.

Hysteria may follow the administration of nitrous oxid and oxygen as well as after other anesthetics in neurotic individuals.

Many times I have been asked about primary shock occurring during the performing of operations in the analgesic stage under nitrous oxid and oxygen. I believe there is no danger; at least, no cases of untoward symptoms have been reported, and personally I have never observed any. Many operators speak of primary shock when, in reality, they mean reflex cardiac or respiratory inhibition. The two conditions are entirely different and a differential diagnosis should be made. Since nitrous oxid and oxygen produces central nerve blocking from the very beginning of administration, it is difficult to see how either of these two conditions could occur.

Nitrous oxid and oxygen analgesia and anesthesia should be induced from the beginning with a combination of both gases, which insures a better and more scientific narcosis.

Someone asks regarding the administration of oxygen following anesthetization. Following all anesthetics it is a distinct advantage to give a small amount of oxygen. This gas overcomes any cellular anoxemia that might be present, and also oxidizes acidosis bodies, if they be present.

In regard to an assistant, it is of advantage to have one, for a number of obvious reasons.

In conclusion, let me impress upon you the importance of the law of anesthetic accommodation, viz, that—"Living units of the animal body will more readily adjust themselves to altered conditions of existence when the conditions are applied gradually." Therefore, with all anesthetics, the narcosis should be induced gradually and uniformly.

The next order of business for Section II was the reading of a paper by Dr. Arthur D. Black, Chicago, Ill., entitled "Something of the Etiology and Early Pathology of the Diseases of the Peridental Membrane, with Suggestions as to Treatment."

[This paper is printed in full at page 1219 of the present issue of the Cosmos.]

Discussion.

Dr. Henry L. Banzhaf, Milwaukee, Wis. I can hardly hope to add anything of great value to this splendid paper, except possibly to emphasize a few of its important items.

We all realize that the future of dentistry depends upon the young men in this country. From Maine to California we have groups of young practitioners doing scientific work, following in the footsteps and extending the work of our older scientists, and I think we should show our appreciation of their efforts. I take great pleasure at this time in expressing my appreciation of the character of the work that is being done by our younger fellow practitioners, and of the character and quality of the work that is represented in this paper.

Until three or four years ago, I was greatly distressed with the free deposition of salivary calculus upon the lingual surfaces of the lower teeth and the buccal surfaces of the upper molars in my own mouth. For reasons which seemed important to me at that time, I gave up the eating of three meals a day, and for three years and more, except on specially festive occasions, I have limited myself to breakfast and dinner, and have since had very little trouble, if any at all, in keeping my teeth clear of these deposits.

It appears from what the essayist says that it does not make very much difference what the quality or character of our food may be, but that the quantity we eat is the important factor. So, after all, we are brought back again to the old thought of faulty alimentation, faulty metabolism, and perhaps most of our patients, as well as we ourselves, eat too much.

The essayist's slides showing faulty contact points have greatly interested me. It is always a source of astonishment to me that some dentists, after repeatedly listening to complaints of food packing between the teeth, can make the remark to their patients, after having examined their mouths and with faulty contacts staring them in the face, "You require no dental service." This paper should teach us to realize that we should provide separation by the means at our command, since there is no excuse for any dentist allowing his patients to suffer from faulty contact points.

About two years ago I heard Dr. G. V. Black made the statement that he advised his patients to wash these food pockets with normal salt solution. I have followed this method for a period of a year or two with splendid results.

The new thought emphasized in the paper is that we should be careful and thorough in making our diagnoses of cases of gingivitis, and institute treatment before active and septic pericementitis has developed.

In many cases the occlusion on the right side is quite perfect, while on the left side there is an open bite or malocclusion due to malposed teeth. The essayist has called our attention to the fact that it is necessary to correct such malocclusion by grinding the cusps or removing a third molar which might be the cause of the trouble. Since the advent of the gold inlay and the improved methods of fitting crowns and making perfect contact points, it is certainly possible for us to practice preventive dentistry, and to provide our patients with occlusion on both sides, thereby preventing lesions due to the causes that have been pointed out.

The essayist has cited the warnings of Drs. Mayo and Billings in regard to the possibility of endocarditis resulting from peridental infection. While I have had no experience in the observation of that trouble, I have often noticed excessive nervousness in patients suffering from pyorrhea and exhibiting excessive deposits of serumal or salivary calculus.

We do not need one or two hundred instruments for curing pyorrhea; we do not need a larger army of men who are specially prepared to treat that disease, but we need a larger army of men with more earnestness, more scientific knowledge, and a better understanding of etiology, oral pathology and bacteriology, and the chemistry of digestion, men who will use their brain to practice preventive dentistry more intelligently.

Dr. Prime, Oxford, Neb. I would like to ask the essayist whether he knows any method whereby he can maintain contact when the first molar has been lost, and the bicuspids have separated as a result.

Rev. Dr. O. Homburger, Chillicothe. I would like to ask by what method the essayist would bring about contact between a second and third molar in the lower jaw.

Dr. J. R. Callahan. It is not customary for the chairman of a convention to enter into the discussions, yet I take the liberty to say that this paper, to my mind, is one of the strongest pleas for prevention. The great aim of all modern medicine and surgery, including dental surgery, is prevention. Here is a comprehensive plea in that direction.

A point which the essayist has mentioned, I have taken advantage of, and its adoption might be of benefit to others. When a patient asserts that he brushes his teeth thoroughly two or three times per day, and yet is unable to keep them free from stains and deposits, the dentist should have grave doubts as to the thoroughness with which his directions are followed by this patient. If he can impress upon the patient's mind that the stains and deposits, when they first lodge upon the teeth, are quite soft and can be easily removed by careful brushing, good progress will be made toward prevention.

Dr. Black (closing the discussion). I will first answer the questions which were asked. Dr. Prime asks how to restore the contact between the bicuspids when they have separated as the result of the extraction of the first molar. It depends a good deal on the conditions presented in each case what we should do. I am glad this question has been asked, because it gives me an opportunity to impress further the fact that we cannot have any set rule of procedure, but must institute treatment upon the evidence obtained in each individual case. There might be a case in which the second molar was pretty far away from the second bicuspid, and a cavity was present in one or both of these teeth; it would then be best to insert in that mouth a bridge which would serve to maintain the contact between the bicuspids and the anterior teeth. There might be the other extreme in which the second molar was very close to the second bicuspid, so that a filling might be placed in any one of the three teeth, which would serve to restore and maintain the contacts of all of them. In another case, if there were considerable space between the second bicuspid and second molar, and a slight space between the bicuspids, an examination of the occlusion might show that the second bicuspid had moved distally as far as it could, the planes of the upper teeth preventing it from further movement. In this case I might cut a cavity in one of the bicuspids, and build out the filling to contact.

There are other cases in which the movement of the teeth has been so great that food does not wedge between them. In such cases the patient might be better off if left untreated, because, if there is a wide separation between two teeth, food does not pack between them, and the gum septum will usually not be inflamed.

In answer to the question of Dr. Homburger, I would like to take a look in his mouth, because here is another individual case. Here is a man outside of our profession, and in a better one—viz, the ministry. I would like to inquire why he asked that question.

Rev. Dr. Homburger. Food has been lodging between these teeth; there has been no other trouble so far as I can discover, other than the discomfort of picking the food out.

Dr. Black. Here is a typical case. Perhaps we should extract the third molar, or possibly it would be best to cut a mesio-occlusal cavity in it and insert a filling or an inlay, making a proper restoration of the contact. Perhaps there is, as is quite common, a mesio-occlusal filling in the second molar, and separation was not resorted to in inserting it, therefore the tooth has moved too far mesially, in which case all or part of the filling should be removed, and another filling placed which would restore both the proper width between the first and second molars, and the contact between the second and third molars. It is our duty to study each case and find out what has brought about the condition which permits the impaction of food, and then do whatever is necessary to correct it, even though that may be, in some cases, the extraction of a tooth. In this case, if nothing is done, the patient may eventually lose both the second and third molars, because the peridental membrane will become diseased between those teeth, and be gradually detached from the roots. The infection which sets in may spread from that position all around the arch. I consider that there is no greater service we can do to our patients than to make careful examinations of the soft tissues, and correct these inflammations.

We should make an accurate record of the condition of the patient's mouth, aside from the cavities which are present. The examination should include an inspection of the free margins of the gums, and wherever there is inflammation present, it should be recorded, and its cause noted. The means of treatment of each area of inflammation should be recorded, and when the patient returns six months later, he should be re-examined to see whether the gingivitis has disappeared, which means an important accomplishment toward the prevention of pyorrhea.

A lateral abscess should be treated in just the same manner as any other abscess. An incision ought to be made to let the pus out, and after the abscess is once drained, the inflammation will subside sufficiently to allow the pus to discharge alongside of the root, as it has probably done for months or years before. To prevent the recurrence of such an abscess, it might be best to extract the tooth, or to cut away some of the tissue and thus eliminate the pocket.

Dr. Banzhaf speaks of the use of medicines. In my opinion, the day is past—though exception may be taken to this general statement—for the use of antiseptics in the treatment of diseases of the peridental membrane. What has been the indication for the use of antiseptics in the treatment of these diseases? The micro-organisms which we wanted to destroy. General surgeons used to argue the same way and to do the same thing ten or fifteen years ago; they now call that the age of antiseptic surgery. You will hardly be able to find a surgeon in the country today who is using that method. They do not use powerful antiseptics, because they have found that they do more harm than good, because any antiseptic which is strong enough to destroy micro-organisms is also strong enough to interfere with the healing process of the tissue. If a surgeon of today opens an abdomen in a case of appendicitis, and finds the appendix ruptured and the abdomen more or less infected with pus, he does not apply an antiseptic, but washes the abdominal cavity with sterile water or normal salt solution, for the purpose of removing as many of the micro-organisms as he can without interfering with the resistance of the tissues, thus leaving them in the best possible condition for working out their own healing. This is the age of aseptic surgery, and this treatment we should apply in infections of the peridental membrane. Only an experienced observer can appreciate the difference in the action of the tissues in response to this treatment as compared with their behavior following the use of the strong antiseptics which we formerly employed.

(To be continued.)

DENTAL SOCIETY OF THE STATE OF NEW YORK.

Forty-fifth Annual Meeting.

(Continued from page 1183.)

The next order of business was the Report of the Correspondent, Dr. E. B. Prentiss, New York, entitled "Oral Radiography in its Relation to the General Dental Practitioner," as follows:

Report of the Correspondent.

ORAL RADIOGRAPHY IN ITS RELATION TO THE GENERAL DENTAL PRACTITIONER.

I had about decided upon another subject for this year's report when a hint dropped by Dr. Hillyer led me to change my plans, the result being the theme announced, "Oral Radiography." It has been my purpose to treat the subject from the standpoint of the general dental practitioner rather than of the specialist.

I have obtained the opinions of some of the best experts in this country, knowing full well that their experienced advice will be invaluable to the dental practitioner who is about deciding to undertake this special work. A great many men have felt the need of an X-ray equipment so convenient as to be brought into use frequently and enabling the finished pictures to be obtained in a very short time; yet they have hesitated to instal an outfit until obtaining fuller knowledge concerning the practicability of such work, and better acquaintance with the dangers to be encountered, and the precautions to be taken, the equipment to be selected, etc.

Keeping these points in mind, I addressed the following letter to several men who have had long experience in this line of work, and especially in dental and oral radiography:

My dear Doctor,—As Correspondent of the New York State Dental Society I am addressing this letter to you. You will be rendering a distinct service to our society and be of great assistance in helping to solve a perplexing problem if you will give us your personal opinion and clinical experience in regard to the following questions:

(1) Do you consider it practical, and if so, essential, that the general dental practitioner should have installed in his office an apparatus for Oral Radiography?

(2) What particular apparatus do you consider the best suited to the needs of the dentist?

(3) What training is necessary in order to become proficient in the safe management of such equipment?

(4) In your opinion, is the danger of injury from the use of the X ray to be seriously considered?—and what precautions should be taken for the proper protection of the operator when handling the same?

An early reply will be greatly appreciated in order that I may include it in my report to be given at the annual meeting of the State Society in May.

Thanking you in advance for any information you may be able to give,

Very truly yours.

In reply I have received seven letters from men who have made this work a distinct specialty—as follows:

Dr Howard R. Raper, of the Indiana Dental College, Indianapolis, Ind.

My dear Doctor,—I consider it both practical and essential that the general dental practitioner have a radiographic outfit in his office. Otherwise the radiograph will not be used as often as it should be, and as a result the greatest and best dental service will not be rendered.

The general practitioner of dentistry needs an X-ray coil of such size as to make good dental radiographs on films held in the mouth in exposures of from ten to twenty seconds. The more difficult work, requiring the use of a larger X-ray coil, should be sent to specialists. Of the smaller machines, such as I would advise the practitioner to buy, there are two types. (1) The Ruhmkorff, or induction coil, and (2) the Tesla, or high-frequency coil. If the supply current be "direct," buy a small induction coil. If the supply current be "alternating," buy a suitcase high-frequency coil. A word of warning regarding the suitcase high-frequency coils: While one or two makes are really quite efficacious, by far the most of the coils of this type are mere toys. Insist upon a demonstration before purchasing one of them. If the buyer does not consider expense, he may purchase a large induction coil, or the latest type of coil, called interrupterless coil, or transformer. The heaviest kind of work could be done with these machines.

Personally, I had no training at all. I never saw a radiograph made until I made one myself. It is not necessary, therefore, that a man have the work demonstrated to him. He can learn from reading. When I recall the number of books on electricity, photography, and general radiography that I read to gain my knowledge of the subject, the chaff I had to wade through to get, after all, but a few facts, it seems to me that in giving the profession my book "Elementary and Dental Radiography" I have made the problem of self-education a very simple one for the practitioner who wishes to take up the work.

I know of no place where a man may take a postgraduate course in the work. Though I have considered the establishment of such a course some time during the summer months, at the Indiana Dental College, I have concluded that it would be impracticable. I would not care to try to teach men who were too lazy to learn from the text-book on the subject. True, a man studying from a text-book may need a little special personal assistance—but only a little, which he could probably receive in ten or fifteen minutes from any radiographer. The course given in our colleges should consist of from ten to twenty lectures, and clinical experience in one or more cases.

X rays are dangerous or not—just as arsenic is dangerous or not—according to the manner in which they are used. Improperly handled, they will cause cancer and death; properly handled, they will produce no disastrous results whatever. If the operator will observe a few simple rules, he may practice radiography a lifetime and never produce any pathological effect on his patients. No man should, under any circumstances, engage in the art of radiography without using a lead screen or cabinet for personal protection. To all who contemplate engaging in the work, I would say, Buy a lead screen first, then the balance of the radiographic outfit. The writer uses a homemade lead screen, the lead of which is one-eighth inch thick. No sensible man with open eyes and good ears would stand on a railroad track and allow a train to run over him—because it is such a simple matter, you know, to step off the track. Likewise, no sensible man, whose eyes are open to the dangers of the X rays, will expose himself to their deadly action—because it is such a simple matter to stand behind a screen.

Lewis Gregory Cole, M.D., New York, N. Y.:

My dear Doctor Prentiss,—Replying to your letter of March 22d, I would state that I believe it would be just about as practicable for the general practicing dentist to make radiographs of the head and teeth, and properly interpret them, as it would be for me to attempt to fill teeth or put in bridges.

Harold S. Vaughan, D.D.S., M.D., New York, N. Y.:

Dear Doctor,—I consider it practicable for the general dental practitioner to have an X-ray apparatus in his office. As to its being essential, that depends on whether the dentist wishes to do the work himself or refer it to others. If such an apparatus were at hand, its benefits would be utilized more frequently.

The induction coils of such makes as the Kelley-Koett, Wappler, or Kny-Scheerer are very practical and give good oral radiographs with three to five seconds' exposure. For the heavy work of the general roentgenologist the interrupterless transformers are best suited, but they are not necessary for oral work. The high-frequency or Tesla coils are cheaper but less powerful; and require exposures of fifteen to thirty seconds or more, and are therefore of less value, though satisfactory oral work can be obtained with them.

The beginner should be instructed by a competent radiographer as to the necessary precautions about exposing the patient to the X rays—bearing in mind that some persons are more susceptible than others. The dangers to the operator are to be seriously considered and precautions taken to screen the tube from him. This can be accomplished

—(1) By a lead or lead-glass screen around the tube. (2) By operating the apparatus from behind a lead screen. (3) Best of all, by operating the switch and rheostat from outside the room, the operator looking through a small lead-glass window, the side of the room being lead-lined.

E. W. Caldwell, M.D., New York, N. Y.:

Dear Doctor,—In answer to your letter of March 22d, I have to say:

(1) I think it practical, but essential only in towns where no roentgenologist is available.

(2) Induction coil apparatus.

(3) It depends largely upon the patience and the ability of the man. Some men learn to do creditable work in a few weeks and others fail after years. Fortunately the dental work is not difficult.

(4) Danger should be considered serious. Lead screen with rubber gloves, shield for tube, etc., should be used.

Dr. C. Edmund Kells, Jr., New Orleans, La.:

Dear Doctor,—I take pleasure in replying to your letter of the 22d.

(1) A few months after Professor Roentgen announced his discovery I installed an apparatus, and have never been without one since; during the past year have probably used it more than ever.

As now perfected it is a practical proposition, and I consider it essential to a practice which strives to give its *clientèle* the very best service possible.

(2) For dental work the most powerful systems are not necessary. A 12-inch coil with chemical break will take skiagraphs with films held within the mouth in from three seconds down to a flash, according to the density of the parts; this on ordinary films and not using a screen. With quick films and with screens this time can be greatly cut down—that is, the three seconds can; the flash, of course, could not.

(3) You have got me there—because it must all depend upon the man. However, this should not be learned from a "correspondence school," but from a good safe operator—which can be quickly done. After the "learning," a little patient work is necessary, that's all.

(4) With the proper "plant," capable of rapid work, and using *all* well-known safeguards, the danger from the use of the X rays for *dental work* is a negligible quantity. The precautions are—*a*, Tube incased in a ray-proof cover of some kind. *b*, The use of a filter. *c*, Short exposures and not repeated indefinitely the same day. *d*, Operator always wearing gloves.

I trust I have covered the ground sufficiently. If not, I will be pleased to give you any further information in my power.

And now, in turn, I would like to ask you a question: Do you think it would be interesting to have a practical demonstration of X-ray work at the coming meeting of the National at Kansas City?

By *practical* demonstration, I mean a full equipment taking skiagraphs for the dentists or their patients and developing and finishing the pictures "while you wait."

Sinclair Tousey, M.D., New York, N. Y.:

Dear Doctor,—Replying to your inquiry, there is no reason why a dentist should not become an expert radiographer—and several have done so in different parts of the country. So that my counsel against the use of this method by the general dental practitioner is not from any doubt of his ability, but from my knowledge of the time and study and the cumbersomeness of the apparatus required to produce satisfactory results with safety to patient and operator. Several friends of mine who installed the apparatus in a moment of enthusiasm continue to send their patients to a specialist because they have not been able to give it the study required to become proficient. And we all know that it was in radiography about the mouth that X-ray burns were most frequent in the early stages of the science. The dentist should not take it up for occasional use in his practice unless he is able to give sufficient time and study to it to become expert.

(1) I do not consider it practical for the general dental practitioner. But the X ray is essential to dentistry, and in every locality there should be some physician or dentist expert in its use in its application to dental radiography, to whom dental cases may be referred.

(2) Of course a photographic dark-room is required for developing films.

The least cumbersome and most easily handled X-ray apparatus is a high-frequency coil like the largest portable Victor apparatus. This has the advantage of moderate cost, but of course requires longer exposures and does not give as good results where the whole face must be penetrated, for radiographs of the antrum or the entire jaw. For this work I personally use my largest apparatus, a 15-kilowatt direct current converter, forming an outfit measuring 10 x 4 x 8 feet, in addition to quite a ponderous tube-stand and protective shield. The exposures are from an eighth to a quarter of a second. In connection with the smaller outfit it is essential that the X-ray tube be inclosed in a protective shield (say of lead-glass), which limits the X ray to the proper part of the patient and protects the operator entirely.

(3) The operator should spend a considerable number of hours in an X-ray laboratory learning the manipulation of the apparatus, how to regulate the degree of vacuum in the X-ray tube, and how to develop the films. This facility can be acquired in any X-ray laboratory, but the proper posing of the patient is something requiring special study. Another matter which is almost universally neglected is the study of the X-ray dosage. A person may see radiographs made and note the absence of disagreeable consequences without ever knowing the safety limit of exposure. I was called into a case in a western city where a doctor had been using the X ray successfully for seven years, and finally attempted to make a radiograph of a man's hip twelve inches thick. No pictures resulted from either of two attempts, but a terrible burn followed, which had to be cut out like a cancer, and there was a suit for $50,000 damages. The exposures were longer and stronger than any he had ever made previously, and before applying them he should have known how to measure the dosage and what the effect would be.

The necessity for a knowledge of X-ray dosage enters into dental radiography in the way of determining how many exposures, and of what strength, may be made in a case requiring a number of pictures. The fact that the X ray has a cumulative effect is of vital importance. The same dose divided up in the course of a week has just as much effect as if it were one continuous exposure.

(4) The danger of injury to the operator is very great, and the only safety lies in absolute protection from exposure. I made the mistake in the beginning of considering it necessary to hold the film in the patient's mouth, and though I tried to protect my hands with opaque gloves, my fingers are marred by keratoses which fortunately have never developed into epithelioma, but which resist all effects at cure. A few exposures produce nothing but benefit to the individual patients, but a great many exposures, from their cumulative effect, are extremely dangerous to the operator. Regardless of the inconvenience, the X-ray tube should be inclosed in an opaque shield, because indiscriminate repeated exposures of the operator standing near a naked X-ray tube produce sterility, various blood diseases akin to leukemia, loss of hair, dermatitis, or epithelioma.

The operators whose deaths are recorded in the papers every few months are probably men who thought that their X-ray work would not be extensive enough to require special precautions. One special thing is that the fluoroscope should never be used either for examination or for testing the radiance.

Dr. F. T. Van Woert, Brooklyn, N. Y.:

Dear Doctor,—(1) I do consider it practical, and while not essential, think it would be a great advantage to any practitioner to instal in his office an apparatus for oral radiography.

(2) There are a great number of apparatus on the market, but I think those manufactured by Waite & Bartlett, or the Wappler Mfg. Co., are as practical as any, and within the means of almost anyone.

(3) There is very little training necessary for one to become proficient enough in dental radiography for all practical purposes.

(4) I am of the opinion that the X rays are very dangerous and should be very seriously considered—particularly by the operator. But there are appliances which make it simple to eliminate this danger and which are supplied by anyone manufacturing coils and the like. One thing, in particular, all operators should refrain from—holding the film in position when it is exposed to the rays. The patients should be instructed to do this, as the damage to them is practically *nil*. It is a pretty well established fact that the X rays are cumulative—that is to say, the effect of a single exposure is retained by the subject and each succeeding one is piled upon it, until enough has been accumulated to produce a very serious pathological condition. Hence, anyone anticipating the installation of an X-ray apparatus should purchase the same from someone familiar with all the requirements to eliminate the dangers.

Also the following, from general dental practitioners who have not had any experience in the personal operation of the X ray:

Dr. C. N. Johnson, Chicago, Ill.:

Dear Doctor,—I am just in receipt of your letter asking for my impressions regarding

Oral Radiography. I can answer only the first one, and that in a very imperfect way.

I consider it practical, but not essential, that the general dental practitioner should have an apparatus installed in his office. Without question radiography will clear up many of the conditions which could not well be cleared without it, and it is probable that the more expert one becomes in its use the wider the range of service. In justice to my present point of view I think I must say that I do not believe radiography is quite so reliable in solving certain problems as some of its advocates seem to think. And those who are the most enthusiastic in its praise are quite likely to read into a radiograph of the jaws certain evidence which is not always borne out by facts. For instance, I have found it quite unreliable in diagnosing abscess cavities, their extent, etc. It is very valuable for locating embedded teeth, or other impacted hard substances, and we could not well do without it; but in a large city with experts doing this work I find it more convenient to refer the patient to them than to operate an apparatus in my own office.

Dr. Rudolph H. Hofheinz, Rochester, N. Y.:

Dear Doctor,—In answer to your letter of March 22d, I beg to say, that Oral Radiography has become an essential factor in diagnosing dental lesions both of a pathological and a mechanical nature. It is my opinion that a practitioner with a competent assistant could have an apparatus installed in his office. This would be more a matter of convenience, however, than necessity.

Oral radiography does not differ from general radiography, and can be obtained by any good radiographist. A higher degree of special efficiency and interest may be gained if the radiographist be a practicing dental surgeon. A rational solution of this question would readily be found if the orthodontist made a specialty of radiography in connection with his own work. He resorts to its use more frequently than the general operator, and his dental intelligence would greatly assist the general practitioner.

A radiographist must have a thorough technical knowledge of his apparatus, and that in itself reduces the danger of injury to *nil*. He must have a well-trained eye for photography, without which he is very apt to look at a picture from the wrong angle. Personally I prefer the result of a specialist in radiography, be it oral or otherwise, to that of the general practitioner who only occasionally uses the apparatus.

Dr. Frank W. Low, Buffalo, N. Y.:

Dear Doctor,—I prefer to go with my patient to an expert. I can so demonstrate what I want to know about, that the expert can make a more satisfactory exposure than I can; at least until I have become an expert. This I have never even tried to become.

Leuman M. Waugh, D.D.S., Buffalo, N. Y.:

Dear Doctor,—Your letter has not been forgotten. I have had the unfortunate experience of training a new assistant, and the woman whom I selected has been very slow in grasping things, and as a result my correspondence has suffered. I know it is too late now, but to show my good-will, I shall tell you what I had in mind.

My opinion will not be based on experience. I am about to put in an apparatus, and your report will help me in the selection of what I need. You ask especially for an answer to question No. 1.

I do consider it eminently *practical*. I believe it to be *essential* to the most efficient dentistry. However, I do not believe that it need be a part of every general practitioner's equipment. In fact there are many who would not use it often enough to really master it. In some practices in the remote districts a prejudice against it would have to be overcome. What I do believe that there is a crying need for, is *dentists* who are sufficiently versed in the normal structure and pathology of conditions about the mouth and face, who will take up the work and not only do radiography for dentists, but will interpret the picture, make a diagnosis, and if desired outline the treatment. I might say much about disappointment resulting from work done by men who have not especially studied conditions about the jaws and who do radiography for dentists, but the above positively expresses my opinion.

I shall not venture to answer the other questions, except No. 4. In conversation with Dr. Raper, I learn that he feels that nothing short of a well-made, preferably a home-made, lead screen should be used. When this precaution has been taken he feels as safe as may be; but since the work is only ten years old, no one knows what it may do when followed longer. Personally, I am satisfied to take it up and do all that my practice may demand.

The replies received have treated the question in such a thorough manner, have gone into such minute detail, and have been both so favorable and unfavorable, that I cannot do better than to leave the subject for your discussion, and feel that, thereby, those who have been in doubting frame of mind may be able to come to a very definite and safe conclusion as to the course to be followed.

I wish to add that Dr. Geo. M. MacKee of New York, who had done a great deal of special work along this line, has very kindly consented to be present and give his views in person. I have therefore not included his reply in the main body of this report.

Respectfully submitted,
E. B. PRENTISS, *Correspondent.*

Discussion.

Dr. GEO. M. MACKEE, New York. I desire to thank the president and members of the society for allowing me the privilege of the floor. I also desire to thank Dr. Prentiss for his kindness in inviting me to discuss this question in person, and for his trouble in obtaining a postponement of one day to allow time for me to come from Washington, D. C., where I was attending another meeting.

I find, by reading the various letters that Dr. Prentiss has received, that there is quite a difference of opinion with regard to the use of the X ray in dentistry. For instance, as extremes, we have Dr. Cole, a radiologist, who considers it about as practical for the general dentist to make a dental radiograph as it would be for Dr. Cole to attempt the filling of teeth. On the other hand, some men who are not radiologists consider it both practical and essential that every dental office be equipped for dental radiography. I do not wish to take a position at either end of this chasm, but place myself in the center—namely, I desire to be conservative.

Being a radiologist and a specialist it is difficult not to be a trifle biased and a little in favor of high specialization in all lines. But I will endeavor to be broad-minded, and to discuss the question in such a manner as to help rather than hinder you in an effort to decide what can be done and what should be done.

The questions asked by Dr. Prentiss are fairly specific, although a trifle ambiguous, but in order to save time and to avoid digressing I will first read and then specifically discuss each one to the best of my ability.

"(1) Do you consider it practical, and if so, essential, that the general dental practitioner should have installed in his office an apparatus for oral radiography?"

The main factors here are "essential" and "practical." Let us consider, first, the practicability. Certainly there are no insurmountable obstacles in the practice of oral radiography. The success of the work will depend largely upon the man; if he has the necessary incentive, ambition, energy, and money, there is no reason why he should not undertake the work. In other words, from a scientific standpoint such an undertaking is practical. On the other hand, it is difficult for me to conceive of a general dentist being able to devote the time necessary to become proficient in radiographic technique and interpretation without letting his general practice suffer. Particularly is this so in the case of the busy practitioner who must accept small fees. It must be remembered that it requires several years of effort before one can master the proper technique and give a trustworthy opinion or interpretation. I should say that from a financial standpoint it would be foolish for the average dental practitioner to enter this field, and when everything is considered I should say that it is not practical for him to do so.

There is one way out of this difficulty, however, and that is, if the general practitioner is unable to spare the time for the work, he can obtain an assistant, give him sufficient time for acquiring the necessary skill, equip a laboratory, and place the matter upon a practical, scientific, and profitable basis. I would like to say here that the making of suitable radiographs is not nearly as difficult as their interpretation and verification. I have been doing this work for over ten years. I have no difficulty, with the apparatus obtainable at present, in producing a suitable set of radiographs in most of the cases, but I feel, in spite of years of experience, that I still know very little about interpretation.

To sum up this question, I will say that the practicability depends entirely upon the individual. The sum total of the work requires time, skill, care, and money. If these can be given, then the work is practical. In a general way I should certainly say that it is not practical for any but a few favored dentists to do this work.

Now as to the "essential" feature, or the necessity for each general practitioner doing his own radiographic work. In the first place, is it necessary for every patient to be radiographed both before and after dental work? I should think not, but such a question is not within my province to decide. If such is the case, it would really seem advisable for every dentist to do his own radiographic work, and perhaps in time it will come to this. At the present moment, however, it would seem safe to assume that only a certain percentage of cases require radiographic examinations. The actual number of such cases falling within the practice of any one man, based upon my own experience, would not justify one in saying that an equipment was essential to every office. No matter from what angle one starts to argue these subjects, the paths all lead to the financial question. It is doubtful if the patient would be saved any money in case the dentist did the work, for the latter would naturally charge a fee commensurate with the time, expense, etc., of the operation. This fee is hard to obtain, especially in the case of the general dentist. Most of you are underpaid as it is, and yet, small as are your fees, the patients object to them. It is always possible, by properly approaching a radiographer, to obtain a reduction in fee to almost any extent—at least the fee can and will willingly be made in accordance with the size of your own fee, the income of the patient, and the scientific interest you may have in the case. Would you be willing to do more than that? In all cities, large or small, there are radiographers to whom cases can be referred. To my mind, what is most needed just at present is a more friendly, more thorough, and more scientific co-operation between the dentists and scientific men who are making radiography a specialty.

I know some dentists who are doing excellent radiographic work, but they are, for the most part, either limiting themselves to radiography, are oral surgeons, or, if they have a large general practice, they have an assistant who devotes himself almost exclusively to radiography. It is my experience that one dentist will hesitate to refer a radiographic case to another dentist—the reasons for this are obvious.

Without further discussion, allow me to say that I do not consider it essential for the general dentist to assume the rôle of a radiologist. The advisability of his doing so is a different matter, and rests entirely with the individual.

"(2) What particular apparatus is considered best suited for the needs of the dentist?"

This matter is of no great importance. Suitcase outfits are useless, as are, also, static machines, for the simple reason that they will not produce enough current. A Ruhmkorff coil with an electrolytic interrupter offers the most for the money. With this apparatus perfect results can be obtained. The newer and more expensive types of apparatus, such as the interrupterless transformer, offer advantages in greater speed and less trouble. Speed, of course, is essential in many instances, as it precludes the blurring of the image due to motion. If the parts to be radiographed are stationary, slow exposures will produce as good results as rapid ones, with much less expense in the way of tubes, etc. With a coil, satisfactory film radiographs of the teeth can be made in from 1 to 5 seconds; plate radiographs can be taken in from 5 to

20 seconds, and the accessory sinuses in from 20 to 45 seconds, providing a direct primary current can be obtained. With an alternating current more time must be allowed. With the transformer, the exposures would be as follows: Film radiographs, 1/4 to 2 seconds; plate radiographs, 1 to 5 seconds; accessory sinuses, 5 to 15 seconds.

Additional essential apparatus are a suitable radiographic table or chair, a tube-stand with protecting shield, one or more X-ray tubes, milammeter, protection booth for the operator, a good dark-room, as well as innumerable small items.

"(3) What training is necessary?"

In the first place, one need not be an electrical engineer, and no special electrical training is necessary. One must, however, understand his apparatus, and should, in fact, understand the fundamental features of all types of X-ray apparatus, so as to appreciate the limitations and possibilities of these various types before a purchase is made, and to obtain the greatest amount of satisfaction and safety in their use. One must become a thorough student of the X ray, for it is an exceedingly dangerous as well as useful agent. The training necessary for a beginning can be obtained by studying text-books and reading articles on the subject that are found in reliable dental, medical, and other scientific journals. Also by attending courses such as the one given by the Second District Dental Society.

"(4) In your opinion, is the danger of injury from the use of the X ray to be seriously considered?—and what precaution should be taken for the proper protection of the operator when handling same?"

The X ray is a very dangerous agent, and should only be employed by those who are expert in its use. One must understand the nature of the rays of varying quality that are emitted from every tube when in action. One should know what quality of ray is employed when the exposure is made and the amount of this quality used during the exposure. In addition, one must be familiar with the quantity of any given quality of ray that it is safe to employ on any of the various parts of the body. Without this knowledge one never knows when to expect an injurious reaction on the part of the patient's skin, nor how to avoid it. There are various types of apparatus designed for the estimation of the quality and quantity of ray, but time will not allow me to even enumerate them.

The protection of the operator is a comparatively simple matter. Under no circumstance should he ever allow the ray to fall upon his own person. Whenever the X-ray tube is in action he must be in a lead-lined booth, having a lead-glass window, and containing the switches, etc., so that he can see and manipulate the apparatus without leaving the booth during the exposure. The operator who takes proper precautions will never receive the slightest injury. On the other hand, carelessness or indifference may lead to disastrous results either to the patient or operator, or to both.

Dr. HENRY W. GILLETT, New York. I shall approach this subject in my discussion from the same standpoint as has the Correspondent, namely, that of the general practitioner. I am familiar with the work only as done for me in my office, and I will report my experience from that standpoint.

Most of what I shall say will apply to the first question asked, therefore I am going to refer first to other questions, and get them out of the way.

With regard to the second question—"What particular apparatus is considered best suited to the needs of the dentist?"—the point I desire to mention is that in my own office we have installed an apparatus which takes up no floor space except that occupied by the tube-stand. This we find a great convenience.

I will make no reference to the third question.

With regard to the fourth I will state my position in this way: We must necessarily accept the view that the X ray is a dangerous agent and one to be handled carefully. From that aspect I deem myself particularly fortunate in having as my assistant Dr. L. E. Palmer to carry out the details of the work. I said to him in the beginning, "See that you yourself and the patient are well protected," and I have left to him the detail of accomplishing this result. I have once or twice consulted him as to whether he felt satisfied that he had gone far enough in securing self-protection as well as protection of the patient. He assures me he has done so, and I am convinced that he takes every proper precaution in that direction. I believe that safety for both patient and operator is easily assured, but I feel that it is very important that the necessary steps to insure safety shall invariably be observed.

With regard to the first question, that is, as to its practicability and as to whether it be essential that the general practitioner should have in his office opportunity to make constant use of the X ray, I think we have heard enough from the reports to feel convinced that it is readily practicable—it certainly has proved so in my own case. As to whether it be essential or not, I would phrase my reply somewhat like this: I believe it to be essential to the practice of dentistry with the highest efficiency. I find myself utilizing the X ray probably a dozen, if not twenty times, now, where I used it once before I had it in my own office. As an example, it occurred one day last week that I wanted eleven different teeth radiographed in one day. It is quite a common thing for me to send three, four, or five patients into the X-ray room in one day, and I believe that every operator who provides in his own office convenient opportunity for its use will find himself making constantly increased use of that opportunity. The ability to say to patients, "Please step into the X-ray room," in contradistinction to saying that you wish them to go to Dr. So-and-so and have a radiograph made; of being able to have the wet film in eight or ten minutes, and to examine it for yourself as you go on with your work, instead of waiting until the next day; of being able to judge immediately for yourself concerning the particular case you are at the moment operating upon; the convenience of being able to get a correct view of the anatomical relations of the operating field, and if necessary to make at once a new radiograph, or to say to your associate that you would like to have a radiograph at a slightly different angle, as the one in hand does not bring out what you wish to see, instead of waiting another day for it from the hands of the specialist—the convenience of these factors so far overshadows the inconvenience, the expense, and the difficulty of the installation and the detail work involved that I have arrived at the point where I would scarcely know how to do without my X-ray outfit. It has become essential to the proper conduct of my practice. I am saying this not only from the viewpoint of my own personal convenience, but from the standpoint of living up to my responsibility to my patients.

The question of expense has been raised, and I want to refer just here to a very practical point. I find it much less expensive for the patient to have a fee entered of ten dollars for a radiograph than it is to have the operator spend an hour or two hours trying to find out something that ten minutes in the X-ray room would define accurately. I find it of much greater advantage to them to pay a fee for a radiographic examination, where indicated, with its usual prompt disclosure of conditions, than to pay what would frequently prove an equal or larger fee for time spent in searching for obscure causes of pathological manifestations or for inefficient treatment of undefined conditions. Chronic ill conditions in our field usually become simple when accurately diagnosed. Frequently a radiograph will show the futility of any course of treatment, and so save the patient a series of sittings and the operator a humiliating failure with its attendant loss of prestige. The ability to accurately diagnose septic conditions in the mouth, the ability to locate and define obscure abscess conditions, the ability to define advanced pyorrheal conditions, is of the very greatest advantage to our patients, and the opportunity offered for a prompt diagnosis is of the very greatest service to them. I have had two cases within a few days which have been sufficient in themselves to have warranted in my estimation all the expenditure and all the effort that has been made in my office in the installing and in learning the use of the outfit. I believe that I have saved the lives of two patients within a fortnight because I had at hand the apparatus to define the things I wanted to know and define them promptly. In one case the discovery was incidental. When investigating conditions about a third molar, we discovered extensive septic conditions about the first molar, and I am convinced from the subsequent history of the case that these conditions were responsible for pathological manifestations that had been puzzling the patient's physician for a period of two years, and which began to improve within twenty-four hours after the operation resultant from the discovery made by the X ray. In the other case the patient had been in my hands for years with conditions which were worse than I suspected, and had reached the stage where he was threatening suicide, and because I was able to put my hand promptly on the information I wanted, I think I have started him on the road to recovery.

The value of the radiograph in root-canal work cannot be overestimated; the value of having it at hand for the prompt answer of the many questions that come to us in dealing with obscure conditions in root-canals is very great. To cite another case as a concrete example: Within two or three weeks I have been able to entirely change conditions in an important tooth because I had definite information to start with as to what had happened to that tooth. I was able to unravel the difficulties that had perplexed two previous operators on the Pacific coast, and in a short time to arrive at a simple solution of what had been a complex case; and it was just because I had the apparatus at hand, so that on inspection of the first film I could say to my associate, Dr. Palmer, "Please give me a film from this angle." With the information resulting from the second film I was able to start right in my work—when to have taken the wrong course with the tooth would probably have meant its sacrifice.

I scarcely need dwell at all to this audience on the comfort of being able to know before entering root-canals something concerning their length, direction, size, etc., but I do want to say a word concerning something which I believe will come to the front before long—that is, self-protection for the operator as related to the results of his work in root-canals. This thought was planted in my mind by Dr. F. T. Van Woert during our trip to Chicago last winter to the Brophy dinner. Every operator in this room has realized repeatedly in the past that his root-canal results were frequently different from what he had supposed them to be when he had completed his operation. With the radiograph we have a way of determining what the efficiency of our root surgery has been after it is completed. Now let us suppose a condition of affairs which may readily arise—that an operator believes he has found all the canals there are in a tooth, and that he has filled each one of these canals to its apex. Let us imagine that he has failed to find some canal, or that he has failed to fill the apical third or half of a root-canal. Suppose that septic conditions develop and the case gets into hostile hands, and there comes an occasion for the review of these conditions before the courts—a situation quite possible. What is going to be the reply of the operator to the court when asked why he did not take advantage of the known facilities of his profession to determine, when he had finished this work, whether or not it was properly performed? What answer can be made to the question, Why did you not protect your patient from these possibilities? I have given a good deal of thought to the hypothesis presented by Dr. Van Woert somewhat along these lines, and I am beginning to feel that the certainty of safety, the certainty of self-protection, and, beyond that, the certainty of knowledge that we have done our best for the patient, can only come to us when we adopt as routine practice the radiographic inspection of our surgical work in root-canals. I am convinced from consultations I have recently had with medical men that the time is close at hand when they are going to demand from us the elimination of abscess foci from our field. I am strongly of the opinion that any practitioner who will provide himself with the means for diagnosing the conditions in advance, and for inspecting his work at its completion, will much more readily accomplish this result and will have much greater satisfaction in the practice of his profession.

Dr. A. R. Starr, New York. I have not had any practical experience with the X ray, and unfortunately know very little of its physical properties, but I do appreciate its advantages from the diagnostic standpoint. We appreciate it to such an extent in the college with which I am connected that we have a series of lectures on the subject every year, and every student is obliged to take a practical course of demonstration of its use before he can graduate, and is also obliged to take a special examination on the subject. That is how much we appreciate its diagnostic value, and that is how much we anticipate the probability that the use of this method may sometime become general. Personally I wish I could have an X-ray picture both before and after every operation upon root-canals, because, as I said in a previous discussion, some of us, I think, would get quite a shock if we could see these radiographs of root-canal fillings. It is undoubtedly of great value not only in root-canal work but in many other ways. Dr. Gillett mentioned the advantage in estimating the length of the root-canal, and that factor alone will be of great aid to us in our work upon root-canals.

As regards the danger to the operator and patient, I cannot speak from personal experience, because I have not used the X-ray apparatus, but I do not believe the danger feature is entirely eliminated at the present time. I have had an example of that in my practice quite recently. A patient who lived out of town had a condition which required the use of the X ray. I advised her to go to a specialist in New York for a radiograph, but because of the fact that she lived so far away and did not have time to stay in the city to have the work done, she went to a local hospital in the town in which she lived and had an X-ray picture taken. The operator told her that it was rather an old apparatus, and that he would have to make considerable exposure to get a proper picture. I believe she was subjected to an exposure of three minutes, and that patient received a burn on the side of the face and lost her hair over an area of nearly two square inches upon that side of the head. It seems to me that there is no excuse at the present time for such results.

As I said before, it would be of great benefit to us if we could take a radiograph of every root-canal operation, and we should keep a record of those radiographs, for it would be an excellent means of instruction. The chief difficulty in following that plan would be the financial one. There is no question about the scientific advantage of it, but probably there would be difficulty in some cases in getting sufficient remuneration for the amount of time expended. I think as a rule patients are more willing to pay a good fee to the specialist than they are to the general practitioner, and I firmly believe that one of the reasons why pyorrhea specialists are so successful in combating that disease is because they charge such a fee that they scare the patient into taking proper care of their own mouths.

Dr. Leslie E. Palmer, New York. The practical side of the paper has been so well covered by the preceding discussion that I merely want to make a few rambling remarks, possibly touching a few high points on the other side, and go into a little of the practical detail of doing X-ray work.

In the beginning I wish to say that I think it is certainly an advantage to any practice, and an essential to every well-equipped office. The letter written by Dr. Raper possibly expresses my thought on this subject better than any of the others, but my one criticism on his letter is that it would tend to lead one to think that the use of the X ray is a perfectly simple matter. It is not entirely simple, any more than any other problem you handle in your dental work. It requires practice, and with practice it does become simpler. As Dr. Gillett said, the great advantage of doing the work in your own office is the greater frequency with which you make use of the X ray. If one sends the work out to a specialist, even if he is in your own town, it generally takes twenty-four hours before he can expose the film, develop it, and have it thoroughly dried and returned to you; whereas, in a large majority of cases, if this work is done in your own office it means simply that the patient has to leave the chair for a few minutes to have the picture taken, and this can be finished up while the patient is still in the chair, and you can go ahead with an added knowledge of what you are dealing with.

Until some few years ago, in order to get the proper preliminary knowledge necessary for using the apparatus, it was necessary to delve through large treatises on the subject, pick out what seemed the most interesting, and then, after securing the necessary amount of theory, go ahead and find someone who had had some practice, get some of his knowledge, and combine the two. The articles by Dr. Raper that appeared in the *Items of Interest* about a year and a half ago have eliminated all of the superfluous material and compressed the thing into a nutshell, as it were, and I very strongly recommend these articles to anyone interested in the work. Even though one has had a great deal of experience, there is much to be gained from them. After having covered these articles rather thoroughly, combined with the demonstration that the manufacturer gives who sets up the apparatus, you are, I think, in position to work out your own salvation.

As to the different types of apparatus, as Dr. MacKee said, the coil is probably the most satisfactory. The big interrupterless machine is too powerful and too costly to be a necessity in the dental office, while the high-frequency machine does not carry sufficient power.

The rays are without question dangerous, and this should always be borne in mind and guarded against. They are a possible element of great danger, and should be always recognized as such. The two first results that one may experience from over-exposure are burns and sterility. The burns are not those we ordinarily know which raise blisters, but more in the form of a dermatitis, not especially sore, but look more like sunburn. I have had none myself, but have seen them developed on others rather seriously.

The question of sterility is one that we must always consider. There is no doubt but what one constantly exposed to the rays will be rendered sterile. That brings up the question as to a few of the things we need to do to guard against such possibilities. In the beginning the men who used the X ray regarded it very much as we regard the electric light, and used it with the same amount of freedom. At one time nothing was thought of standing in front of the fluoroscope and having the bones of the body shown up, and the men who did that from day to day are the ones who suffered from serious results such as we read of in the papers from time to time. To get down to the definite dental work, one should always insist on the patients' holding the film themselves. It does not take long, and the patients can hold it in place where directed. They only have to stand the rays for a few seconds and it does not affect them, but you who would be exposed to the rays very often, cannot stand it three or four times a day, week after week. Never stand in front of the tube, because most of the strong rays come from that side of the tube. Do not use a fluoroscope unless you are perfectly protected. For the protection of the patient the tube should be covered and should have only a small opening to allow the rays to come out. As further protection a sheet of aluminum interposed between the patient and the tube will absorb many of the soft rays and give an equally good picture. The X-ray apparatus as set up in running order seems to be a pretty complicated affair, but after one becomes accustomed to the use of it and dissects the various parts, it is not so complicated as it would seem at first sight.

I cannot help feeling, notwithstanding some of the beautiful dental radiography that is done by some of the medical specialists, that the dentist is much better equipped to produce and interpret dental results than anyone else.

Dr. PRENTISS (closing the discussion). Owing to the lateness of the hour and because of the fact that, while I myself have had no experience in this work, it has been so ably discussed by those who have had experience, I will not say anything further in closing. I wish, however, to thank all who have taken part, and those who have answered the letters of the Correspondent; and especially to thank Dr. MacKee, who made the trip here especially for this occasion, for the able and efficient discussion he has given us.

(To be continued.)

EDITORIAL DEPARTMENT.

A GENERATION AFTER.

ONE cannot take even a superficial view of current dental literature without noting the widespread interest that is being manifested, both within and without the ranks of the dental profession, in the causes, prevention, and treatment of dental caries. Three decades ago, when Miller announced the results of his studies of the problem, and explained in detail the steps by which he had arrived at his conclusions as to the causation of this all but universal human disorder, the effect produced upon the dental mind was both varied and interesting. A few who were familiar with the history of the subject, and whose training in allied lines of thought enabled them to correctly estimate the value and importance of Miller's researches and ultimate findings, sympathetically applauded the greatness of his achievement; but in the main the announcement of the discovery of Miller was caviar to the general, and was regarded as possibly an academic and scientific triumph, but nevertheless one having but little interest or real importance to the practical dentist.

Like many great scientific discoveries, Miller's findings were in a sense born in advance of the recognized need of the time. He had solved the problem of how caries is produced, but had not satisfactorily explained why it is produced; his researches did not throw a direct light on the correlated problem of susceptibility and immunity to dental caries, in which aspect of the question was involved the solution of the practical problem of the prevention of caries. No one realized more fully than did Miller the necessity for further investigation before we could arrive at a satisfying answer to the question of the practical dentist—or, indeed, of his patients: "What can we do, in the light of all this scientific investigation, or as a result of it, to prevent dental caries?" It was to the solution of this question that the mind of Miller was directed when his life's career was suddenly terminated.

There are few short cuts to the truth, and the building of scientific knowledge must be by slow, painstaking endeavor if the finished structure is to endure. Hence it was necessary to begin at the foundation of the caries problem, and to determine first of all what it is, and what factors enter into its production. *That* Miller did; and because his splendid work, in clearing the ground and laying the foundation of our knowledge firmly and well, did not eventuate in a complete structure ready for occupation, only those technically interested in what may be regarded as the architectural features of his scientific building really appreciated what he had accomplished.

In the period intervening since the announcement, a generation ago, of Miller's results, the need for more light on the problem of dental caries has stimulated thought and investigation all tending toward its solution, so that in due course we may know the "why" as well as the "how" of the causation of tooth decay. The importance of the problem, it goes without saying, consists in the fact that it is not simply a scientific one within the limits of dental professional interest, but it concerns the health and happiness of humanity—and that in an amazing degree, if we consider all the factors involved in the disorder itself and the importance of its sequelæ. The problem of caries is engaging general attention as a sanitary and sociological question, hence the pressure of the demand—both intrinsic and extrinsic, so far as dentistry is concerned—for the kind of investigation that will ultimately bring out a full and satisfactory answer to the problem of dental caries, *i.e.* how it is originated, what causes its production, and how it may be effectually prevented.

The demand for an answer to these phases of the question is practically manifested in the large volume of work that is now being collectively done in the study of caries; and while the importance of much that is being reported from time to time in our literature may not seem to have a self-evident or important bearing on the subject, it is to be remembered that the work of proving what it is *not* is equally as important as the work of proving what it is—so that the ground is being cleared by the elimination of theories and views which, while they remain, serve to obscure the real truth. Thus, while much that is being now done is of the nature of negative proof, the work is none the less valuable because it is negative. On the whole, we seem to be approaching the goal toward which all this effort of scientific research has been tending; the atmosphere of dentistry seems to be pregnant with the spirit of discovery, and we may confidently look forward to the solution in the near future of our great problem, which when solved will enroll the dental profession among the benefactors of humanity.

Bibliographical.

Dental Jurisprudence: The Law Relating to Dentists and the Practice of Dentistry. By Wm. E. Mikell, Professor of Law in the University of Pennsylvania. 8vo, 570 pages. Price $2.75 net. Philadelphia and New York: Lea & Febiger, 1912.

While not every dentist need be his own lawyer, he surely owes to himself, his family, his patient, and his profession a clear understanding of his relations to the commonwealth. Dental colleges have come to realize the necessity of legal knowledge for their students, and have embodied courses on this subject in their curricula; and an increasing number of states are requiring by law a knowledge of dental jurisprudence as a prerequisite to the right to practice dentistry. The eminent usefulness of such knowledge becomes apparent from a minute's consideration of possible civil suits for claims or damages or criminal suits for malpractice in which a dental practitioner may innocently become involved—and many have been the trials and mistrials that have wrecked dentist's lives.

The subject-matter is here presented by one who is not only an eminent authority, but whose genuine sympathy with the class of readers and clients to whom his book is addressed is agreeably felt. It is surely more than a mere coincidence that Philadelphia is the writer's residence, and that he is the third in a notable triumvirate that have given the dental profession a treatise on its legal status—R. J. Williams in 1884 and W. F. Rehfuss in 1892 having preceded him. The style is facile and fluent, singularly free from burdensome legal "jargon," and the chapters on the status of the dentist, the right to practice dentistry, relation between dentist and patient, liability of patient to dentist, liability of dentist to patient for breach of contract, for malpractice, and to the state and to jury duty, and the dentist as a witness, encompass every situation and circumstance under which a dental practitioner may confront the law. Chapter X contains the statutes of the United States, Great Britain, and their colonies, governing the practice of dentistry. Most of these statutes are reprinted in full, but in a few cases sections not of immediate use or interest to dentists or dental students have been omitted.

As a business investment, the time spent in reading this book seems more valuable than a perusal of the rambling and vapid "business talks" which have recently been spread broadcast among dentists. If a dentist must be a business man, he must first of all know the legal rights and privileges that pertain to his profession, which is now recognized both by statutory law and by judicial decisions as a specialty of medicine and surgery.

In the Introduction, Dr. Edward C. Kirk stands sponsor to this remarkable work, thus concluding: "The work is confidently recommended to teachers as a trustworthy text-book, and to the dental profession at large as a reliable reference work on the subject within its scope. It embraces an amount and character of information which, when included as part of the educational equipment of the dental practitioner, cannot fail to safeguard him from the unfortunate consequences of many acts in which from ignorance or inadvertence he may too easily become involved."

As a matter of taste, the time-honored traditional legal size and sheepskin binding might perhaps add to the general excellence displayed in the mechanical execution of this volume.

The American Pocket Medical Dictionary. Edited by W. A. Newman Dorland, A.M., M.D. Eighth Edition, revised and enlarged. Price $1.00 net. Philadelphia and London: W. B. Saunders Co., 1913.

This new edition of this ever-useful cicerone has been carefully revised, and a large amount of new matter has been added, in which the new terms that have appeared in dentistry come in for a liberal share of recognition.

The method of printing the phonetic transcription of many terms seems to us less useful than a brief derivation of the word would be. A phonetic transcription, as a rule, is more difficult to read than the term *per se,* and experience shows that such transcriptions do little good toward eradicating solecisms, provincialisms, fads, or affectations from professional language. Derivations, on the other hand, especially of rare and new terms, help to fasten these terms in the mind. It would, however, seem unnecessary, and even undesirable, to print the Greek words from which so many of our terms have been derived, in Greek type, which to a great many perusers is no more than a vague memory of student days, and to the majority simply "Greek." The practice of marking the accented syllable in every term, as adopted throughout the book, is commendable.

Aside from its most practical value, which needs no further comment, this little 32mo giant of 677 pages, in smart flexible leather cover and gold edges, commends itself by its decorative appearance in a way that we do not usually associate with modern medical books.

Microscopy, Bacteriology, and Human Parasitology. A Manual for Students and Practitioners. By P. E. Archinard, A.M., M.D. Second Edition, revised and enlarged. Illustrated with 100 engravings and 6 plates. (The Medical Epitome series.) Price $1.00 net. Philadelphia and New York: Lea & Febiger, 1912.

This handy epitome offers to the dental student an attractively and fluently written discourse most suitable for collateral reading in conjunction with the lectures given in dental schools on bacteriology and hygiene. For reviewing or quiz purposes the liberal number of questions appended to every chapter is very useful—and books that offer that feature have always proved popular with students.

The dental practitioner, too, unless he belong to that large class of whom it has been said that they "live in a cavity," will find the present little volume very helpful in keeping him posted with the technique of bacteriology, and he may find here enough inspiration regarding the inoculation of culture media with bacteria, the inoculation of animals, infection and immunity, anti-bodies and opsonins, to start a little research of his own, to try to make his own autogenous vaccines for his pyorrhea patients, and to make his own diagnoses of tuberculosis, syphilis, glanders, tetanus, and a score of other infections that may be manifested in the mouth.

The illustrations and typography of the book measure up to the usual high standard of the Medical Epitome series.

PHYSIOLOGY. A Manual for Students and Practitioners. By A. E. GUENTHER, Ph.D., and THEODORE C. GUENTHER, M.D. Second Edition, thoroughly revised. Illustrated. (The Medical Epitome series.) Price $1.00 net. Philadelphia and New York: Lea & Febiger, 1912.

What has been said of the volume on Microscopy and Bacteriology of this series applies equally well to this book, the general arrangement and typographical features of which are the same. Perhaps a more liberal supply of illustrations would add to its other attractive features.

Text-books on physiology generally deter by their imposing volume. Here the subject-matter is attractively condensed without omission of any essentials, and the dental student and practitioner, both, will find what they must know on secretions, digestion, circulation, respiration, metabolism, and the muscular and nervous mechanism—the one, in order to connect this important subject intelligently with the many other overlapping branches of his study; the other, in order to practice dentistry professionally, not as a mere mechanic but as a doctor of dental science.

REVIEW OF CURRENT DENTAL LITERATURE.

SCHOOP'S METAL-SPRAYING PROCESS.

By ZAHNARZT A. LICHTWITZ, GUBEN.

For the last thirty years experiments have been made with the aim of discovering a process for distributing metals in any thickness desired over a given surface by a direct spray. The most promising of these methods have been invented by the German engineer Schoop, who first sprayed molten metal by means of a jet of gas or vapor under high tension over properly prepared surfaces, thereby producing a resistant coat. The second method he evolved consists in hurling finely powdered metal against the surface to be coated under gas pressure of from two to three atmospheres. The third invention of Schoop consists in a small and handy metal-spraying apparatus, which quite resembles a plumber's torch, and by means of which noble metals, fed into the apparatus in wire form, and glass, can be atomized. The thickness of the resulting metal coat can be regulated to any desired thickness from thousandths of a millimeter to ten millimeters. The coat obtained is uniformly dense and homogeneous, and can be made adherent or removable. The hardness of an atomized coat is harder than that of a cast one, resembling rolled or swaged metal. The temperature at which the atomized metal is being discharged from the apparatus is so low that even highly inflammable materials can be coated, and the finger can be held in the spray without injury.

On the basis of these facts, Lichtwitz believes that the metal atomizing process, after some experimentation, can be made applicable to making metal plates by simply coating the prepared model, and attaching teeth directly thereto without the interference of troublesome backings, to making splints and prosthetic appliances after resections, even to making gold fillings, thereby considerably enhancing the accuracy of the work and simplifying the technique. In his opinion this method is destined to displace entirely the casting process, which he considers to be a failure, and he invites experimentation with this new method.

DIATORIC PORCELAIN CROWNS FOR MOLARS WITH PULP-CHAMBER RETENTION. By Dr. Emilio Barrena.

A method is presented for replacing badly broken-down molars with diatoric porcelain crowns in such a way as to insure sufficient strength to withstand the stress of mastication. The devitalized tooth is ground down with a carborundum stone to about 1 mm. above the cervical gum margin. The pulp chamber is squared with a fissure bur the end of which has been filed off to prevent perforation of the bottom of the cavity chamber. The root-canals are then treated and filled. Should any portion of the tooth be destroyed below the gum margin, the overlying gum is forced away by packing with gutta-percha. When the tooth is thoroughly prepared, an impression of the root and bite are taken in modeling compound, and a suitable crown is selected of such a length that its lower border comes to within a distance of from 1 to 2 mm. of the cervical margin of the root, when the root is in occlusion with its antagonist. A piece of casting wax is then softened, shaped into a cone, pressed into the diatoric crown, and the crown and wax are then pressed in place in the pulp chamber, and the patient is requested to bite, to insure correct articulation. The surplus of wax on the cervical margins is trimmed away with a warm spatula. Crown and wax are then removed from the root together, and invested and cast, thus obtaining a gold base which perfectly fits the pulp chamber. This base is polished out of the mouth, and after grooving the pulp portion of the cast gold base and the interior surface of the pulp chamber wall, to insure increased adhesion, the crown is cemented to place. This method can be adapted to all kinds of facings, the resulting crown being sufficiently strong to serve as a bridge abutment.

[*British Dental Journal*, London, September 15, 1913.]

VULCANITE AND VULCANIZATION. By Chas. Rippon, Dewsbury.

Rippon offers a few practical hints regarding dental rubbers, as follows: For ordinary cases, all dental rubbers, if vulcanized according to the instructions sent with them, give good results. A dental rubber may, according to its content, be adapted to any desired case. Heavily filled rubbers—pink and white—make perfect cores for thick cases, which may be vulcanized at the ordinary temperature and time without fear of their being porous. Heavily filled rubbers are less liable to alteration on revulcanization than the ordinary base rubber, viz, those rubbers less heavily filled. The purer the rubber, the more flexible will be the vulcanite, but the greater will be the alteration on revulcanization. When a flask is to be closed in the vulcanizer, this must be done before the temperature reaches 247° F., at which point rubber begins to harden. The usefulness of a self-closing flask is very apparent. Care must be taken to have sufficient water in the vulcanizer to insure the steam being always in a saturated condition during the period of vulcanization; hot air does not give the same result as steam, being slower and less reliable on account of its lesser conductivity for heat.

BACTERIOLOGICAL RESEARCHES REGARDING THE VALUE OF ANTISEPTIC CHEMICALS. By J. Miran, Vannes.

Miran reports the results of bacteriologic experiments conducted in the Pasteur Institute, with instruments contaminated with streptococcus bacilli and sterilized subsequently with cyanid of mercury. The purpose of this investigation was to test the merits of the habit of many operators of dipping or immersing for a longer time their instruments into an antiseptic solution after using them in a patient's mouth. Cyanid of mercury solutions of 2:1000 and 4:1000 in combination with sodium borate were employed, and nickeled instruments which had been contaminated by streptococcus bacilli were immersed in this solution for two hours. Despite this apparently thorough sterilization, streptococcus cultures could be made on gelatin from these instruments. Even after four hours' immersion, streptococcus cultures were obtained, and it was only after leaving an instrument in a 2:1000 cyanid of mercury solution over night that no cultures could be obtained. These experiments show the entirely illusory bactericidal effect of antiseptic chemicals, even mercury compounds, which are the most efficient at our command. The belief of many practitioners, therefore, that the immersion of instruments in an antiseptic solution will render these sterile, is exploded.

[*Journal of the American Medical Association*, Chicago, October 4, 1913.]

THE RESPONSIBILITY OF THE DENTIST AND PHYSICIAN IN REGARD TO MOUTH INFECTIONS AND THEIR RELATION TO CONSTITUTIONAL EFFECTS. BY DR. T. B. HARTZELL, MINNEAPOLIS, MINN.

Anatomic and physiologic considerations show that the teeth and the protected interstitial areas present a most favorable field for bacterial growth. These bacterial breeding-places, together with the deep pockets which form in the presence of the heavy bacterial coat that the protected tooth surfaces usually bear, give rise to a multitude of organisms which of necessity pass into the stomach and bowels, and frequently alter, by their products and presence, the whole chemistry of digestion, so that an infected mouth may produce four distinct pathologic effects: First, that produced by the dissemination of bacteria through the medium of lymphatic drainage; second, that produced by bacteria through the open bloodvessel; third, the damage sustained by the individual through the change in the chemistry of digestion caused by bacterial poisons; fourth, that produced by a general bacteremia, which not infrequently is a direct result of the dissemination of bacteria in the blood stream. Statistics gathered by the writer in a community with a young and vigorous population, and covering 1020 cases of mouth infection, show that there is about one case in every ten in which severe constitutional lesions occur. There really seems to be no function or tissue of the body which may not be reached by infections occurring in, or originating through, lesions in the oral tissues. It seems eminently proper, therefore, that physicians should scrutinize more closely the mouths of their patients in all their routine examinations, should insist on radiograph examination to discover impacted and diseased teeth, and should advise the extraction of diseased teeth, unless the patient is in the hands of a competent dentist who comprehends the vital relation which diseased and impacted teeth bear to the general health of the individual.

[*Deutsche Zahnaerztliche Wochenschrift*, Leipzig, No. 6, 1913.]

GOLD CROWN WITH REINFORCED CUSPS. BY DR. SCHMEDING, BREMEN.

Schmeding reviews the disadvantages inherent in the current methods of making gold crowns. The method of adjusting a ferrule to the prepared root, swaging a cusp and soldering it to this ferrule, necessitates accurate fit of the cusp to the ferrule, hence considerable grinding; moreover the line of solder is almost always visible, since the solder is of a lower karat than the gold plate. The one-piece swaged crown is of good appearance, but the cusp being no thicker than the barrel, the crown is quickly worn through. Reinforcing of the cusps by flowing solder into the crown frequently produces inaccurate fit. If the cusp is cast to the ferrule, the latter must be thicker than when a swaged cusp is employed; moreover, the union between the ferrule and the cast cusp is sometimes so unsatisfactory that soldering must be resorted to after all.

The writer has designed a method by which cusps of a thickness of 0.5 mm. are obtained. After obtaining an impression, the crown is swaged in one piece of gold plate of 0.25 mm. thickness, and tried in the mouth as to articulation, allowance being made for a second hood or cusp of 0.25 mm. thickness. This other cusp is then swaged of 0.25 mm. thickness, fitting accurately over the masticating surface of the one-piece crown, and slightly extending over the sides all around. This extension allows of a better reproduction of the contact points, and gives the crown a better shape. The reinforcing cusp is then soldered to the crown. After polishing, the crown appears as if it had been made of one piece, and its durability is assured.

[*Oesterreichisch-Ungarische Vierteljahrsschrift fuer Zahnheilkunde*, Vienna, No. 2, 1913]

SPLINTING LOOSE TEETH BY MEANS OF A REMOVABLE APPLIANCE. By Zahnarzt E. Luniatschek, Breslau.

The appliance suggested is designed to allow for the immobilization of several loose teeth by an appliance that engages no more than two firm adjoining teeth. In order to immobilize four loose lower incisors, for instance, the writer devitalizes these, together with the two canines. The root-canals of the latter are enlarged, and hollow tubes threaded inside are inserted. On the labial surface of each of the incisors, above the cervico-marginal ridge, a hole is bored horizontally with a bur of the diameter of the threaded tubes, in such a way that they will be approximately parallel to one another. The tubes are then cemented to place, ground down flush with the lingual surface, and a screw post with cone-shaped head is screwed into each one. An impression is then taken of the lingual surfaces of the teeth, and a lingual bar is cast into which countersunk holes are bored for the reception of the screws, which will fasten every tooth individually to the bar. The vertically situated screws in the canines can be tightened with a watchmaker's screwdriver, while for the horizontally placed screws an old bur suitably ground down and fitted at the other end with a lead or tin ball to facilitate manipulation is used as a screwdriver. For esthetic purposes, one or more facings can be cemented to the bar by means of suitably shaped backings cast together with the bar.

The writer claims for his appliance the advantage of easy removal, possibility of making alterations and repairs, sufficient immobility, no interference with treatment of the gingival tissues, and esthetic appearance. It seems, however, that besides the fairly complicated construction of this appliance, the necessary devitalization not only of the loose teeth, but especially that of the firm abutment teeth, is open to objection.

[*American Journal of Surgery*, New York, June 1913.]

REPORT ON NITROUS OXID AND OXYGEN ANESTHESIA. By S. Leigh, M.D.

[*International Journal of Surgery*, New York, April to September 1913.]

OXYGEN AND ANESTHESIA. By F. H. McMechan, M.D., Cincinnati, Ohio.

SHOCK. By A. W. Colcord, M.D., Clairton, Pa.

THE PREVENTION OF SHOCK. Editorial.

TRAUMATIC SHOCK AND THE EMPLOYMENT OF BLOOD-PRESSURE ESTIMATION IN ITS PREVENTION AND TREATMENT. By J. C. Bloodgood, M.D., Baltimore, Md.

[*New York Medical Journal*, New York, November 1912.]

THE GWATHMEY-WOOLSEY NITROUS OXID AND OXYGEN APPARATUS. By J. T. Gwathmey, M.D., and W. C. Woolsey, M.D., New York.

The advantages of nitrous oxid and oxygen in general anesthesia are so well known to dental practitioners that it seems almost superfluous to dwell upon this anesthetic mixture at length. The growing popularity, however, which nitrous oxid and oxygen is gaining in general surgery is so remarkable that a brief mention of some of the many articles on this subject that have appeared in medical magazines at short intervals may not be amiss, as it may reassure the dentist who has been employing this anesthetic in his practice, of the wisdom of his choice.

Says Dr. Leigh: "The profession is rapidly getting to view this matter in its proper light, and I think I can safely predict that in a year or two there will hardly be a well-equipped hospital in this country that will be without a proper apparatus and a well-trained anesthetist administering what is undoubtedly, so far, the safest and best of anesthetics—nitrous oxid and oxygen." The complicated and expensive machines which have flooded the market have in this writer's opinion done as much as the untrained anesthetists to bring the method into disrepute.

Colcord finds that nitrous oxid anesthesia causes a rise at first in blood pressure, due to partial asphyxia, then a gradual fall, seldom getting below the normal line. We find in this form of anesthesia an absence of the wide excursions of the blood pressure during cutting or manipulation of the tissues, hence a lesser tendency to vaso-motor exhaustion and shock.

Colcord's painstaking survey of what has been accomplished in the field of prevention of shock is substantiated by Bloodgood's observations. "The two factors," he says, "over which we have the greatest control during operation, are the trauma of the operative procedure and the toxicity of the general anesthetic. Ether has been substituted for chloroform because it is less toxic. At the present time nitrous oxid and oxygen is taking the place of ether, for the same reason." In order to block most or all sensory afferent nerve impulses, he employs local infiltration anesthesia with novocain, in this way temporarily disconnecting the brain from the wound. When this method is used, nitrous oxid and oxygen has another advantage over ether and chloroform—the general anesthesia is so light that painful manipulations excite reflexes. The patients move, muscles contract, so that, under this method, one has almost as good an index of the efficacy of local infiltration as when the patient is awake. Nitrous oxid and oxygen, therefore, obliterates psychic shock and produces no toxic shock. The local anesthesia obliterates the traumatic shock. The best index to the patient's condition before, during, and after the operation is the behavior of the blood pressure, which should be continually watched.

McMechan suggests the use of oxygen during the induction of anesthesia in all subjects whose respiration or circulation is inefficient, and personally employs it until both circulation and respiration have been moderately stimulated, at which time he begins to induce narcosis. (*cf.* Gatch, *Journ. Amer. Med. Association*, November 11, 1911.) For hazardous risks concomitant oxygenation should be used continuously throughout narcosis. In all other cases—aside from intraoral or nasal technics—it finds its acme of usefulness intermittently, to meet the exigencies of individual cases, and more especially at the close of narcosis in all instances when, by rebreathing, over-ventilation of the lungs can be established, and the remnants of the anesthetics in the alveoli of the lungs and in the circulation of the patient and cellular tissue can be washed out, as it were. McMechan also describes a modified Gwathmey apparatus attached to an autogenor of his design.

The Gwathmey-Woolsey nitrous oxid and oxygen apparatus is fully described by the originators themselves, who claim for it, among other advantages: Absolute and perfect control of the gases flowing at a low pressure; ease of warming the gases whenever the patient's condition demands it; an even automatic flow of gases, as adapted to analgesia, and small size and portability.

[*Deutsche Monatsschrift fuer Zahnheilkunde*, Berlin, October 1913.]

DENTAL DISEASES AMONG SCHOOL CHILDREN AND THEIR EFFECTS UPON EFFICIENCY. BY F. P. WURFSCHMIDT, KONITZ.

When in 1911 W. G. Ebersole published the results of the National Oral Hygiene Educational Campaign among the "Marion School dental squad" of Cleveland, Ohio (see DENTAL COSMOS, June 1911, p. 787), and the principal of this school, Cordelia L. O'Neill, indorsed the success of this experiment in dental hygiene from the teacher's point of view (see "Oral Hygiene As It Appeals to Educators," DENTAL COSMOS, December 1911, p. 1393),* a great deal of skepticism and some belittling and injudicious criticism was encountered. Neither was the number of cases observed sufficiently large to allow of overwhelmingly convincing conclusions. Still, a way had been shown by which to determine the benefits of this movement from a scholastic point of view.

The correctness of the statements made in the publications alluded to is fully indorsed by the investigations of Wurfschmidt, who since 1906 to date has observed the influence of dental disease upon the efficiency in public-school scholarship of no less than 836 boys and 805 girls, ranging in age from seven to fourteen years. By the aid of an elaborate system of statistical tables, the individual items of investigation in which have been culled from the publications of the most

* For a full explanation of the school hygiene experiment at Cleveland, with tables, etc., see "Experimental Oral Euthenics," etc., by Prof. J. E. Wallace Wallin, Ph.D., DENTAL COSMOS, 1912, vol. liv, pp. 404-13 and 545-66.

notable German, English, and American dental school hygiene advocates and educators, the writer proves convincingly that the pain due to dental diseases attracts the child's attention to his suffering and away from the subject of instruction. This distraction may last a shorter or longer time, and be more or less intense. Other pain caused primarily by toothache or sensations of unease have the same effect. The loss in time incurred by toothache is quite remarkable when we read that this dentist, since 1904, has treated 600 school children during school hours, who were sent to him by the teachers on account of severe toothache. These children, without exception, belonged to very poor parents who were unable to pay for dental treatment. The percentage of children, therefore, kept away from school by toothache is very considerably larger than this number would indicate, since the greater number of children in this school were able to pay for dental service and were treated by private dentists.

The influence of dental disease upon the other organs also greatly affects the scholastic efficiency of the child. The general sensation of malaise deprives the child of its natural vivaciousness and ambition, prevents clear and ready conception of the instruction offered, impedes concentration and retention of the impressions received. A feeling of fatigue, dulness, and sleepiness prevails, which may assume the proportions of mental derangement. Nervous disturbances and loss of sleep due to toothache frequently hold children back in their studies, and the continual pain in some instances leads to permanent impairment of apperception, preventing the child from forming any inspiring interests, and from digesting the early impressions so important for his future.

Thus what every capable teacher has long known is here demonstrated statistically, viz, that poor marks in scholastic work, lack of attention and failure to be promoted stand in direct ratio to dental disease, and that poor teeth constitute a grave menace to the physical and mental welfare of a people.

Among the many measures that have, within recent years, been taken in Germany to combat this long-neglected national disease, the writer mentions the encouraging fact that Prof. Dr. Kirchner, director of the Prussian Ministry of the Interior, is working on a bill contemplating legislative measures for the combating of dental caries on a nation-wide scope.

[*Oesterreichisch-Ungarische Vierteljahrsschrift fuer Zahnheilkunde*, Vienna, No. 2, 1913.]

ALVEOLAR ATROPHY AND PYORRHEA ALVEOLARIS. BY ZAHNARZT A. KASARNOWSKI, ST. PETERSBURG.

After reviewing the dissenting opinions of such authorities as Younger, Hopewell-Smith, Miller, Michel, Arkövy, and many others, this writer proposes the differential terminology indicated in the title of his lengthy paper, summing up as follows: Alveolar atrophy comprises those retrograde disturbances in nutrition which either occur as physiological phenomena—viz, senile atrophy—or are of pathological origin—viz, sclerotic, rhachitic, and traumatic atrophy. All these forms of alveolar atrophy occur without concomitant inflammatory phenomena. The atrophy of the gingiva keeps pace with that of the alveoli, and no pockets are noted. Gingivitis, no matter of what nature, must not be considered as the cause of pyorrhea alveolaris, although it is always present in the latter disease. The most marked symptom of every case of pyorrhea alveolaris is the exudation of pus from the alveolus. Pyorrhea alveolaris, therefore, is a purulent inflammation of the alveoli caused by the action of ectogenous or hematogenous bacteria which find their primary lodging-place in the alveoli. Since pyorrhea occurs in the absence of tartar, there is no reason to consider tartar as the exciting cause of the disease. The deposits covering pyorrhetic roots are of secondary nature, and, being foreign bodies, must always be removed in treatment. The recession of the gums in pyorrhea progresses more slowly than the atrophy of the alveoli. As long as gingival tissue remains, the disease may be improved. The gingival tissue cannot grow to roots which have lost their pericementum, but it can approach them, and thus support them mechanically; laceration, excision, etc., of the gingival tissue is therefore contra-indicated.

Periscope.

Restoring the Color of German Silver.—German silver which has lost its luster during manipulation can be brightened up again by heating and dipping in oxalic acid. —*Schweizerische Vierteljahrsschrift fuer Zahnheilkunde.*

Seventy per Cent. Alcohol Most Suitable for Disinfection.—According to Beyer's investigations alcohol has its greatest disinfecting power at 70 per cent. Absolute alcohol is a less effective disinfectant.—*Muench. Med. Wochenschr.*, per *Deutsche Monatsschrift fuer Zahnheilkunde.*

Collecting Spilled Mercury.—Mercury that has been spilled on the instrument table or the floor can be collected conveniently by drawing a circle around it with a very wet sponge, as the pellets do not easily run over the wet circle.—*Schweizerische Vierteljahrsschrift fuer Zahnheilkunde.*

Instrument for Inserting Silicate Cement Fillings.—By burring a hole into the end of a broken excavator and cementing into it a piece of celluloid, a serviceable instrument for inserting silicate cement fillings can be made. The celluloid can be filed to any desired shape.—*Deutsche Zahnaerztliche Zeitung.*

Antagonizing Model of Metal for Setting Up Teeth.—In setting up the teeth for an upper or lower denture, it is practical to pour a model of the antagonizing jaw in Spence or Melotte metal. Such models are more durable, and are not worn or broken in articulating the teeth to them, thus insuring an accurately articulating plate that requires no grinding or resetting of teeth.—*Oesterreichische Zeitschrift fuer Stomatologie.*

First Dentition in the Monkey (Macacus Rhesus).—The young Macacus Rhesus —with probably others of this species—at six weeks of age possesses twenty deciduous teeth, which erupt practically at the same time, while in the young of the anthropoid ape and man not the slightest symptoms of an eruptive process are noticeable at such an early age, with the exception of congenitally erupted teeth, which are a rare anomaly. The eruption of the teeth in the Rhesus is one rapid uninterrupted process, while in the anthropoids and in man the various types of teeth erupt at certain definite intervals. —J. Scheff, *Oesterreichisch-Ungarische Vierteljahrsschrift fuer Zahnheilkunde.*

Condition of Extracting Forceps.—In order to perform a satisfactory extraction, the forceps must be in first-class condition, and their edges must be sharp. It is practical to warm the forceps before extracting, whereby the pain is reduced. The analogy of the warmed razor used for satisfactory shaving may be cited in this connection.— M. J. Crépieux-Jamin, *Bulletin du Syndicat des Chirurgiens-Dentistes de France.*

Strengthening Bridge Work and Preventing Distortion in Soldering.—In order to render bridge work more durable and to prevent breaking or tearing at the soldered joints, these joints should be strengthened with iridio-platinum wire. It is even better to unite the abutments first by an iridio-platinum wire soldered to them, and to incorporate this wire into the body of the bridge when soldering. In this way, distortion during the soldering operation is also prevented, and an accurate fit of the bridge in the mouth assured.—*Oesterreichische Zeitschrift fuer Stomatologie.*

Method of Avoiding the Cement Line in Porcelain Inlays.—After preparing the cavity according to accepted principles, the gold or platinum foil is burnished and filled with Harvard cement while in the cavity. A metal wire, which is allowed to protrude sufficiently to allow of easy manipulation, is embedded in this cement filling, which, after it has set, is withdrawn together with the matrix, which will be found to adhere firmly to the cement. Over this first matrix, a second one of the same gage is carefully burnished and pressed so as to insure absolute contact between the two. The second matrix is then withdrawn, and in it the porcelain inlay is baked. In this manner the thickness of the matrix is entirely eliminated, and such an accurate fit of the inlay is obtained as to leave no visible cement line.—*La Province Dentaire.*

Disposing of Vulcanizer Steam.—It is often urged that the vulcanizer should be allowed to cool down gradually, and this advice is good, but it is difficult to follow in the great majority of cases owing to want of time. An easy method of disposing of the steam is to affix one end of a small length of flexible tubing to the blow-off tap and to put the other end in a pail of water. The result is no smell, no noise, no steam or moisture blown into the workshop, the vulcanizer is cooled down in a few minutes, and plaster of Paris and other stock are saved from the ill effects of dampness.—A. Ernest, *Ash's Monthly.*

Necrosis Due to Stale Novocain Solution.—It is still a common practice among dentists and medical men to use for infiltration anesthesia novocain which has been kept in solution for some time. The consequences in two cases have made the writer careful to use only fresh solutions. He states that every possible precaution for asepsis was taken; but the 2 per cent. solution, kept closely corked, and boiled before using, had been made several weeks previously. In one case 3 cc., in the other 7 cc. of this was injected. In both cases the results were alarming; persistent analgesia, much swelling, and in the latter case dangerous hemorrhage, lasted for many days. The writer injected 5 cc. of the solution of novocain into his forearm, and thereby provoked extensive edema and tissue necrosis which persisted for several weeks. He considers that no appreciable decomposition of the drug could have occurred, as its anesthetic properties were unimpaired. He also excludes the action of living organisms on the tissues, for the solution was sterilized before use. He inclines, therefore, to the view that the solution had become infected with organisms, the toxins of which might yet be potent after boiling.—*Deutsche med. Woch.*, per *British Dental Journal.*

Interdental or Intermaxillary Lacing in Mandibular Fractures.—This method is very simple, and the oldest known, it being mentioned by Hippocrates. It is suitable for simple fractures in the incisor region. Wire ligatures are passed through the interdental spaces on each side of the fracture. Three ligatures are applied, the first taking in one tooth on each side of the fracture, the second two teeth, and the third three teeth on each side. The longest ligature is tightened first, and the shortest last. This method allows movement of the jaw. By using intermaxillary lacing, the lower jaw is absolutely immobilized by being laced to the upper. This may be done by applying Angle's bands to the upper and lower teeth, and lacing them together by wires passing around studs on the buccal surfaces.

A much more satisfactory method is that devised by Dr. Pickerill and described in the *British Medical Journal.* A wire ligature of silver or gilded copper is passed around two teeth, preferably bicuspids in the upper jaw, and another around the corresponding teeth in the lower jaw; the ligatures are left loose. These horizontal ligatures are then connected by a vertical wire, which is also left loose. Both sides of the mouth having been laced in this way, the horizontal ligatures are tightened. The lower jaw is next made to articulate correctly with the upper, and then the vertical ligatures are tightened up. The patient lives on a diet of soup, porridge, arrowroot, etc. Such food can pass between the teeth around the back of the last molar. The mouth is kept clean by using antiseptic mouth-washes. This method is also useful in "first aid," in which cases string or catgut can be substituted for wire ligatures.—J. L. Saunders, *New Zealand Dental Journal.*

A Few Therapeutic Agents.—Formocresol, consisting of equal parts formalin and cresol, is without doubt a specific for putrescent pulps, rendering the contents of the root-canals aseptic in one or two treatments.

Euroform paste consists of orthoform 1 dram, europhen $1\frac{1}{2}$ drams, petronol $2\frac{1}{2}$ drams, petrolatum (white) $2\frac{1}{2}$ drams, and is an excellent anodyne for pain following extraction. A small piece of gauze is saturated and packed in the socket for a few hours.

Phenol-sulfonic acid is prepared by the reaction of concentrated sulfuric acid upon phenol; 97 parts by weight of acid are gradually added to 93 parts by weight of phenol. This is an ideal bone-stimulant to be used in chronic alveolar abscess where there is slight necrosis. It will also be found useful as a counter-irritant in pyorrheal pockets, and for desensitizing remnants of pulp in the apical region.

Euca-percha compound is a solution of dental base-plate gutta-percha in eucalyptol compound, this compound being composed of menthol 64 grains, thymol 96 grains and eucalyptol 4 fluidounces. When used as a root-canal filling, to be followed with a gutta-percha point, it is superior to chloroform and gutta-percha, on account of the antiseptic action of the thymol and menthol.—A. N. Kearby (citing from J. P. Buckley), *Texas Dental Journal.*

Malignant Disease of the Tongue and Mouth.—Robert Abbe says that sarcoma of the round or spindle-cell type is apparently congenital in origin, though long latent, and may best be cut out. Carcinoma, on the other hand, is always the result of irritation, either by a tooth, a dental plate, tartar, a pipe-stem, or tobacco. Tobacco seems to be the most frequent offender, for advanced cancer of the mouth is extremely rare except in one who has been an excessive smoker or has chewed tobacco. It is usually after twenty or thirty years that the beginning of an epithelioma shows, and insidiously advances. It usually starts either at the contact points of the pipe or streams of hot smoke on the tongue, or in the folds where the nicotin lies in the mouth, or where the quid rests between cheek and gum. The practical lesson is that, when the first spot of leucoplakia appears, it is wiser to cease the use of tobacco at once and forever. When the inside of the cheek is extensively invaded by carcinoma, it may still be cured by excising a part of the cheek, but half of the lower jaw must be excised to permit free play in eating and to obtain sufficient sound tissue to close the defect. The writer concludes that thorough surgery is the supreme reliance in malignant disease of the mouth, and early operation the patient's chief hope of cure. Radium has its uses, but in advanced cases of cancer its good effect is transient; in giant-cell sarcoma and in leucoplakia, however, it is a specific.—*Med. Record* per *N. Y. Med. Journal.*

Malignant Disease of the Mouth and Pharynx.—Trotter holds that more mistakes are made in the direction of pronouncing tumors inoperable than in attempting operations which cannot be completed. The reason for this, he believes, is that in advanced gland cases of malignant disease of the mouth and pharynx, the principal mass is usually under the upper end of the sterno-mastoid and fixed to it near its insertion. This gives the erroneous impression that the growth is fixed to the spine. Glands beneath the muscle are also likely to appear ill-defined and diffuse, when they are in fact not so. When glands not under the muscle are indefinite and accompanied by brawniness of the skin and edema, it is generally quite useless to operate. Trotter regards it as being very remarkable how the common and internal carotids and the vagus escape involvement in gland masses until very late. Such masses tend to spread backward and involve the muscles on the floor of the posterior triangle long before they attack the common carotid. When the common carotid and vagus are involved, it is doubtful whether the operation should be carried out, and much would depend on the kind of primary growth and the condition of the patient. Removal of these two structures is a serious addition to the danger of the operation in itself, but it implies such extensive disease that cure is practically impossible. The limits of operability, then, lie less in technical difficulties than in the uselessness of the operation.—*Lancet* per *Journ. Amer. Med. Association.*

A Simple Method of Gold Plating.—The method of gold plating here described is both simple and inexpensive, and can be readily carried out by anyone who has an electric power supply. The first requisite is the bath, for which any glass or porcelain vessel of sufficient size will answer, although the best shape is that of a rectangular tank, deep and narrow, because such a bath requires the minimum quantity of solution to work it. Into this bath about 125 to 150 gm. of cyanid solution are poured; an anode of pure gold—a plate two or three centimeters square—is fixed at the positive pole of a current of 110 to 220 volts, with a 10 or 16 candlepower lamp resistance, and a strip of German silver is atttached to the negative pole.

To hasten the action, hydrochloric acid is poured into the bath over the gold anode, and this chemical at once produces a brisk effervescence, the fumes of which must on no account be inhaled. After two or three minutes the cathode, *i.e.* the strip attached to the negative pole, is withdrawn.

If the deposit of gold is slow in appearing, a few drops more acid should be poured over the anode. The quantity of hydrochloric acid required varies according to the intensity of the current, and the correct amount can be ascertained in the following manner: If effervescence continues after both anode and cathode are removed, there is an excess of acid, which can be corrected by adding more cyanid solution till effervescence ceases; a yellowish deposit at the bottom of the bath, near the anode, shows that the current is too weak—to be remedied either by replacing the 10 candlepower lamp resistance by a 16 candlepower one, or by adding a little more cyanid solution; blackish deposit of German silver at the cathode indicates an excess of current or of acid, and the addition of more cyanid will put this right.

When the bath has been regulated, it must be protected from the air and dust. The piece to be plated is immersed from two to three minutes, being of course suspended from the negative pole in place of the German silver, which is only employed to get the bath into proper working order. Successive layers are obtained by immersing the piece for a couple of minutes, brushing with a wire brush, and re-immersing.

It is essential that the piece be perfectly clean, and absolutely free from the slightest trace of grease. The best way to insure this is to use a wire scratch-brush. The actual cost of working is very small, as the same solution can be used repeatedly, and there are no batteries to be renewed.—*Edwards' Dental Quarterly.*

Disintegration of Metals at High Temperatures. Condensation Nuclei from Hot Wires.—In a preliminary account of experiments upon the disintegration of metals, more particularly the platinum metals, the theory was put forward that the disintegration of the platinum metals was due to direct oxidation. The fact that platinum does not, under any circumstances, combine directly with oxygen has caused a diffidence in suggesting that the influence of oxygen is other than catalytic, and there are, moreover, certain experimental facts which at first sight appear to militate against the theory that tne disintegration is due to direct oxidation. In the present experiments, the wire is heated by a current developed from an alternater and transformer set and placed within a chamber where various gases can be measured as to pressure. The rate of loss of weight of the Pt-wire is roughly proportional to the oxygen pressure, which points to the formation of an endothermic oxid. Experiments in a constant-volume gas chamber, in which the loss of Pt to loss of oxygen is determined, give results which approximate in the case of air to 2Pt : O, and in the case of oxygen to Pt : 2O. It does not seem probable that this large amount of oxygen is simply absorbed: it must be combined chemically, at any rate for the most part. During the cooling of the oxid after its formation at the hot wire some decomposition takes place, and the amount of decomposition will be greater the lower the oxygen pressure. If we assume that the quantity of oxygen absorbed by the deposit is small, the composition of the oxid in the experiments in oxygen must be either PtO_2, or some higher oxid. If the oxid is also present in the deposit in air, there must be a considerable amount of Pt mixed with it, this Pt being the result of dissociation of the oxid during cooling.—J. H. T. ROBERTS, *Philosoph. Magazine*, per *Brit. Dental Journal.*

Diagnostic Symptoms of Ludwig's Angina.—When the teeth are the starting-point, the inflammation involves the periosteum of the lower jaw and thence all the surrounding tissues. No matter how it commences, it spreads along the connective tissue by direct continuity. In these cases it is not transmitted by lymphatics. The lymphatic glands do not become enlarged by infection carried to them through the lymph-stream from the infected focus, but are involved by the connective tissues surrounding them.

The disease is characterized by febrile disturbances, chills and high fevers, which are soon followed by difficulty in mastication and deglutition, and this may suddenly occur in an otherwise healthy individual. In the region of the submaxillary gland a hard, indurated, and sensitive tumor makes its appearance, which cannot be definitely outlined as in a more superficial glandular involvement. There is an infiltration of the connective tissue which surrounds the muscles of the neck, and of the alveolar lingual sulcus, the soft palate, and the pharynx. Marked redness of the skin does not manifest itself at first, but later, where the swelling has invaded the cellular tissues of the whole of the affected side, the neck is distended, hot, red, and inflamed, and it conveys a boggy sensation to the palpating finger and readily pits on pressure. When the sublingual cellular tissues become engorged, the tongue is of necessity forced upward, causing the mouth to open and the tip of the tongue to protrude. There is more or less ankylosis of the jaws, and the partially open mouth allows a free escape of saliva, which is of a foul odor. If this condition is not relieved, spontaneously or surgically, the pressure symptoms become more pronounced, the tongue presses backward and downward against the glottis, causing constriction, edema, and death.

Two of the features which are usually constant in this condition are the woodlike hardness of the floor of the mouth and the marked dyspnea.

Of 106 cases reported by Thomas, the primary focus of infection, dental caries, was noted in 36 cases, the third molar being involved in four. So far as reference to special teeth is concerned, they were always molars, usually the third lower, those nearest to the submaxillary region.—C. N. RUSSELL, *N. J. Dental Journal.*

Hints, Queries, and Comments.

PYORRHEA ALVEOLARIS ALLIED WITH KIDNEY- AND GALL-STONES.

I have had under observation during the last six months two very interesting cases in which a severe development of pyorrhea occurred coincidentally, or as a precursor of—in one of the cases a very large kidney-stone, and in the other a severe development of gall-stones.

Case I. Mr. S., age about forty-five, has had a chronic case of pyorrhea which I have been able to hold well in hand for two or three years, but which a few months ago became rather violent. His first symptom of a serious nature was an attack of acute neuralgia, the focal point of which I found in a pocket well under and between the bifurcation of the roots of the lower second right molar. Increased irritation and inflammation of the whole area of the two arches was noted at this time. The patient was atonic and had general symptoms of malaria. After two or three days of treatment I removed the tooth for the relief of the neuralgia, which was successful, but the pyorrhea continued to develop violently, and nothing I could do appeared to check it. I referred the patient to two or three other men without result, and by this time his mouth was in a very badly inflamed and offensive condition.

The acuteness of the inflammation gradually subsided in a degree, but left the pocket streaming with pus. After some two or three weeks the patient developed boils upon the back of his neck, which continued until I lost touch with him for a time, and one day he appeared at my office having just come from the hospital, where he had gone for the removal of a large kidney-stone of such development that the kidney itself was removed. The unusual activity of the pyorrhea had subsided.

Case II. Mrs. J., age about fifty, of splendid physical appearance and a mouth that always gave the appearance of perfect health, was one in whom, during years of observation I had never noticed a symptom of pyorrhea. A few months ago she developed very rapidly a serious case of pyorrhea, involving nearly all her teeth and with pus pockets extending in one or two instances well toward the end of the root. Treatment during two or three weeks was unsuccessful, after which she developed a severe case of gall-stones and was operated upon for their removal.

My own limited observations of pyorrhea have led me in recent years to always suspect these allied troubles, and where the symptoms are acute I always advise an examination; yet in all the literature upon the subject I have seen very little discussion of the alliance of these conditions, and of the faulty metabolism which, it appears reasonable to deduce, influences the development of them.

I should like to know the observations of those who are making pyorrhea a serious study, relating to this alliance of pyorrhea with other calcific deposits.

P. D. Brooker, D.D.S.

Columbia, S. C.

PRESERVING THE FOIL MATRIX FOR A PORCELAIN FILLING WITHOUT DISTORTION.

The foil matrix for a porcelain filling may be safely protected from harm by placing it in a bottle filled with water—the bottle should be filled so full that no air-bubble remains after the cork has been inserted.

To remove the matrix, the bottle is inverted and the matrix allowed to settle on the cork. Holding the inverted bottle over the sink, the cork is slightly loosened and the water allowed slowly to escape.

A foil matrix may be safely sent by mail when protected in this manner, as no jar will distort it.

Frankfurt, a/M., Germany.

Obituary.

DR. HENRY A. SMITH.

Died, September 10, 1913, in Cincinnati, Ohio, in his eighty-first year, Henry A. Smith, A.M., D.D.S.

For more than half a century, Dr. Henry A. Smith, who passed away on September 10th, at his home in Cincinnati, Ohio, has been one of the best-known practitioners in his home city. He was dean of the Ohio College of Dental Surgery for over thirty years, and during this period of fruitful activity became one of the leading authorities in his profession in the middle West. The deceased was an enthusiast in advancing research work in dental surgery, and his efforts were crowned with distinctions that were awarded him throughout the country. Not only did he devote his life to imparting his great skill and learning to others, but he was ever indefatigable in performing the duties which a large and select practice imposed upon him.

Dr. Smith was born at Oxford, Ohio, on February 28, 1833, and received the degree of D.D.S. from the Ohio College of Dental Surgery in 1857. His prominence in dental art and science earned him the deanship of the Ohio College of Dental Surgery, which also honored him with the title of emeritus professor of operative dentistry. He took a very active part in dental society matters, and was a member of the National Dental Association, the Ohio State Society, and local dental societies. His interests in studies relevant to his chosen profession were evinced by his work in the domain of the arts, which culminated in the degree of A.M. being conferred upon him by the Miami University of Oxford, Ohio.

The deceased is survived by a widow, two daughters, and one son, Dr. Henry T. Smith, of the Ohio College of Dental Surgery.

Interment was made at Oxford, Ohio.

DR. P. H. WRIGHT.

The following obituary notice and accompanying resolutions were prepared by the Committee on Necrology of the Mississippi Dental Association, and adopted by the association at its meeting in June 1913:

Dr. P. H. Wright of Oxford is dead. "Death rides on every passing breeze; he lurks in every flower." When one is basking in the pleasant breezes of happiness and prosperity, it does seem sad that he must die; but there is a Providence that shapes our ends—there is an overruling Power that decides our destinies, and determines the length of the days which we are each to enjoy. Let us accept this dispensation in the right spirit, and while we mourn his absence from this association and from the familiar scenes of life, let our sorrow be softened by the reflection that his soul is in heaven, and that he has escaped the remaining ills of earthly life.

Dr. Patrick Henry Wright, eldest son of Patrick H. and Anna Clark Wright, was born near Tyro, Tate county, Miss., June 11, 1862, and died at Oxford, July 5, 1912. In his early life he professed faith in Christ and joined the Baptist Church, always taking an active part in church work, and living a consistent Christian life. He was married to Miss Julia E. Ward of Senatobia, Miss., February 1888. She died October 8, 1897, leaving three children, Pauline, Anna, and Fred Wright. He married again, in February 1900, his second wife being Miss Mary Kimbrough of Oxford.

Dr. Wright received his literary education in the common schools, with one year at the State University, and was graduated from the dental department of Vanderbilt University in 1887. He first practiced at Senatobia, removing in November 1887 to Oxford, and here he continued in active practice up to the time of his death.

Dr. Wright joined this association in 1887, and in the twenty-five years of his membership had many honors conferred upon him; among them, being president, as also president of the Board of Dental Examiners. We have never had a more loyal and enthusiastic member. He was always willing to do what he could to promote the interest of this association. He was also an honorable member of the National Dental Association, and we have known him to travel almost across the continent to attend one of its meetings.

Dr. Wright was one of the best dentists our state has ever had, and always enjoyed a lucrative practice. He was a man of ability, a sterling friend, a most genial companion, kind and sympathetic, of unswerving devotion to the principles of right and honesty. These he manifested nowhere more markedly than in all his professional relations. He was always an ethical, studious, and observant practitioner; quiet, modest, and most considerate and careful of the feelings of his fellow man.

Dr. Wright was a good citizen, always manifesting a lively interest in anything that was for the good of his town, county, and state. He was most charitable in his nature, never turning anyone away who was in distress, or in financial need. His character was unblemished and his home life beautiful. He was a kind, generous, devoted husband and father, a dutiful son and loving brother.

In the death of Dr. Wright, our State Association and the dental profession of this country loses a most worthy and honorable member.

RESOLVED, That we offer our tenderest sympathy to the bereaved family. May Heaven vouchsafe to them consolation and peace in their bereavement!

RESOLVED, That this token of our sympathy be placed upon our minutes, and a copy properly prepared and sent to the family of our friend and co-worker.

W. T. MARTIN,
ROBT. K. LUCKIE,
J. E. HARGIS,
Committee.

Brief Necrology.

Dr. W. T. DUNCAN of La Salle, Ill., on September 30, 1913.

Dr. EVERETT J. MITCHELL of Hattiesburg, Miss., on October 18, 1913.

Dr. L. C. PORTER of Montgomery, Cal., on September 5, 1913, of cancer.

Dr. E. F. GLENN of Charlotte, N. C., on September 1, 1913, of paralysis, in his sixty-second year.

Dr. JOHN WM. WALLACE of Louisville, Ky., on October 19, 1913, of neuritis and complications, in his sixty-second year.

Dr. JOSEPH V. IRELAND of Logansport, Ind., on September 17, 1913, of paralysis, in his forty-first year. Deceased was a graduate of the Indiana Dental College.

Dr. CHAS. E. DUNN of Louisville, Ky., on September 25, 1913, of a complication of diseases, in his seventy-third year. Deceased was a graduate of the Baltimore College of Dental Surgery.

Dr. EFFINGHAM WAGNER of Montgomery, Ala., on October 22, 1913, following an operation, in his fifty-sixth year. Deceased was a graduate of the Baltimore College of Dental Surgery.

Dr. WM. E. KEARNS of Pittsburgh, Pa., on September 18, 1913, of pneumonia, in his forty-third year. Deceased was a graduate of the University of Michigan, College of Dental Surgery.

Dr. BARRY W. HAYES of Palmyra, Wis., on August 31, 1913, after protracted illness, in his twenty-sixth year. Deceased was a graduate of Marquette University, Department of Dentistry.

Dr. WILLIAM R. MEEKER of Louisville, Ky., on September 18, 1913, of injuries received in a streetcar accident, in his seventy-eighth year. Deceased was a graduate of Ohio College of Dental Surgery.

Dr. EDWARD ROCHETTE of Billings, Mont., on November 20, 1913, following an operation for appendicitis, in his forty-fourth year. Deceased was a graduate of University of Minnesota, College of Dentistry.

Dr. JAMES T. STUART of Montgomery, Ala., on October 30, 1913, in his forty-third year. Deceased was a graduate of the Baltimore College of Dental Surgery, and at one time dean of the Milwaukee Dental College.

Society Notes and Announcements.

PANAMA-PACIFIC DENTAL CONGRESS.

The work of organizing the Panama-Pacific Dental Congress is progressing in a most satisfactory manner, and it is confidently expected that by January 1, 1914, twenty months before the opening of the congress, all the preliminary work of organization will have been accomplished.

A few foreign countries and a few of our states have yet to appoint executive committees to carry on their part of the work of publicity and securing program and memberships. Within the next two weeks invitations will be sent to those who are selected by the Committee of Organization to act as officers of the various sections of the congress, and in each case an urgent request will be made for a prompt reply, that there may not be experienced in this matter the delay which in some cases has attended the appointment of state and national executive committees.

Three hundred thousand "stickers," bearing the seal of the congress and the date on which it will convene, have been sent to dealers in dental and pharmaceutical preparations throughout the world, all of whom have expressed a willingness to attach them to every package and letter sent to their customers between now and August 30, 1915. Demands are already being made for more stickers, and probably one hundred thousand more will be distributed. The congress will in this way be brought to the attention of every dentist in the world, not once, but many times, and no one will be allowed to forget the date on which he should be in San Francisco to participate in what promises to be the world's greatest dental congress.

Work is progressing rapidly on the auditorium in which the congress will meet, and it will undoubtedly be housed in one of the largest and most complete buildings ever erected for such a purpose.

The congress will be in keeping with the exposition of which it forms a part, and every effort will be made to provide for the comfort and entertainment of every member. That work on the buildings for the Exposition is advancing rapidly may be noted from the fact that the Machinery hall is now over eighty-five per cent. finished. This building is 968 feet long and 368 feet wide; over 7,500,000 feet of lumber has been used in its construction, and it is the largest frame building in the world.

Arthur M. Flood, *Sec'y*,
San Francisco, Cal.

INTERNATIONAL DENTAL CONGRESS.

It has been thought advisable to arrange so that those who wish to attend the International Dental Congress, in London, next summer, may go on the same steamer, if they wish.

The plan is to arrange to sail on a steamer leaving New York immediately after the closing of the National Dental meeting, which will be held in Rochester, N. Y., from July 7th to 10th.

Those who wish to join the party sailing at that time will please notify me, at 560 Fifth ave., New York City, at as early a date as possible, in order that the steamship company may know how many to provide for.

Herbert L. Wheeler,
Transportation Committee, N. D. A.

OHIO STATE DENTAL SOCIETY.

The forty-eighth annual meeting of the Ohio State Dental Society will be held in Memorial Hall, Toledo, December 2, 3, and 4, 1913. The program of papers and clinics carries the names of men of worldwide reputation. At a "Health and Science" conference on Wednesday evening we expect the governor of the state, Hon. James M. Cox; the presidents of the National Dental Association and of the American Medical Association; Dr. Kirk, editor of the Cosmos; Dr.

Simon Flexner of Rockefeller Institute, and Dr. McCampbell, secretary of the State Board of Health.

Make hotel reservations early and arrange to attend the best and biggest meeting this society ever held.

F. R. Chapman, *Sec'y.*

MINNEAPOLIS DISTRICT DENTAL SOCIETY.

The Minneapolis District Dental Society will hold its annual meeting in the Masonic Temple, Minneapolis, Minn., January 16 and 17, 1914. From the data now at hand, this meeting promises to be a gathering of many of the best men in the country.

A. A. Zeirold, *Sec'y,*
902 Donaldson Bldg., Minneapolis, Minn.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

The regular meeting of the Academy of Stomatology will be held Tuesday, December 16, 1913, at the College of Physicians, Twenty-second street above Chestnut street, Philadelphia, Pa., at 8 p.m. Mr. Wm. W. Atkinson will read a paper entitled "The Vital Aspect of the Amalgam Alloy Question, and Some Practical Suggestions."

Norman L. Jameson, *Sec'y,*
1429 Spruce st., Philadelphia.

INSTITUTE OF DENTAL PEDAGOGICS.

The next annual meeting of the Institute of Dental Pedagogics will be held in Buffalo, N. Y., January 27, 28, and 29, 1914. The Executive Committee is planning to present an exceptionally interesting program, which no dental teacher can afford to miss.

J. F. Biddle, *Sec'y,*
Pittsburgh, Pa.

MARQUETTE DENTAL ALUMNI ASSOCIATION.

The Marquette Dental Alumni Association will hold its eighth annual clinic, and dealers' and manufacturers' exhibit, at the auditorium in Milwaukee, on January 22 and 23, 1914.

E. A. Flancher, *Sec'y,*
Milwaukee, Wis.

NATIONAL DENTAL ASSOCIATION.

Meeting of 1914—Date Advanced.

At the urgent request of the Local Committee of Arrangements at Rochester, the Trustees of the National Dental Association have advanced the date of the next meeting one week; therefore the eighteenth annual session will be held in Rochester, N. Y., July 7, 8, 9, 10, instead of July 14, 15, 16, 17, 1914, as originally selected. The officers, the local committee, and all other committees are going to put forth every effort to make this meeting, which is the first under the reorganization, the best in the history of the association, and we feel confident that the increased membership and interest in our association will prove a decided advantage in many ways.

Homer C. Brown, *President,*
Columbus, Ohio.
Otto U. King, *Gen. Sec'y,*
Huntington, Ind.

KINGS COUNTY (N. Y.) DENTAL SOCIETY.

School Oral Hygiene Work.

The first meeting of the Kings County Dental Society for the year 1913–14 was held at the Brooklyn Masonic Temple on Thursday evening, October 9, 1913.

The chairman, Dr. Simon Shapiro, in his inaugural address reviewed the various activities of the society during last year, showing its progress, and then spoke of the bright prospect for the coming year. He laid particular stress on the excellent work accomplished by the Oral Hygiene Committee, it having succeeded in establishing a dental clinic in school No. 109 in the Brownsville section of Brooklyn, where ten dentists of that section are giving dental services gratis to the poor children of the school. The outfit and supplies were obtained by voluntary contributions, with the hearty co-operation of the dental supply depots. Similar clinics for other sections of Brooklyn are being contemplated by the society for the near future.

The essayist was Dr. Alfred Russell Starr, professor of operative dentistry in the New York College of Dentistry, who presented an instructive paper on the preparation of cavities, more particularly those for gold inlays.

The paper was heard with close attention by his audience. Dr. F. T. Van Woert discussed the paper, followed with remarks by Drs. Prensky, Nevin, Robbins, and Herman.

The officers are as follows: Simon Shapiro, president; L. M. Robbins, vice-president; S. H. Filler, secretary; Benj. Shapiro, treasurer; A. Sternhartz, librarian. Executive Committee—M. William, chairman; Max Jaffe, M. Nevin, H. C. Offenbach, and J. Herman. Oral Hygiene and Infirmary Committee —J. F. Lief, chairman; Julius Pensak, secretary. Membership Committee—A. Friedenberg, chairman. Law Committee—L. M. Robbins, chairman. Committee on Ethics—A. Ritt, chairman.

FLORIDA STATE DENTAL SOCIETY.

At the thirteenth annual meeting of the Florida State Dental Society, Atlantic Beach, the officers elected for the ensuing year were as follows: J. W. Darsey, president, Palatka; G. B. Tison, first vice-president, Gainesville; W. E. Van Brunt, second vice-president, Tallahassee; A. M. Jackson, recording secretary, Lakeland; Alice P. Butler, corresponding secretary, Gainesville; C. L. Nance, treasurer, Tampa.

Alice P. Butler, *Cor. Sec'y.*

PENNSYLVANIA BOARD OF EXAMINERS.

The next regular examination of the Pennsylvania Board of Dental Examiners will be held in Philadelphia and Pittsburgh on Wednesday, Thursday, Friday, and Saturday, December 10, 11, 12, and 13, 1913. Application papers can be secured from the Department of Public Instruction, Harrisburg.

For further information, address

Alexander H. Reynolds, *Sec'y,*
4630 Chester ave., Philadelphia, Pa.

NEW JERSEY BOARD OF EXAMINERS.

The New Jersey State Board of Dental Examiners will hold their regular annual meeting and examination in the Assembly chamber of the State-house, Trenton, N. J., on December 1, 2, and 3, 1913. Applications must be filed at least ten days prior to date set for examination.

After January 1, 1914, all applicants for a license to practice dentistry in New Jersey—"Shall present to said board a certificate from the superintendent of public instruction showing that before entering a dental college, he or she has obtained an academic education consisting of a four years' course of study in an approved public or private high school, or the equivalent thereof."

Also, after January 1, 1914, a bridge, consisting of three or more teeth exclusive of abutments, and one Richmond crown, will be required as a practical test in prosthetic dentistry, in place of a full set of teeth soldered upon a gold or coin-silver plate hitherto required.

For further particulars, apply to

Alphonso Irwin, *Sec'y,*
425 Cooper st., Camden, N. J.

TEXAS BOARD OF EXAMINERS.

The next regular meeting of the board for examination of applicants for certificates entitling them to practice dentistry in Texas will be held in San Antonio, Texas, beginning December 15, 1913, at 9.00 A.M. The meeting will be held in the Chamber of Commerce hall. The fee of $25.00 should be in the hands of the secretary by December 10th. For official application blanks and further information address

C. M. McCauley, *Sec'y,* Abilene, Texas.

CALIFORNIA BOARD OF EXAMINERS.

The next meeting of the Board of Dental Examiners of California for the purpose of examining applicants for a license to practice dentistry will be held in San Francisco at the College of Physicians and Surgeons, beginning on December 3, 1913, at 10 A.M. All applications must be filed with the board on the morning of December 3d. Each application must be accompanied by a fee of twenty-five dollars, and the necessary credentials—diplomas or licenses from other states —together with a recent unmounted photograph of the applicant.

For further particulars, address

C. A. Herrick, *Sec'y,*
133 Geary st., San Francisco, Cal.

IOWA BOARD OF EXAMINERS.

The next meeting of the Iowa State Board of Dental Examiners for the examination of candidates will be held at Iowa City, Iowa, commencing at 9 A.M., December 1, 1913.

J. A. West, *Sec'y*,
417 Utica Bldg., Des Moines, Iowa.

IDAHO BOARD OF EXAMINERS.

The Idaho State Board of Dental Examiners will meet in Boise, Monday, January 5, 1914, at 9 A.M., in the State Capitol building.

Albert A. Jessup, *Sec'y.*

SOUTH DAKOTA BOARD OF EXAMINERS.

The next regular semi-annual meeting of the South Dakota State Board of Dental Examiners will be held at Sioux Falls, S. D., on Tuesday, January 13, 1914, at 1.30 P.M. Applications for examination should be made between the dates of January 1st and 10th.

Aris L. Revell, *Sec'y*, Lead, S. D.

DISTRICT OF COLUMBIA BOARD OF EXAMINERS.

The next examination of applicants for license to practice dentistry in the District of Columbia will be held at the George Washington University, January 5, 6, 7, and 8, 1914. Applications should be in the hands of the secretary two weeks before the date of the examination. Fee, $10.00.

Starr Parsons, M.D., D.D.S., *Sec'y*,
1309 L st., N.W., Washington, D. C.

WISCONSIN BOARD OF EXAMINERS.

The Wisconsin State Board of Dental Examiners will convene in Milwaukee, at the Hotel Maryland, December 15, 1913, at 10 A.M., for examination of applicants to practice dentistry in Wisconsin. High-school diploma, application, and $25.00 fee, to be filed with the secretary five days prior to the above date. Dental diplomas to be presented in advance of the examination.

F. A. Tate, *Pres't*,
W. T. Hardy, *Sec'y*,
422 Jefferson st., Milwaukee.
