RATIONALE OF THE USE OF BACTERIAL VACCINES IN PYORRHEA ALVEOLARIS.

By A. PARKER HITCHENS, M.D., Glenolden, Pa.

(Read before the Pennsylvania State Dental Society, at its annual meeting, Philadelphia, Pa., June 30, 1914.)

SPECULATION as to the reasons why we succumb to certain diseases, how we throw them off and are thereafter no longer susceptible to them, is as old as history. The scientific study of these questions, however, dates only from the discovery of bacteria and of their relation to infectious disease. Out of these studies have developed methods by which the body may be assisted either to prevent disease-producing germs from gaining a foothold, or to eliminate them after they have become established.

It is, therefore, not surprising that dentists, confronted with the difficult problem of pyorrhea alveolaris, have early looked to these methods for assistance. The results, moreover, have been so encouraging that before long bacterial vaccines will be an indispensable adjunct in the treatment of this infection.

In discussing this subject, it will be interesting to review briefly the preparation of the vaccine and its administration, before considering the theories which underlie its use.

COLLECTION OF THE SPECIMEN.

For the preparation of an autogenous vaccine, the specimen must be collected in such a way as to exclude all extraneous bacteria. For this purpose Dr. Head has invented a tiny spear-shaped platinum spoon fixed in an adjustable holder. After cleansing the mouth, the gum margin and the tooth are very lightly seared with a red-hot metal instrument of suitable shape and size. The spear is then heated to redness and plunged directly through this sterilized area. After being allowed to remain for an instant, it is drawn straight out without touching anything. A properly labeled tube of suitable culture medium is in readiness, and, after withdrawing the cotton stopper with a twisting movement to remove adherent filaments, the

contents of the spoon are carefully transferred to the surface of the medium. The small quantity remaining in the spoon is spread out in a thin layer upon a microscope slide. This is allowed to dry in the air, and, together with the tube, is sent to the laboratory.

At the laboratory the slide is stained by Gram's method and studied under the microscope to determine as nearly as possible the varieties of bacteria present. An ordinary nutrient agar medium containing red blood corpuscles offers a favorable substratum for all the more common bacteria which have so far been encountered in pyorrhea alveolaris. An exception is the fusiform bacillus of Vincent, which requires such complex methods that no one has yet made the attempt to use it for a vaccine.

The best method for obtaining pure cultures of the bacteria is as follows:

Three Petri dishes containing blood agar are held in readiness. With a platinum loop, as much as possible of the material is transferred from the original culture tube into one of these dishes. If it is very dry, it may be moistened with a drop of sterile bouillon; then, with a sterile glass rod bent in the shape of the "profile" of a shovel, the material is spread over the surface of the medium. Without reinoculation, the glass rod is rubbed thoroughly over the surface of the other two Petri dishes, and the three are placed in the incubator for twenty-four hours. By the time the rod reaches the third dish, relatively few bacteria are left upon it, and each of these is so separated that, when it develops, its progeny forms an isolated spot upon the medium, which is known as a *colony*. Since it consists of but one species, it is called a *pure* culture.

All plates should be studied with a lens, by both reflected and transmitted light. The recognition and identification of these tiny colonies makes the task of isolation extremely difficult. As each type of colony is recognized, the tip of a sterile platinum wire is touched to it and then rubbed over the surface of a tube containing blood agar. After twenty-four hours' growth, these cultures are stained and examined for morphology and freedom from other bacteria. For obvious reasons, it is absolutely necessary to omit all sporogenic bacteria from the vaccine.

ANAEROBIC CULTURES.

Anaerobic cultures should also be made, since the pyorrhea pocket offers ideal conditions for the development of anaerobes. The plates may be prepared exactly as for aerobic cultures and placed in sealed jars—Novy jars, for instance —in which the oxygen is replaced by hydrogen. The addition of alkaline pyrogallic acid solution to absorb the remaining traces of oxygen is advisable.

The study of plates and the fixing of colonies is carried out in the same way as for aerobic cultures, with the addition that the subcultures are grown in anaerobe jars.

PREPARATION OF THE VACCINE.

Everything now being ready to proceed with the preparation of the vaccine, the question arises as to which of the isolated bacteria are responsible for the infection. I am in thorough agreement with Dr. C. P. Brown when he makes the following statement:

> The question of selecting the proper bacteria from those isolated in a given case is one susceptible, at this stage in our knowledge, of endless discussion. A definite and final decision cannot now be rendered. Some have started out with the preconceived idea that the cocci only are pathogenic. They have discarded the bacilli present without further consideration. Goadby and others have attempted to pick out the bacteria responsible for the infection by a determination of the opsonic indices to the germs isolated. More recently the complement fixation test has been suggested for the same purpose. Such investigations may be of great scientific interest, but I must question their practical value. Besides increasing out of all proportion the labor required for the preparation of the vaccine, I believe the chances for error both in technique and in interpreting the result obtained are so great that one may not safely eliminate any organism present in the specimen. We believe it is better to make a

vaccine containing all the different types found, discarding only those obviously non-pathogenic or sporogenic bacteria.

A small quantity of sterile physiological saline solution (0.85 per cent.) is added to at least one tube of each type of micro-organism. After the growth is scraped from the surface of the medium with a platinum loop and suspended in the salt solution, the suspension is transferred to a sterile test tube, which is sealed off in the blowpipe flame. It is shaken thoroughly to break up clumps of bacteria, and a small quantity is removed for counting; the tube is re-sealed and immersed in a water-bath at a temperature not exceeding 60° C. for at least one-half hour. After the bacteria have been killed, the suspension is diluted with sterile physiological saline solution so that the final product will contain a certain number of bacteria per cc.

Many methods of counting have been suggested, but the method of Wright retains its popularity. A capillary pipet is furnished with a rubber teat, and marked with a blue pencil about one-half inch from the end. The finger of the operator is pricked just back of the nail, and as the blood runs out it is drawn into the capillary tube exactly to the mark. Removing the capillary end, the column of blood is allowed to travel up the tube for a short distance; then the tube is dipped into the bacterial suspension. This in turn is drawn into the tube exactly to the mark. By pressure on the rubber teat, the two tiny columns are forced out upon a clean microscope slide; they are thoroughly mixed by alternately drawing them up into the tube and forcing them out. A drop of the mixture is then placed upon another clean slide and spread out in a thin layer by drawing the edge of another slide over it. The slide is fixed with a saturated solution of mercury bichlorid and stained with methylene blue and eosin, or one of the other blood stains —Wright, Leishman, Giemsa. Under the microscope the red corpuscles and bacteria in several fields are separately counted. Since there are equal parts of bacterial suspension and blood, and since the normal number of corpuscles per cmm. of blood is 5,000,000, it is a simple problem in proportion to figure out the number of bacteria per cc. in the suspension.

In diluting the bacterial suspension, it is convenient to adjust the numbers so that each cc. of the finished product will contain 300,000,000 staphylococci, if these organisms are present, and 50,000,000 each of the other bacteria found. The vaccine is preserved by the addition of 0.25 per cent. tricresol.

After the preparation of the vaccine, we must be certain by tests that, first, it is sterile, and second, that it contains no products harmful to the animal body.

The first test is made by placing a few drops in each of one or more fermentation tubes containing freshly sterilized 2 per cent. dextrose bouillon. After these tubes are incubated seventy-two hours, they are examined for growth; if no growth is found, the vaccine may be considered sterile, although the tubes should not be discarded for at least ten days.

The second test consists of injecting subcutaneously into a guinea-pig from two to five cc. of the vaccine. If the guinea-pig is living and well at the end of seven days, the vaccine may be released for use, although the animal should be kept under observation up to the fourteenth day.

I am well aware that many laboratories turn out autogenous vaccines within from forty-eight to seventy-two hours. It is impossible that products prepared and delivered in this length of time can have been properly tested. A curtailing of the check-test period is only justified in extremely urgent cases.

When treatment with the vaccine is commenced, it is suggested that the first doses be small—1/5 to 1/4 cc., and given at intervals of from five to seven days, and that the doses be increased or not according to the indications. The effects of pyorrhea and of its treatment with vaccines are far-reaching and concern the patient's entire economy. For this reason it is felt that vaccine treatment should

be instituted only in collaboration with the patient's physician.

The so-called "short method" of preparing autogenous vaccines must be condemned without qualification. The material collected is often spread carelessly upon the surface of a culture medium, frequently plain agar; it is incubated over night and the growth suspended in saline solution, possibly counted and diluted according to the count, or merely to a doubtful turbidity index. It is heated to about 60° C., perhaps in a tube which has not been sealed and completely immersed, and receives tricresol either before or after the heating. Sometimes check tests are made for sterility, more often they are not. In this connection it must be understood that substances intended for subcutaneous injection must be prepared with infinitely more care than those intended for oral administration.

THEORETICAL CONSIDERATIONS.

For an intelligent comprehension of the scientific basis underlying the use of bacterial vaccines, it will be necessary to review briefly the development of our present ideas concerning immunity.

Metchnikoff, in his study of the white blood corpuscles or leucocytes, observed that they had the power of ingesting and destroying bacteria and other foreign bodies. Ehrlich at the same time, in his investigation of the blood serum, found that in the course of infection it took on new chemical properties, which were specific for the bacteria concerned; these newly formed substances he called antibodies, because they were antagonistic to the bacteria.

Further light was thrown on the subject by Sir Almroth Wright, who noted that the leucocytes ingest and destroy bacteria only after the latter have been acted upon by certain antibodies—which he called opsonins—in the blood serum. Wright thus brought into harmony the French and German schools of immunity by showing that both the biological and chemical elements of the blood are necessary for the removal of invading bacteria. The nomenclature, however, of all these theories is so intricate that it can be thoroughly understood only by those who have made a lifelong study of the subject, whereas all the principles essential for a clear understanding of immunity can be found in the more simple language of Prof. V. C. Vaughan.

Vaughan had for several years been studying the chemistry of the bacterial cell, when Rosenau and Anderson called attention to a phenomenon which, at the time, seemed to upset our ideas of immunity. Richet, a French observer, had already noted the same phenomenon, and believing that he had found a condition which was the opposite of prophylaxis, he called it *anaphylaxis*. In his investigations of certain poisons derived from sea-urchins, he found that an injection of this poison into a dog, instead of rendering the animal immune to a second dose, actually made him more susceptible.

Rosenau and Anderson observed that guinea-pigs injected a second time with horse serum after a lapse of at least fourteen days were killed by this ordinarily harmless albuminous fluid. The pioneer investigations of these American scientists have laid the foundations of our present knowledge of anaphylaxis.

Anaphylaxis concerns the effect of proteins or albuminous substances upon animals; it concerns all proteins, whether they are poisonous in themselves or not; for instance, egg-white and normal horse serum act precisely as the proteins of the plague bacillus or of the typhoid bacillus. And, furthermore, the proteins of dead bacteria act practically in the same way as the proteins of living bacteria. It must be remembered, however, that anaphylactic symptoms can be produced only by proteins foreign to the animal: that is, anaphylaxis cannot occur in a guinea-pig from the repeated injection of guinea-pig serum, nor can the symptoms be produced in a horse by the injection of horse serum.

If we inject a guinea-pig parenterally —that is, by any route except by the gastro-intestinal canal—it does not appear to suffer the slightest inconvenience.

If, however, we inject this animal, two or more weeks later, with the same protein, it will die within one or two minutes and with very definite symptoms accompanying death. This is one manifestation of anaphylaxis.

For an explanation of this phenomenon, it was necessary to go back to the above-mentioned work of Prof. Victor C. Vaughan upon the chemistry of the protein molecule. Vaughan had shown that a protein, treated chemically according to his method, is split into two parts—the one poisonous, the other non-poisonous. The poisonous part obtained from all proteins is the same; whether it results from the splitting of egg-white or from the splitting of typhoid bacilli, the symptoms leading to death in the guinea-pig are identical. The poisonous part, then, is a poison and has no other function or effect; one dose has no bearing upon the effect of a subsequent dose, no hypersusceptibility is produced, and no tolerance, even by repeated administration.

The non-poisonous part, on the other hand, is specific in its action. The non-poisonous part of typhoid bacillus protein will immunize an animal against typhoid infection, but not against infection with colon bacilli; the non-poisonous part of horse serum will sensitize a guinea-pig to horse serum, but not to goat or sheep serum.

Vaughan has promulgated the theory that a similar splitting action occurs in the tissues, and that instead of being the opposite of immunity, anaphylaxis is merely one of its manifestations, the only difference being the amount of the poisonous part liberated within a given length of time.

When foreign proteins are injected into the tissues of an animal, the body cells at once set to work to remove this protein. They prepare a ferment capable of splitting the protein molecule, which, possibly because of its size, is not diffusible, into smaller fractions able to pass into the circulatory system and be thence eliminated. These fractions of protein molecule, similar to those obtained by Vaughan chemically, are: a poisonous part which, after the first injection, is liberated slowly and is therefore harmless in its effect, and a non-poisonous specific part which stimulates the body cells to produce a specific, ferment-like substance. About two weeks after injection the protein has been entirely removed from the tissues, the poisonous part has been eliminated so gradually that no symptoms have resulted, and the non-poisonous part has stimulated the tissues to generate a large amount of specific protein-splitting ferment.

The guinea-pig, then, at the end of two weeks after the first injection of, let us say, horse serum, contains in his tissues no trace of horse serum; but he does have within his body a large quantity of protein-splitting, ferment which may remain in the tissues for a long time; and, even if it disappears, the power to generate this ferment upon demand may remain permanently. If we now inject into this guinea-pig a second dose of horse serum, the proteins contained therein are at once attacked by the specific ferment; digestion occurs almost immediately, resulting in the liberation of a large quantity of the poisonous part of the protein molecule; the animal is overwhelmed by it, and dies usually in less than five minutes. A dose sufficiently large to cause death depends upon the method of injection; if injected into the circulation or into the brain, 1/20 cc. is sufficient; if injected subcutaneously, however, at least 5 cc. is usually necessary.

As to the bearing of this phenomenon upon infectious disease, Vaughan has used typhoid fever as a typical illustration. Infection results from the entrance of a few typhoid bacilli into the tissues under circumstances which permit their growth and multiplication. There is normally present in the body a small amount of a non-specific protein-splitting ferment which attacks the typhoid bacilli, liberating the non-poisonous part, which in turn begins to stimulate the tissues to the production of a specific anti-typhoid ferment. We know that in guinea-pigs it takes from eight to fourteen days

to produce enough ferment to cause serious symptoms of intoxication upon the injection of a second dose of the protein. This period corresponds exactly to the incubation period in typhoid fever. It is during this time that the typhoid protein-splitting ferment is produced in increasing quantities, while the typhoid bacilli are rapidly growing in numbers. The ferment sets free the poisonous part in gradually increasing quantities with the final appearance and progressive increase of fever and the other symptoms of the disease. This process continues up to the point where the number of typhoid bacilli destroyed equals the number reproduced in the lesion. This balance is maintained for a time, until the number of bacilli destroyed exceeds those reproduced.

A patient recovered from typhoid fever or a person who has been injected with typhoid vaccine has in his tissues a large amount of typhoid protein-splitting ferment, so that, when typhoid bacilli later gain entrance to his tissues, they are at once attacked and destroyed before they have a chance to develop. Obviously there is no intoxication because the amount of typhoid proteins is infinitesimal compared to the amount necessary to result in anaphylactic shock.

A demonstration of the presence of specific ferments in the blood as a result of foreign proteins in the tissues is afforded by the Abderhalden test. Abderhalden thought that if foreign proteins were removed from the tissues by a splitting of the protein molecule, and if the blood contained ferments with this power, their presence could be demonstrated by test-tube experiments.

The research was fruitful of positive results, and an application of it is now recognized as being of great value in the diagnosis of pregnancy, even during the early weeks.

It is now easy to understand the action of bacterial vaccine in pyorrhea alveolaris. At the seat of disease are certain bacteria which are merely living proteins. In order to remove them. we inject identical proteins into healthy tissues. The specific ferment content of the blood is thereby increased, the bacteria are dissolved, and thus removed. It is therefore obvious that the requisites to success in vaccine therapy are, first, that the vaccine injected must contain bacterial proteins identical in kind with those causing the infection; second, that the ferment produced locally must come in contact with the infecting bacteria. For one with proper training, it is not difficult to determine the kind of bacteria causing an infection, nor is it difficult to either obtain a stock vaccine representing these bacteria or to prepare an autogenous vaccine identical with them; and it is a very simple matter to inject these bacterial suspensions beneath the skin of the patient. If the patient is not in the last stages of disease, there is not one chance in many thousands that his tissues will fail to produce the proper antibodies or ferments.

Unfortunately, the mere presence of specific ferments in the tissues is not tantamount to destruction of bacteria at the focus of infection. Bringing these ferments in contact with the infecting bacteria is the most difficult part of the treatment. Bacteria in pyorrhea can thrive locally, because serumal and salivary calculi and other foreign bodies present weaken the resistance of the tissues, and also because a barrier, resulting from the inflammation, prevents the antibodies from coming in contact with the bacteria. If this were not the case there would be no infection, because the blood contains normally antibodies which are able to destroy bacteria. In proof of this, it is sufficient to call attention to the fact that primary blood infection almost never occurs. With bacterial vaccines, we merely increase the concentration of antibacterial ferments in the blood, so that a greater amount will reach the bacteria in question.

It may be easier to understand the effect of pyorrhea alveolaris upon the body generally if we think of the disease from the standpoint of physical chemistry. Dialysis plays an important part in this connection. A dialyzing membrane consists either of animal tissue or of paper treated in such a way that its density corresponds to that of an animal membrane. Crystalloids—that is, sub-

stances which will osmose—will pass through the membrane, because their molecules are very small and separated from one another. The substances which do *not* osmose are known as *colloids;* these include the proteins. In the digestive process, proteins pass through several stages, finally becoming peptones and then amino-acids. The protein molecules, which are relatively very large, are split up until, in the peptone stage, they have become small enough to pass through the dialyzer.

Turning now to the pyorrhea pocket, we see that it is very similar to a dialyzer. It is lined with inflammatory tissue which is sometimes called a pyogenic membrane. This membrane is composed chiefly of granulation tissue, and is but poorly supplied with bloodvessels. The bacteria are thus able to protect themselves against the antibacterial powers of the blood. The small amount of antibacterial ferment which may penetrate to them is not sufficient to eradicate the bacteria. It merely helps to destroy those with which it comes in contact, splitting them into the poisonous and non-poisonous parts. The presence of these ferments is not entirely necessary, since bacteria have the power of digesting themselves under certain conditions. This is called autolysis. The poisonous part, consisting of very small molecules, readily penetrates the membrane and passes into the circulation, causing the constitutional ailments so often accompanying pyorrhea. The non-poisonous part, however, is composed of molecules so large that it cannot penetrate the membrane until it is further digested and broken up into inactive substances, possibly amino-acids.

This theory answers the objection formerly raised against the use of bacterial vaccines. It was thought that, since bacteria are already present in the tissues, by putting in more, even though dead ones, one merely adds fuel to the fire. But we see, according to the above hypothesis, that the conditions surrounding bacteria injected into healthy tissues are entirely different. Any local reaction, resulting from liberation of the poisonous part, soon disappears, because the poisonous part is quickly absorbed, and the non-poisonous part is left to exercise its function of stimulating the tissues to form specific ferments. This explains, furthermore, the benefit of local massage by careful brushing of the teeth. The pressure possibly squeezes the non-poisonous part through the pyogenic membrane so that it can pass into normal tissues and there exert its function. It seems scarcely necessary to add that foreign bodies, such as calculi and tartar, must be removed from the root surfaces; their mechanical irritation results in the production of inflammatory tissue, which offers far more favorable conditions than healthy tissue for the growth of bacteria.

SUMMARY.

(1) The treatment of pyorrhea alveolaris with bacterial vaccines depends upon the use of suspensions representing the bacteria responsible for the infection.

(2) In preparing the vaccine, one should not discard any germ found in a carefully collected specimen.

(3) Bacterial suspensions injected beneath the healthy skin stimulate the tissues to the formation of specific ferments.

(4) The ferments thus formed are efficient only when they come into direct contact with the infecting bacteria.

(5) In pyorrhea alveolaris, this is accomplished by proper local treatment.

(6) Proper brushing of the teeth and gums acts as a massage, bringing the blood to the infective elements and squeezing out into the tissues the non-poisonous part of the bacterial protein molecules.

(7) The disease tends to become chronic, and poisons the patient, because the small molecules of the poisonous part diffuse readily, while the larger molecules of the non-poisonous part do not dialyze into tissues where they can stimulate the production of antibacterial ferments.

(8) It is clear, then, that the use of bacterial vaccines as an adjuvant in the treatment of pyorrhea alveolaris is rational, but that it can accomplish little if unassisted by local means.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE DENTIST'S EYES.

By THOMAS G. ATKINSON, M.D., L.R.C.P.Lond., Chicago, Ill.

DID you ever engage in the old schoolboy trick of seeing who could hold out his arm the longest? Even if you won the contest, you did not make much of a time record; a few minutes, at the most, was all your muscles would stand of that constant, unopposed contraction.

Yet that is precisely the kind of thing to which you are subjecting your eye muscles all the time—especially the ciliary muscle, that little circular muscle which surrounds the crystalline lens in the eye and by its contraction changes the curvature of the lens, enabling you to see near objects clearly, and which is therefore called the muscle of accommodation.

There is no class of men who subject their eyes to greater strain than dentists. The nature and necessities of their work impose upon them three conditions of vision:

(1) They are obliged to work all the time at near point.

(2) They must have a detailed view of the small field they work on.

(3) They are forced to maintain steady vision, at one range, for long uninterrupted periods.

These three conditions involve a very trying strain on both the muscles and the retina of the eye. Dentists stand, for hours at a stretch, with their vision fixed steadily on a very small field, close to their eyes—almost at the end of their noses—doing the finest kind of mechanical work on the minute structures of the teeth. This means that—

(1) The external muscles of the eye, which direct it toward the object, are in constant, steady contraction.

(2) The ciliary muscle, which gives correct focus to the image, is in even more concentrated and persistent contraction.

(3) The retina, which receives the light upon its outspread nerve-endings, is under continued stimulation with a monotonous, nagging detail.

The wonder is that the eye stands for it at all. The arm would not, as we have seen. Fortunately, the eye muscles are better trained than those of the arm, and will stand a lot more steady effort. Indeed, a pair of quite normal eyes, in a healthy individual, can hardly be overworked as long as they are used properly.

But suppose the eyes are not normal. I do not mean diseased, but suppose their refraction is not normal. Then the constant muscular and nervous strain becomes a very serious matter, just as is a long-distance footrace to a man with a sprained leg. Then the eye muscle is overworked, and—what is perhaps worse—the adaptation between the various muscles and nerves, which normally work in perfect accord, is disturbed. The person is obliged to put additional power into this muscle or not quite so much into that, and so all are working under some kind of handicap.

Even so, the eyes will still manage to make good when they are not used much for close work. And even when they are so used they will often overcome the handicap for quite a long time; then they usually give out quite suddenly and utterly. Under the trying use to which dentists subject them, if their refraction is not normal, they *always* give out sooner or later.

It is of the utmost importance that the dentist satisfy himself that his refraction is normal; and if it be not, then it is imperative that he have his refraction properly corrected. Dentists

are constantly advising people to make sure that their teeth are sound, especially if they live under conditions which are trying to the teeth. By the same token, dentists ought to make certain that their refraction is normal, in view of the trying use to which they are subjecting their eyes, and considering the importance of good vision as a part of their stock-in-trade.

There are three common errors of refraction, each of which gives its own peculiar train of troubles.

HYPEROPIA.

This is the commonest error. The hyperopic eye is too short for its refractive power, so that light rays are focused farther back than normal. This means that the hyperope is under two handicaps:

(*a*) He has to contract his ciliary muscle more than normally to see near objects clearly, and this gradually induces permanent hypertrophy and spasm.

(*b*) He does *not* have to converge any more than the normal person, so that the adaptation between convergence and accommodation is upset.

The result is a congestion of the eye and a nervous disturbance. The eyes become inflamed and bloodshot, the patient suffers with brow headaches and nervous irritation, and finally the overworked eye muscles give out and vision is blurred.

MYOPIA.

The myopic eye is too long for its refractive power, so that the image is focused too far forward. This makes less than normal accommodation necessary for near vision. It might seem, at first blush, that myopia should not be a serious hindrance to near vision, but rather a help to it. And, in fact, it is not of itself as great a handicap to the dentist in his work as hyperopia. Its chief disadvantage lies in distant vision.

We must remember, however, that myopia involves just the same break in the relation between convergence and accommodation as too much muscular effort; and, furthermore, there is always a tendency on the part of the myopic eye to grow more and more myopic, and, in fact, to become diseased, if it is not corrected.

Myopia produces no headaches or congestion, as a rule, but causes nervous disturbances, and ought to be corrected.

It should be observed that both hyperopia and myopia may be overcome in near work for a long time, and thus remain unnoticed. The mere fact that one can see his work is no surety that these errors do not exist. Where they do exist, and are being overcome, it is at a serious cost of nerve and muscle, which will sooner or later have to be reckoned with.

ASTIGMATISM.

The astigmatic eye is the most troublesome of all, especially when it is also hyperopic or myopic (compound astigmatism). It is, as its name implies, an eye the curvature of which is not the same in all meridians, so that rays cannot be focused at a point. This condition really has nothing to do with the eye muscles or their function, but lies in the shape of the cornea. However, it gives a very blurred image, which the ciliary and external muscles (especially the latter) are continually striving to remedy by twisting the axes of the eye. Hence the principal symptoms of this disturbance, outside of poor vision and nervousness, are a headache around the temples and back of the head, and dizziness.

Astigmatism affects far and near vision alike, is the least able to be compensated by the eye, and is usually associated with other errors. Happily, it is susceptible of the most accurate correction of all the errors of refraction.

I repeat, the dentist, in view of the steady, exacting strain which his work imposes on the eye, and the imperative part played by good vision in that work, cannot afford to take chances on the handicap of an error of refraction. It ought to be a routine part of his preparation for the practice of his profes-

sion to undergo a thorough and competent examination as to his eye refraction; and if any error exists, however slight, it should be carefully corrected and his eyes rendered normal before he sets out upon his life-work.

CARE OF THE EYES.

Not only does the dentist recommend his patients to undergo periodic examinations of their teeth to make sure that they are sound, but he enjoins upon them a constant care of the teeth and gums to keep them in good condition. So, also, when the eyes are normal, or after they have been rendered normal by proper lens correction, there still remains the necessity of watchful care of the eyes under the trying exigencies of dental work. For even normal eyes will give out if they are abused, or subjected to hurtful conditions of usage. I therefore append a few brief, simple rules for the care and hygiene of the eyes, which I hope every dentist will keep in mind constantly and make a part of his daily habits:

The eyes must be protected from dust. When riding in an automobile, goggles should always be worn. In any case, it is a good plan to wash the eyes thoroughly every evening with copious flushings of warm boric acid or normal salt solution.

Exposure to sudden extremes of temperature and to high winds is to be avoided. When obliged to face sudden changes of temperature, the eyes should be closed for a few moments until the conjunctiva gradually becomes cooled or warmed, as the case may be.

Infection, to which the membrane of the eye is exceedingly sensitive, must be scrupulously guarded against. Everything which touches the eye—including the hand—must be perfectly clean and sterile.

The dentist should have his work on a level with his eyes, as much as possible, so as not to pore over it with head bent downward. Such a posture induces congestion of the eyeball. This applies especially to myopic persons, for by this posture myopia is often made progressive and malignant.

Work should be done in daylight whenever possible. When it is not possible, daylight should be reproduced as nearly as practicable with indirect, well-diffused artificial light.

Next to daylight, electric light is most desirable. It gives an almost white light; it burns with comparative steadiness, it yields the most light for the least bulk; its intensity is most easily regulated; it does not vitiate the air; and it does not affect the temperature to any appreciable extent.

Good illumination is imperative. The inadequate intensity of an image made upon the retina by insufficient light requires that the image be held there for a proportionately greater length of time, and thus musculature and the nervous system both suffer.

Too much light, however, is almost, if not quite, as bad as too little. Teasing of the nerve-ends of the retina quickly inflames and exhausts them, and retinitis or retinal neurasthenia ensues.

When working on glittering materials, such as crowns and plates, it is well to protect the retina by wearing slightly tinted glasses.

A strong light should not be faced. The dentist's work unfortunately obliges him to stand with the light falling more or less directly on his eyes. This is offset by wearing an eye-shade.

The eyes must be given frequent short rests by removing them from the work and relaxing their accommodation and convergence for a few moments by looking into the distance.

THE DUNFERMLINE SCHOOL DENTAL CLINIC OF THE CARNEGIE DUNFERMLINE TRUST,

From Its Foundation in September 1910 to March 1914.

By L. STORROW SHENNAN, D.D.S.Pa., L.D.S.R.C.S.Ed., Edinburgh, Scotland.

THE Dental Clinic was inaugurated in September 1910, and has been a great success from the first. Two apartments were fitted up in the large corridor of the Old Baths, but in the near future the clinic will have its quarters in a large new building which is also to house the Medical Clinic and the College of Hygiene and Physical Training, Dunfermline being now the center for such training in Scotland.

No expense was spared in fitting the surgery with the most modern appliances, so as to facilitate the work in every way. The second department was used as a waiting-room. At first the clinic was open for nine hours per week, but in April 1911 the time was increased to twelve hours per week, an arrangement which has continued up to the present time.

For some time one whole day of six hours was tried, and another half-day of three hours; but more work has been done under the later arrangement of four hours on three days per week, and the resulting exhaustion to the school dentist has not been so great. There is no doubt that the work is more exhausting by far than that of ordinary private practice.

At first two trained nurses (one for each half of the whole day) were assigned to the clinic; later, one trained nurse and a secretary; later still, one trained nurse and one female clinic assistant. The presence of the nurse gives the children confidence, as she gets to know them at the school medical inspection and the medical clinic. The female assistant also gives help in the medical clinic, so that she too gets to know the children.

At first the secretary (and now the nurse) made all appointments, entered operations, made arrangements for inspection at the various schools, and sent lists with the names of pupils expected each day to the headmasters and headmistresses. This method, however, involved so much clinical work that now attendance cards are given out, showing the name of child, school and class, home address, day and hour of visit, time of leaving school to keep appointment, and time of arriving at and of leaving the clinic. This has been found a sufficient link between the school and clinics for casual cases, as the children have to show these cards to their teachers. In the case of the treatment of children who have been examined in the respective infant departments, a full list of those whose parents have agreed to allow treatment is supplied to the headmistress, and the children are sent up in groups of six each half-hour or eight each hour for two hours each clinic morning—this being the time set aside as far as possible for these children. Sometimes the children are accompanied by their parents.

Systematic inspections are restricted to children of ages from five to ten in the primary departments, the older children in these classes being usually more backward mentally, hence their presence at a more advanced age.

Notes of treatment to be adopted were at first entered in British Dental Association charts, but now a card index system is used, which is much more convenient.

Notification circulars are sent to parents or guardians to intimate the results of the examinations, and they are requested to return them signed if treatment for their children is desired.

Specimens are here shown of the cards and notices which are employed in connection with the work.

There is no lack of material, and the children are extremely plucky. On an average most attendances are given by children of from six to nine years of age.

Many children—of ages ranging from four to fifteen years—come of their own

[*Notification Circular.*]

CARNEGIE DUNFERMLINE TRUST.

SCHOOL DENTAL CLINIC.

DEFECTIVE TEETH.

In the interests of a child's future health decayed teeth should be attended to at the earliest possible date by a properly qualified dentist.

The first double teeth of the second set begin to come between the ages of 5½-7 years. They cannot be replaced and ought to be kept through life. These teeth are extremely important, as the child must do nearly all its chewing with these until it reaches the age of 12 years. Decaying teeth of the first set are very likely to spread decay to and injure the second or permanent set.

The health and future prospects of the child may be seriously affected by delay; a sound set of teeth is one of the signs of physical fitness, and the whole nutrition of the body depends directly or indirectly on the condition of the teeth.

Decay of the teeth is in a great measure the result of the action of destructive microbes in the mouth, and the matter from them or from "gumboils" disorders the stomach and makes the breath foul.

Headaches, neuralgia and swollen glands are often caused by decaying teeth. Indigestion, "bloodlessness" (anæmia), blood-poisoning, and a host of other evils are caused by decaying teeth, and they form channels for the development of fevers, diphtheria, consumption, and other diseases.

Teeth should always be well brushed with a tooth-brush night and morning, with soap and water, or with some powdered chalk. School children may obtain a tooth-brush or a box of tooth powder at the Clinic for 1d.

To
The Parents or Guardians of
. . . . . .

This child's teeth have been found to need attention. You are strongly recommended to have the necessary treatment carried out at once; or, if you consent, the child will be treated by the School Dentist.

Please sign the printed form at the bottom of this sheet, and return to the Head Teacher.

I agree to have my child's teeth attended to by the School Dentist.

Signed . . . . . .

DUNFERMLINE, ... 191

Moreover, these forms are useful because they give the authority of the guardian to do what one thinks necessary. If an anesthetic is required, a special form of circular is sent out.

CARNEGIE DUNFERMLINE TRUST.

SCHOOL DENTAL CLINIC.

BATH STREET,

DUNFERMLINE, ... 191

Sir,

I have finished putting your ..... teeth in order by filling those savable, but to put the mouth in a satisfactory state there still remain some teeth or roots which require removal.

To prevent pain and shock to the child I propose to have gas administered for their removal. If you consent to this being done, kindly fill up and sign the attached form and return it to me as soon as possible, as special arrangements are necessary.

Defective teeth and painful gums mean incomplete mastication and consequent digestive troubles, which lead to serious complications later in life.

Yours faithfully,

.....

School Dentist.

NOTES.

accord. In these cases the same cards are used, but no notification is sent to the parents, and appointments are made as vacancies occur. About one and one-half hours of the clinic morning are devoted to these casual cases, who have either come of their own accord or have been sent by teachers or parents.

Tooth-brushes and powder are supplied at a small charge.

Session 1910-11.

In September 1910, as the appliances were not all sufficiently forward to admit of beginning work, I examined the primary department of two schools. Unfortunately, an analysis of these was not made suitable for comparison with those given for the later years. It was intended to treat these pupils systematically, but this intention could not be carried out, as so many children came voluntarily from all the schools.

Sufficient apparatus being in place in

October, 213 children, of the ages from 4 to 14, received treatment during the months of October, November, and December.

The attendance being still most encouraging, I undertook regulation work in addition.

During this time I had the assistance of a lady secretary. She proved of great value in making arrangements and keeping records of work done.

Work went on smoothly in January, February, and March, and between April and June I inspected the primary department of another school, comprising 282 pupils, 150 boys and 132 girls of ages 4 to 10. Here 271 were found to have defective teeth, as follows:

(January, February, March: Extractions mainly of deciduous teeth. April, May, June: Extractions include 3 permanent teeth.)

Session 1911-12.

August to December, 1911. In this period five Wednesdays were devoted to examination of the primary department of another school, comprising 252 children—115 boys; 137 girls.

Only 21, or 8 per cent., had sound teeth—9 boys and 12 girls.

The table (*A*) shows the number of defective teeth in these children at the different ages.

Six impressions were taken for regulation or to show necessity for artificial substitutes, all for girls of ages 10 to 13.

Eight permanent teeth were extracted.

Four special attendances were for extractions under a general anesthetic

(N_2O and O). I am of the opinion that the anticipation of this is more of an ordeal than ordinary extractions which are done at once and before the children can think long about what is going to happen.

January to June, 1912. In this period another school was examined, the results being shown in the table (*B*), the number being 124, *i.e.* 72 boys and 52 girls. Of these only 10 (8 boys and 2 girls) did not require treatment; 85 children received appointments, but only 58 availed themselves of the opportunity. This may have been due to the trouble caused by a strike—as the lists sent to the teachers required revision so often—more than to the parents.

(Out of a total of 1494 extractions, 65 only were permanent teeth.)

Session 1912-13.

During the last three months of 1912 I was absent through illness, but my brother, Alexander Shennan, M.A., L.D.S.Ed., took my place for the time.

The Commercial School infant department was examined—five days' time, of the children had lost their notices, and duplicate notices were made out.

The number examined was 300, *i.e.* 147 boys and 153 girls. Of these 22 had sound teeth, 10 boys and 12 girls.

A new departure was made this session

(Extractions included 38 permanent teeth.)

Session 1913-14 (to March).

In spite of drawbacks from changing of rooms and becoming accustomed to other conditions, and want of some conveniences, the amount of work done has been considerable.

The mouths of those children who were mentally defective were examined at the various schools, but these have to be carefully re-examined later on to obtain accurate measurements of the width and depth of palate, by means of a special instrument which has been constructed under my direction.

I also examined the children in the infant department of the St. Leonards school. Out of 225 on the roll, 212 were examined, 13 being absent.

Number of parents who agreed to treatment for their children, 157; objectors, 23. No replies from 18.

Of the 212 examined,

6 boys and 8 girls had sound teeth.
31 " " 40 " " 1 to 4 carious teeth.
39 " " 40 " " 5 " 7 " "
30 " " 18 " " over 7 " "

Attendances—Sept. 1913 to March 1914	835	1422
Fillings	314	500
Dressings	199	388
In former reports fillings and dressings were not kept separate.)		
Extractions	295	498
Including permanent teeth	8	10
Impressions taken	13	15
Regulations	6	18

Children examined in Board schools slightly dull or mentally defective, 100.

The clinic was closed from November

10th to 21st, and the opportunity was taken of examining the mouths of dull and mentally defective children; fifteen hours were devoted to this work.

In the case of one girl a porcelain inlay was inserted into a cavity and one boy was supplied with a vulcanite plate carrying two artificial teeth.

As some of my friends who have seen the above figures seem doubtful about their correctness, I give the following numbers detailed—fillings, dressings, and extractions for three days of four hours each. It will be noticed that only one permanent tooth has been removed, of the total number extracted during the three days:

1st day.	Boys.	Girls.	Total.
Attendance	22	26	48
Fillings	12	14	26
Dressings	1	5	6
Extractions	8	6	14

(Including 1 permanent tooth.)

2d day.	Boys.	Girls.	Total.
Attendance	22	25	47
Fillings	10	4	14
Dressings	3	6	9
Extractions	9	16	25

3d day.	Boys.	Girls.	Total.
Attendance	18	21	39
Fillings	4	3	7
Dressings	—	6	6
Extractions	10	11	21

The ages of the majority of children were 5 to 8.

WORK DONE FROM SEPTEMBER 1913 TO MARCH 1914. TOTAL PATIENTS, 718.

THE FILLING OF TEETH WITH CAST GOLD INLAYS, AND THE PRESENT STATE OF THE ART IN THE UNITED STATES.

By RODRIGUES OTTOLENGUI, M.D.S., D.D.S., LL.D., New York City, U. S. A.

(Report presented to Section III, Sixth International Dental Congress, London, 1914.)

IN 1908, at a meeting of the Odontological Society of New York, Dr. Wm. H. Taggart announced a new method of filling teeth, by making a pattern of the desired filling, investing the same in a seamless mold and reproducing this pattern by casting molten metal under pressure. At the same meeting he presented a casting machine with which this process could be successfully conducted.

The announcement and description of this new method of filling teeth aroused a greater interest than had any other announcement ever made in relation to dental practice. Within a year thousands of men were utilizing the casting process, and numerous inventors and manufacturers were offering for sale casting machines, with which the claim was made that cast fillings could be made to better advantage than with the Taggart apparatus. Your reporter believes that this will be an appropriate moment for dealing briefly with this subject of machines.

CASTING MACHINES.

Casting machines may be divided into three classes: First, those utilizing direct gas pressure, inclusive, of course, of air, steam, and the like; second, those utilizing the forces exerted by centrifugal motion; and third, the so-called suction machines. Men claim success with all these various devices, but it must be remembered that the minds of men vary, and that personal ideas and standards differ proportionately. Suffice it, then, to say that in the opinion of your reporter no machine is the equal of the Taggart apparatus, in support of which view he may state that experts in the use of the Taggart machine, both in New York City and in Chicago, have made test cavities, for which they have readily made accurately fitting castings which experts with other appliances have been unable to duplicate. Conversely, no one has produced a casting with any rival machine which cannot be duplicated with the Taggart.

EARLY PROBLEMS.

With the adoption of the casting process, operators at once met with difficulties and obstacles, and often produced castings so poor that they could not be used. The faults in the inlays were mainly of three kinds. First, inlays larger than the original pattern; second, inlays showing feathers, in two or more directions; third, inlays spoiled by having minute or even large globular masses attached to their surfaces.

Many extensive and more or less scientific investigations and experiments were undertaken to solve these seemingly insurmountable difficulties. Multifarious theories and explanations were advanced to account for these harassing troubles. It is worthy of note that men of keen minds and of analytical judgment nevertheless advanced antagonizing theories in accounting for quite similar phenomena. I need not take up the time of my *confrères* in this congress by recounting the differing views of these different investigators. But let me say this, that in my opinion there would have been less difference of opinion, and less divergence of reported

results, had the investigators been content to take the art as it was given to them by its originator, following his instructions, using his apparatus and materials, and thus working along exactly similar lines of endeavor. Unfortunately this was not the case. Instead of attacking the problems with unbiased minds, our research workers in the main solved the troubles by mental process first, and then undertook to prove themselves correct by clinical methods which, however ingenious, were all destined to fall short of the truth because of the biased state of the minds of the investigators. To make clearer what I am here stating, men who have never used a Taggart machine met definite failures with some other machine, and spent months of energy explaining and accounting for these phenomena as though it were a fact that they would occur with the Taggart or any and all other machines, when often the particular trouble upon which so much scientific research was expended did not occur at all in the practices of the men who had mastered the Taggart process, using Taggart materials, and the Taggart machine.

For these reasons it is the firm belief of your reporter that the art today would be much farther advanced had the dentists of the world adopted Taggart's apparatus and directions from the outset, and had no other machine ever been constructed. For it is an absolute fact that the men who have done this—those that have studied the process and mastered it, those that use Taggart's machine, his wax, and his investment, and use them always in exactly the same manner, have the satisfaction of knowing that every inlay will accurately fit the cavity for which it is constructed. They also know that on the rare occasions when they meet a failure, it has been themselves, and not the process or the materials, that have failed.

THE SOLUTION OF THE PROBLEMS.

It will be appropriate at this point to explain briefly how the faults met with early in practice are really to be explained and obviated. That they have been obviated is demonstrated by the statement that in the office of your reporter, and of several other exclusive followers of Taggart's direction, no inlay has been discarded nor made over during the past three years. I have this assertion from men of national reputation and of undoubted honor.

Referring to the three main faults, previously mentioned, let us consider them briefly. First, Inlays larger than the original pattern. This was no uncommon experience in the early days of the art, and not a few methods of overcoming the trouble were promulgated. One such method was to coat the outer surfaces of the inlay with wax and then reduce the cavo-surface by immersing the inlay for a short time in a gold solvent. Another proposal was to place the wax pattern in ice-water and to mix the investing material with ice-water. The evident theory was that the chilling of the wax and the use of cold in mixing the investment would counteract the expansion of the mold when heated-up to receive the cast metal. But the true method of producing an accurate casting does not depend upon the utilization, but rather upon the avoidance, of extremes of temperature. The wax should not be chilled; the investment should not be made with cold water, and the mold should not be extremely hot when the cast is made. On the contrary, the effort should be made to work as close to room temperature as possible, the wax and investment thus being neither warmer nor colder than the surrounding air, while the mold itself should be as cool as possible, and consequently as little expanded as possible. Success, indeed, depends more upon a constancy and accuracy of technique than upon the utilization of any extraordinary means of overcoming faults which should not occur at all. Such a method will be presently described.

The second fault, that of having feathers extending from the casting, is directly traceable to three co-operating causes. First, the use of an investment

which will crack during the heating necessary for burning out the wax; second, the presence of these cracks in the investment, especially when the mold is hot at the moment of casting, thus opening the cracks to their ultimate. Third, the use of too great pressure in casting, thus forcing the molten metal into the crevices. The obviation, therefore, depends upon the use of an investment which does not crack at the temperature needed for melting out the wax; second, upon permitting the mold to become as cool as room temperature will allow, and keeping it as cool as possible during the casting, and finally, upon using a low pressure, so as to avoid causing crevices.

Lastly, the presence of globules on the surface of the inlays is mainly due to improper mixing of the investment or to improper application of the investing compound to the surface of the inlay, or to both combined.

THE SUCCESSFUL PROCESS.

The following are the essential steps in the process if accurate results are to be had:

First, the wax used for the pattern should soften at a moderate degree of heat, and should harden at the ordinary temperature of the mouth. It should not be overheated, but should be softened sufficiently to take an accurate impression of the cavo-surface and of the margins, yet kept hard enough so that the mass of the material furnishes resistance under pressure, sufficient to force the outer surface accurately against the cavity walls and margins. The wax once seated, pressure should be continued until the wax has fully hardened. This pressure should be constant and in the direction best assuring the certainty of producing accurate adaptation. Pressure continued in this manner guarantees us that the wax is accurately fitted to the cavity, not a few moments prior to its hardening, but at the final moment of hardening, after which there will be no danger of alteration through contraction, provided the wax is not cast into water colder than room temperature. The best method of assuring the unalterableness of the pattern is to invest it immediately, using water at room temperature.

Having thus procured a pattern fitting at the moment of complete congelation, the next step is properly to invest the same. The investment and water should be always weighed so as to insure definite results. It should be slow-setting, and should be rotated for at least five minutes to insure the expulsion of air-globules. It then should be evenly spread around the pattern, and the surrounding secondary investment poured in such a manner that the operator may be assured that during the process the primary investment does not move so as to expose any surface of the pattern, thus inviting the imprisonment of air during the addition of the secondary investment, which of course should be made with the same mix of material used for coating the pattern.

The wax should be removed with moderate heat, and this heat should be continued until all gases resulting from the combustion of the wax shall have been eliminated. This heat should never be extreme enough to risk injury to the mold by overheating, nor should it be too long prolonged. A definite burner should be used, and a definite time employed, for by this means only can definite results be obtained. The mold should then be permitted to cool to room temperature.

Many wonder what is meant by the phrase "casting in a cold mold." By this is meant that the mold should be as cold as possible. It will necessarily become heated during the melting of the gold, but it is manifest that if the coefficient of expansion and contraction of the investing material at that temperature be the same as the coefficient of expansion and contraction of the melted metal, this slight expansion of the mold aids rather than hinders the accuracy of the result. The gold should be placed in the crucible of the mold, and the blowpipe flame kept small so as to play on the gold rather than upon the mold.

In this manner the gold can be melted to the boiling-point, while the metal ring around the mold will be only a little too warm to be taken in the fingers.

The pressure should be low. Those who use the Taggart machine should have the pressure gage register about 5 lb. when the blowpipe flame is in use. The register will rise to 6 or 7 when the cast is made. Finally a large excess of gold will insure a better casting than where a small nugget is used. The above process accurately used will produce inlays which will fit as well as the wax pattern. No process can do better. If the fit is faulty, either the pattern was at fault or some other step in the process must have been inadequately observed.

METHODS OF MAKING THE WAX PATTERN.

When Dr. Taggart first disclosed his method he directed that the wax should be pressed into the cavity of the tooth itself, carved into desired shape, removed and reproduced in gold by casting. This has now come to be known as the "direct method." But another method is much advocated by many prominent practitioners, which is known as the "indirect method." This involves taking an impression of the cavity in an impression wax and from this making a replica of the original cavity (sometimes called a mold, or die) in which to form the wax pattern. This replica is made of various materials, such as cement, one of the quick-setting silver-tin amalgams, or copper amalgam.

For the indirect method many advantages are claimed, the more valid of which are as follows:

First: If a casting is spoiled, another may be made without recalling the patient. This can only appeal to those using unreliable machines or materials, or inconstant methods. As has already been explained, with a proper machine and a definite technique constantly followed, failure is absolutely not necessary.

Second: Greater facility in carving the pattern to proper form. This is largely a matter of personal preference. Many who use the direct method claim greater satisfaction in carving in the mouth with the adjacent natural teeth as a guide.

Third: Greater perfection of adaptation at the margins, especially at the cervical margin, and more particularly so when this margin is below the gum tissue. In reply, the direct-method men declare that if a perfect impression of all the margins can be obtained with the impression wax, it can likewise be obtained with the pattern wax, and that a better marginal fit will be had if this original first impression be utilized for making the pattern.

Other advantages are claimed for the indirect method, and disputed by the direct-method men, but probably the only real advantage, if indeed this be one, is that the indirect method permits the operator to relegate a larger share of the work to an assistant. By this means he needs only to take an impression of his cavity, give this to his assistant, and at a subsequent sitting receive the inlay ready to cement to place.

There is no doubt that beautiful work is done by men of both schools, and while your reporter believes that the expert with the direct method will always make a better inlay than the man equally expert with the indirect method. he is not at all sure that the percentage of dentists per thousand who could accomplish satisfactory results may not be greater with the indirect method than with the direct.

Against the indirect method it must be said that, if the operator himself should do all of the work, he must lose a great deal of time, for manifestly all the time expended in investing the impression and making the replica is time added to the process.

It would be extremely interesting and instructive to have the question of the adaptation of inlays made by the indirect method scientifically tested. It is the firm belief of your reporter that inlays made by the indirect method are smaller than would be an accurate pattern made in the original cavity. This

explains the ease with which the majority of inlays made in this manner may be set, and the difficulties met with in complicated forms, such as those for M.O.D. (mesial-occlusal-distal) cavities. This also explains why so many advocate that the M.O.D. cavity should be filled with two inlays, interlocking together, whereas the workers by the direct method make a single inlay for this style of cavity.

CAVITY MARGINS.

Your reporter does not consider that cavity preparation is strictly a part of the subject apportioned to him, but he would like briefly to touch upon a single aspect thereof, because of a feature which is not widely known.

There has been much contention as to whether the cavity should be prepared with a beveled margin, or as for a butt joint. Those who favor the beveled margin declare that the arrangement of the enamel rods demands that a bevel equal to at least one-third of the length of the rods is essential to future safety. Those who like the butt joint demand that the margins of both enamel and inlay should be as nearly as possible at a right angle, and they argue that this arrangement leaves the enamel rods strong, because the enamel rod usually lies at a right angle with the tooth surface. They point out that whereas the bevel may be necessary with the gold foil filling, where the foil is malleted against the actual margins of the enamel rods, such is not the case with the inlay, and the beveling only makes a weak margin of gold, which later will turn away and expose a seam for the inroads of new caries.

There is, however, another method of fashioning the margin which is worthy of consideration. So far as your reporter has been able to learn, this method is original with Dr. M. L. Rhein of New York, and has been adopted by only a few others. Yet your reporter has seen such beautiful results with this method that it seems important that it should be reported.

This arrangement must be called the "lapped joint." In treating the approximal surfaces, to which it especially applies, a chisel or disk is used between the teeth, and the margins of the cavity trimmed away to a flat plane, and the trimming is extended until the entire bell-shape form of the tooth has been removed. This yields considerable approximal space, and facilitates the taking of the impression of the cavity. It leaves the approximal margins flat, with the lingual and buccal margins in the same plane, which plane is slightly inclined away from the gum toward the occlusal surface. For fear that I have not made this entirely clear (which is difficult to do without models) let me further state that if we examine these flat approximal margins we will note that they are comparatively wide, with one angle formed by the surface of the margin and the buccal enamel surface, and a second angle formed by the surface of the cavity margin and the dentinal surface of the cavity. It is the extension of the inlay over this flat margin which accounts for the term "lapped joint."

This style of margin may be utilized with the direct method, but it is more readily used with the indirect, for the reason that the extreme buccal and lingual edges of the gold which makes the lap is brought to a very sharp edge, which is easily injured in removal from the mouth. Using the indirect method, the pattern wax is extended over the margins considerably, and this excess is polished off after making the cast, the polishing being carefully done with the gold inlay returned to the metal replica of the tooth.

CHOICE OF GOLD.

A very large number of prominent men, whose opinions must be treated with respect, have concluded that pure gold when cast is not sufficiently hard for filling teeth. To obtain a harder metal various alloys are used, probably the best being pure gold alloyed with from 2 to 5 or even 6 per cent. of platinum.

In spite of the great number of men who have abandoned pure gold, and with all due respect to the opinions of my prominent *confrères,* your reporter is compelled by personal experience to proclaim his allegiance to pure gold, and he is solaced by the fact that he is still sustained in this opinion by the inventor of the method.

After using pure gold for about a year, your reporter observed some of the marring of occlusal surfaces and other troubles, complained of by his *confrères,* and following their lead he used gold alloyed with platinum for about another year, when he came to the conclusion that the greater difficulties in obtaining accurate adaptation more than offset the advantages of a harder surface. There is no doubt that the pure gold can be more accurately cast than any alloy thereof, and consequently it should be some very pronounced advantage which would tempt us to forsake that metal.

Your reporter therefore abandoned the alloys and returned to the use of pure gold. By this time also he was partially awakened to the necessity of more accurately reproducing the occlusal forms of teeth, but later still he became fully aroused on this subject by the several communications of Dr. J. Lowe Young, and at the present time he unhesitatingly asserts that, if anything like accuracy is attained in reproducing tooth form, and occlusion, with the gold inlay, pure gold is the best metal with which to serve the patient, and that under these conditions it will be found quite hard enough to withstand all natural masticatory stresses. In other words it was the malformation and malocclusion of the early inlays, rather than the supposed softness of the metal which occasioned the damages reported, which included everything from bruised surfaces of the gold to the splitting-off of sections of tooth tissue.

OCCLUSION.

We come now to the most important feature of the entire gold inlay proposition. The natural teeth were given us for the mastication of food. They were undoubtedly made for a special design that they might adequately accomplish this function. In proportion as mastication is thoroughly well effected is the individual well or ill. Hence we may declare without opportunity for dissension that the health of a man is to a great degree dependent upon the occlusal form of his teeth, since upon this form must depend the efficiency of these organs in mastication.

In the past the occlusal forms of molars and bicuspids have rarely been copied even in the crudest manner, with gold foil fillings. Nor is it very practical to do this, carving the dense hard gold after it has been placed in the tooth. But with the gold inlay process, using as we do a plastic wax for forming the original pattern, the carving and reproduction of the actual tooth surface is only limited by the skill of the operator.

This subject is of too great a magnitude to be thoroughly treated in a report of this character. Let me only say that a great awakening to the opportunities is even now occurring in the United States. Several enthusiasts are giving their time visiting dental societies throughout the country, explaining and exploiting the new doctrine. Already the spirit of the movement is evidenced by an improved teaching in the schools.

I would be derelict, however, if I did not point out the most important feature of this most important new technique. It was long ago taught and later definitely proved by Prof. G. V. Black, that actual approximal contact of the teeth is essential to the health of the interproximal tissues, and this is as true today as when the dogma was first promulgated. But in the light of the newer teaching we discover why it has been that so often, in spite of accurate approximal contact, the gingival tissues have suffered, gingivitis has ensued, and too frequently septal abscesses have formed. We have wondered how food could have been forced between teeth so close together that it appeared difficult

to pass a silk thread between the classically formed contact points.

This mystery is a mystery no longer. Normally teeth are movable in their sockets, and no contact of adjacent teeth will alone prevent the ingress of food where the masticatory stress of the individual is above the average.

A study of the dental organs in a state of health discloses the fact that one cusp of a molar tooth is received by the fossa of its antagonist in the opposite jaw, while the other antagonizes with a fossa formed by the inclined planes of two opposing teeth. In the first instance we find that the summit of the cusp, as it reaches the bottom of the fossa of its antagonist, is met by a cross sulcus leading lingually and buccally, so that the food crushed at this point is forced in the direction of this sulcus. Where the cusp antagonizes two teeth we find each of these opposing teeth protected by a marginal ridge. This marginal ridge has its inclined plane leading toward the center of the tooth and consequently away from the interproximal space. Moreover, at the extreme depth of this incline we find a crescentic groove or sulcus, the horns of which pass outward and inward, buccally and lingually, so that food crushed at this point is forcibly ejected away from, rather than toward, and into, the interproximal space.

Your reporter is quite ready to admit that this condition is not prominently present in all teeth nor in all types of teeth. But by a study of the best type of teeth shall we learn the protective intention of Nature in this provision. So important does this point seem to your reporter that he makes an earnest appeal, not only for the restoration of the occlusal surfaces of molars and bicuspids, in as exact accordance with nature as possible, but he would urge that the mesial and distal marginal ridges, with their inclined planes and crescentic sulci, be accentuated even to a greater degree than they may exist in other dental members of the same mouth. When we consider that the tooth is already in a state of disease, we cannot take too many precautions to protect it from a new attack.

It is your reporter's belief that much gingival disease has been inaugurated by flat fillings, which have had a tendency to force food into rather than away from the interproximal spaces. Such fillings, while they may have saved the teeth, have injured the tissues of the mouth by packing food against the soft tissues; and have injured distant organs of the body by burdening them with an excessive share of the processes of digestion. All these troubles may be avoided, and the patient's masticating apparatus may be perfectly restored if we conscientiously utilize the opportunities afforded us by the cast gold inlay process.

INLAYS FOR DIFFICULT POSITIONS.

In conclusion let me describe three types of inlays which have been formulated for positions of special difficulty.

First picture to your mind a distal approximal cavity in a molar, complicated by the presence of a cavity at the buccal aspect, near the gum. The tooth substance between the two cavities may be so poor that a thorough excavation would make the two cavities continuous. This is a condition in which it is manifest that a single inlay cannot be used. The procedure is as follows: An inlay is first made for the buccal cavity, and is finished and set so that one edge of it becomes a part of the margin of the approximal cavity. A second inlay is made for the approximal cavity, and when set completes the operation. If well done it will seem to be but one inlay.

In so-called M.O.D. cavities it is the common practice to fashion an inlay for the distal and half of the occlusal part of the cavity, cutting a box or dovetail in the occlusal extension. This is set and a second inlay is made for the mesial portion of the cavity, interlocking with the first inlay when set. As has been already stated, this procedure is seldom requisite when the M.O.D. cavity presents at the outset, but it is an important technique when a cavity

appears in the approximal part of a tooth which already carries an inlay in the other approximal surface, seated and anchored in the occlusal surface. In such cases an interlocking of the two inlays assures permanency for both.

With the first introduction of the gold inlay attempts were made to produce an inlay which would have its conspicuous surface covered with porcelain. Many methods were tried but none has seemed so satisfactory as a method recently shown and now much utilized in the United States. This method even permits the use of a gold inlay in the anterior teeth. The procedure is to make a gold inlay of such form that all that part where strength is required shall be of gold. Such part as would be easily seen is cut away from the wax pattern and a box is formed, one edge of which shall be the margin of the tooth, the box of course only appearing as a box when the inlay is set. After setting the inlay this box is filled with a synthetic cement to match the tooth. Such combination inlays having been made, it was discovered that the beautiful transparency of the cement was lost by having the gold back of the filling, but in the more recent inlays of this character this fault has been largely overcome by cutting windows completely through the gold. These windows afford a better hold for the cement, and by permitting the passage of light restore the translucency.

THE CHEMISTRY AND PHYSIOLOGY OF THE SALIVA.

By EDWARD C. KIRK, D.D.S., Sc.D., Philadelphia, Pa.

(Report read before Section I of the Sixth International Dental Congress, London, 1914.)

IN presenting for your consideration a report upon the Chemistry and Physiology of the Saliva, in the absence of specific directions as to the nature and scope of the report which it was desired that I should make, I have assumed that I should report only upon the work done on this subject in America, and for the period intervening since the holding of the Fifth International Dental Congress in Berlin in August 1909. My report will therefore be made subject to these limitations, as I presume that others will report upon the progress of the work done in their own countries in this particular field.

By far the most important series of researches upon the chemistry and physiology of the saliva undertaken in America is that conducted by Prof. Wm. J. Gies of the department of biological chemistry of the College of Physicians and Surgeons, Columbia University, New York, under the auspices of the Dental Society of the State of New York and of the New York Institute of Stomatology respectively.

The initiatory impulse leading to the serious investigation of the significance of the sulfocyanate content of the saliva doubtless had its origin, so far as America is concerned, in a report made by the Committee on Scientific Research, Dr. F. W. Low being then its chairman, to the Dental Society of the State of New York at its annual meeting in 1905, and similarly in 1906, in which reports attention was focused upon the possibility that the sulfocyanates of the saliva might exert a retarding influence upon carious destruction of the teeth, either directly, by an inhibitive effect upon the micro-organisms concerned in caries production, or by interfering with plaque formation and thus preventing localization of the caries-producing agencies.

The question thus raised excited wide-

spread interest, and—notwithstanding the recorded and apparently convincing work of previous investigators on this same subject, notably that of Hugenschmidt and of Miller—the demand for further knowledge of the rôle, if any, played by sulfocyanates in the saliva, especially with reference to dental caries, determined the Research Committee of the Dental Society of the State of New York seriously and scientifically to investigate the question. The assistance of Prof. Wm. J. Gies of Columbia University, an eminent biological chemist, was sought and his interest aroused in the problem. A series of important researches were undertaken under the direction of Dr. Gies, with the result that the question of the activity of the sulfocyanates in the saliva, in so far as they were assumed to have any inhibitory influence whatsoever upon the inception or progress of dental caries, was answered in the negative.

In connection with the work upon the sulfocyanates conducted by Professor Gies, collateral researches were made upon the biochemistry of the saliva with a view to throwing more light upon the possible relationships which the composition and character of the saliva might bear to the carious process. I cannot do better than present Dr. Gies' own *résumé* of the character and scope of the work which he has carried out, as follows:

Our work in dental chemistry was inaugurated in the fall of 1909, as a result of requests and suggestions by the Research Committee of the New York Institute of Stomatology, Dr. J. Morgan Howe chairman. Realizing the fact that biological chemists had wholly ignored the important field of dental chemistry, and appreciating the special opportunity to serve the dental profession in response to its call for co-operation, I gladly placed the resources of our laboratories behind the proposed investigation of dental caries. This work has been in progress since.

In March 1910, the Research Committee of the Dental Society of the State of New York, Dr. Wm. B. Dunning chairman, invited me to repeat and extend certain experiments which had previously been conducted on the possible relation of salivary sulfocyanate to the condition of the teeth. With the approval of the New York Institute of Stomatology, I accepted this invitation. This work has since been in progress, with an interruption of one year.

Since 1910, then, we have been conducting two series of investigations of dental caries under the auspices of two dental organizations.

When these researches were begun I was greatly embarrassed by my utter ignorance of dentistry. It has taken several years of hard study and earnest work to overcome, to a small extent, that very severe handicap. As a consequence we have accomplished very little, though I feel that we are "getting under way."

For convenience let me refer separately to our researches under the two different auspices referred to above, as indicated by the headings below:

Research under the Auspices of the First District Dental Society of the State of New York.

1909–10. A chemical study of saliva in its probable relation to the decay of teeth (with Alfred P. Lothrop). Two papers, *Journal of the Allied Dental Societies*, 1910, vol. v, p. 262, and 1911, vol. vi, p. 65. Our data failed to show any definite relation between common qualities and constituents of saliva and the condition of the teeth of the individual studied. We were unable to infer, from our data, that caries is due to the positive or negative influence of any one, or any combination, of *purely salivary* constituents. It was suggested that food-acid media might be valuable dentifrices.

1910–11. Further studies of saliva in its probable relation to the decay of teeth, with special reference to sulfocyanate, nitrite, and oral micro-organisms (with Alfred P. Lothrop, Clayton S. Smith, and Elmer W. Baker). Four papers, *Journal of the Allied Dental Societies*, 1911, vol. vi, pp. 289, 297, 323, and 334. Negative findings in the cases of sulfocyanate and nitrite. *Nothing new* on the relation of oral micro-organisms. Importance of chemical studies of mucin emphasized, from the standpoints of plaque formation and effects thereon of food-acid media.

1911–12. Studies of salivary mucin, from the chemical standpoint primarily, with further emphasis on the probable effectiveness of food-acid media as dentifrices and suggestion of important bearings of internal secretions on dental conditions (with Alfred P. Lothrop). Three papers, *Journal of the*

Allied Dental Societies, 1912, vol. vii, pp. 199, 397, and 410.

A *résumé* of the findings in the foregoing papers for 1910, 1911, and 1912 is given in the *Journal of the Allied Dental Societies*, 1913, vol. viii, p. 284.

1912–13. Continuation of the study of a possible prophylactic influence of food-acid media, with further emphasis upon the bearing of internal secretions on dental conditions (with Alfred P. Lothrop). One paper, *Journal of the Allied Dental Societies*, 1913, vol. viii, p. 283. Food-acid media, represented by vinegar diluted with water (1 : 1), applied as dentifrices twice daily for six months, were without discernible destructive effect on extracted teeth (sound teeth and teeth containing fillings of various kinds). Further study has confirmed this finding.

1913–14. Program for the year: *One line* of research is, for the present, historical in character, and consists of the preparation of abstracts of all the essential contributions to the world literature as it now stands on the subject of dental caries, the plan being to publish the abstracts in a comprehensive edition as a monograph on this subject for the future benefit of all students and investigators of dental caries.

A *second line* of investigation relates to a continuance of our study of the possible utility of food-acid media as dentifrices. Included in this line of research will be a further study of the effect of such media on enamel and on dentin.

A *third line* of research involves a chemical study of enamel and dentin, and of the nutritional influences (internal secretions and vitamines, especially) that may modify the mobilization of calcium phosphate and other dental constituents, and thus presumably affect the susceptibility of the teeth to caries.

The *second* and *third* lines of research, evolving on the basis of cumulative findings, are not as clearly defined in our minds at present, *so far as outcome is concerned*, as the first plan above alluded to. The plans will be changed as the results of the researches determine.

The foregoing lines of investigation for 1913–14 have appeared to be urgent; they have temporarily postponed further attention to the general studies with which we inaugurated our research, viz, the causative or coincidental relation of saliva to the condition of the teeth, the systemic conditions that may affect the saliva significantly from the standpoint of dental disease, and the particular relation, if any, of salivary mucin to caries. We intend to return to a study of these subjects as soon as possible.

Research under the Auspices of the Dental Society of the State of New York. Included in Annual Reports of the Research Committee, Dr. Wm. B. Dunning chairman.

1909–10. Investigations on plaque formation and dental caries in relation to saliva, with special reference to previous claims that salivary sulfocyanate inhibits plaque formation (with Emily C. Seaman). Dental Cosmos, 1910, vol. lii, p. 1141. Negative findings.

1910–11. Suggestions of further work. Dental Cosmos, 1911, vol. liii, p. 1324. No work done.

1911–12. An inquiry into the possible relation of sulfocyanate to dental caries, with special reference to the origin of sulfocyanate (with Max Kahn). Dental Cosmos, 1913, vol. lv, p. 40. Negative findings in relation to dental caries.

1912–13. A further inquiry into the possible relation of sulfocyanate to dental caries, with a study of its pharmacology; also suggestions regarding the bearing of internal secretions on dental conditions (with C. C. Lieb and Max Kahn). Dental Cosmos, 1914, vol. lvi, p. 175. Facts pertaining to origin and significance of sulfocyanate, *as a waste product of no functional import in the mouth*, more definitely established.

1913–14. Program for the year: Study of the influence of internal secretions on dental conditions, with special reference to the mobilization of calcium phosphate and other dentin and enamel constituents.

In connection with the sulfocyanate problem Prof. Russell W. Bunting, of the Dental School of Michigan University, has reported in two papers (Dental Cosmos, 1910, vol. lii, p. 1346, and Dental Cosmos, 1914, vol. lvi, p. 285) the results of his researches upon the sulfocyanate question, dealing more particularly with the technique for the detection and determination of sulfocyanates. The technique of Dr. Bunting has been strongly criticized by Professor Gies, the discussion being too elaborate and technical to report upon in detail, but it is recorded *in extenso* in Dental Cosmos for July of this year (1914), vol. lvi, p. 856.

The important question of the localization of the carious process through the fixation of caries-producing bacteria upon tooth surfaces through the agency of the so-called bacterial plaque, as de-

scribed by J. Leon Williams and by G. V. Black, has been developed somewhat further by the suggestion of the writer made in 1909 (DENTAL COSMOS, vol. li, p. 1451) and later experimentally demonstrated (DENTAL COSMOS, vol. lii, p. 737) that the mucinates of the saliva constitute an important factor in plaque formation, as it was found that with caries-producing organisms grown in a mucinous saliva containing fermentable carbohydrates in solution, *e.g.* glucose, the lactic acid produced by the bacterial enzyme precipitated the mucin upon the bodies of the caries-producing organisms, cementing them to the surface, upon which they were permitted to lodge and remain undisturbed.

The work of other investigators, notably of Gies and Bunting, has established the correctness of this view as one of the important means of plaque formation. The work of Bunting reported at the recent meeting of the National Dental Association of America in Rochester, New York, records his experiments in the artificial growing of plaques from saliva upon glass slides and in test-tubes. He finds that such plaques can be grown readily from any saliva, and that they form upon and adhere to the smoothest glass. Inasmuch as the growing of the mucinous plaque is directly dependent upon the soluble carbohydrate pabulum in the saliva, Bunting has undertaken to estimate the total carbohydrate content of salivas, and to study the fermentative processes thereof. He reports that there is a variable quantity of carbohydrate, which may be demonstrated with Fehling's solution after the carbohydrates of the saliva have been split by acid and high temperature and pressure; also that after an incubation of three hours the carbohydrate cannot be determined. He has found a great variance in all the tests made in different salivas as to the relative rapidity with which fermentation takes place upon carbohydrates, and experimentally introduced into various salivas, but he has not been able to find any definite correspondence between his results of fermentation tests and conditions of caries susceptibility and immunity.

The part played by the mucinates of the saliva in plaque formation, also their probable relationship to tartar formation, have assumed by reason of these relations considerable importance, and a number of investigators, notably Professor Gies and his colleagues, Bunting, and the writer, are prosecuting further studies in the hope of determining the rôle which this material plays in several oral pathological states.

An important contribution to the problem of tartar formation is a communication by Dr. G. V. Black (*Items of Interest,* June 1911, p. 436, and repeated in its essential features with some additions in the *Dental Review* for April 1912, p. 337). Some of the conclusions stated by Dr. Black as the result of his investigations of the subject of salivary calculus are remarkable and revolutionary. Previous theories as to tartar formation, Dr. Black states, "seem to suppose that the formation of salivary calculus is due to a play of chemical affinities in the fluids of the mouth itself." "This," he states, "now seems to me to be untenable." He has studied the well-known deposit which has been generally observed to take place upon the surface of artificial dentures, and says concerning it:

> The study of the occurrence of the deposits, followed day by day and often four or five times per day, gave important information. It showed in the most conclusive way that the deposit of calculus is paroxysmal. These paroxysms of deposit occur with extreme irregularity. For a considerable time they seemed to come without cause or effect further than the fact of the deposit. It was soon discovered, however, that a paroxysm of deposit of calculus was generally—though not in all cases—preceded by a deposit of a gummy material that was not dissolved away in running water, hot or cold, and which gave no appearance of calcium salts. Afterward when the plate was otherwise clean, this material remained, giving that part of the plate a shining, varnished look and causing it to feel slightly greasy to the fingers. Generally it is perfectly transparent, not hiding the plate in any degree. I have seen

this material spread over the entire plate, though such an amount of it is rare. More generally it is confined to the neighborhood of the salivary ducts. It is coagulated and whitened by boiling water and by alcohol or phenol. In this it behaves much like albumin. Sometimes the entire deposit will be of this clear material, but the rule is that a white or grayish color appears in the central part and spreads more or less widely over the area. The fact that I observed this order of deposit in my examinations, coupled with the general idea that the calcium salt was a precipitate from the saliva—which I had held in harmony with general opinion—led me to say in my first writing that this agglutinating material was deposited first, and the precipitated calcium salts became entangled in it. It now seems to me that this was an error. After watching it longer and studying the deposit closer, I am more inclined to the opinion that a certain variety, or quality, of the gummy material carries the calcium salt with it because of a chemotactic quality that brings about this addition of salts. The fact remains, however, that the calcium salt is in the form of a precipitate and remains in that form in the hard calculus. This white material is a stronger, thicker deposit than the clear material about it, and it constitutes the bulk of the deposit in the more ordinary paroxysms. The abatement of the paroxysm is usually in the reverse order, the clear material continuing for a short time after the white deposits cease.

Dr. Black calls this clear deposit as a whole "agglutinin of calculus," and states further that "the agglutinin is composed of several varieties of globulin," which later he defines as "any one of a class of albuminous proteid compounds insoluble in water or alcohol but soluble in weak solutions of the neutral salts." "These globulins," he says—

> are the most important of the proteid compounds. The common physiological processes could not be carried on without them. Yet in the condition we are discussing, these globulins serve as the agglutinin in the formation of salivary calculus, and seem to determine its deposit. The thought that these globulins, so important in the animal economy, take part in such a process, and that conditions occur in which the secretions and excretions are loaded with them, including the urine, has been very distasteful to me. But the facts I have been reciting seem to enforce this view. I can no longer think of it as having been formed in the mouth.

The article under consideration continues with a description of a number of slides of specimens of deposits variously stained, and under different magnifications, together with the author's personal experience in controlling the paroxysms of tartar deposit by modifications of diet and by the use of saline purgatives.

Any observations reported by Dr. Black necessarily demand thoughtful consideration. To the writer an analysis of his findings is far from convincing. First, because none of the tests or observations made by Dr. Black with reference to the nature of the clear sticky, gummy deposit which he has reported, seem to warrant the conclusion that the substance which he designates as "agglutinin of calculus" may be properly designated as "globulin." On the contrary, the conditions under which the deposit is formed, and the physical and chemical characteristics of the deposit itself, seem to answer more precisely to the characteristics of precipitated mucin than they do to deposited globulin, whatever form of globulin it may be considered to be by Dr. Black, nor does any of the evidence submitted by Dr. Black in support of his conclusions seem to the writer to justify his generalization that the theory that tartar formation is due to a play of chemical affinities in the fluids of the mouth itself is untenable; for, even granting that lime salts are precipitated in the colloidal organic mass which Dr. Black designates as the agglutinin of calculus, yet to regard the precipitation of lime salts within the colloidal matrix in which they are contained as being chemotactic, and not chemical, involves an assumption not warranted by the observations which Dr. Black reports in his paper and not in harmony with the studies in an analogous field made by Rainey, Harting, and Ord, about 1858. The importance of this department of salivary investigations demands further and careful study.

A question of fundamental importance in connection with the study of the saliva is its varying and variable reaction. The records of observations upon the reaction of the saliva, in so far as they appear in contributions to dental literature, are open to justifiable criticism as to their accuracy. The whole subject of salivary reaction needs careful revision and the utilization of more precise methods for its accurate determination.

Recently the writer has suggested the use of the hydrogen electrode of Hildebrand for the electrometric determination of the hydrogen ion content of the saliva. The electrometric method in this connection is under investigation and promises to yield satisfactory results within the sphere of its applicability. Precise determination of salivary reaction is a *sine qua non* in the further study of the dissolved carbohydrate content of the saliva, especially in connection with fermentation tests. Bunting, who at the suggestion of the writer has been independently studying the electrometric method of determining the reaction of the saliva, records the interesting point that he has found that all salivas give a reading on the alkaline side of the neutral point, but when acids or alkalis are introduced into them, a variable portion of either will enter into combination with the saliva, which he regards as another evidence of the amphotericity of saliva.

It seems probable that before we can arrive at a reliable technique for determining with accuracy the reaction of the saliva in any given instance, it will be necessary to compare the results of observations made with a number of indicators in comparison with the results obtained by the electrometric method. Work upon this phase of the subject is actively in progress.

The dissolved carbohydrate content of the saliva furnishes a problem of major importance. Its significance is apparent when we come to consider its relation to the etiology of dental caries, and more particularly to the vexed question of the observed variability in susceptibility among individuals to that devastating disorder. The theory that caries originates wholly by the fermentation of adherent alimentary food débris falls far short of explaining many of the phenomena of dental caries, and altogether fails to account for the variable susceptibility of individuals to the disorder. The more critically the subject is studied, the more evident it becomes that there is a constitutional or systemic factor in the etiology of dental caries. The writer, with others, has directed attention to the fact that in certain salivas the soluble carbohydrate may be found by the ordinary copper reduction test of Fehling. The origin of this soluble carbohydrate is obscure. The writer has called attention to the probability that disturbances of the hypophysis cerebri, particularly the posterior lobe of the pituitary body, occurring during dentition and pregnancy and through the early periods of rapid growth, may bring about an overflow of glucose into the saliva from the blood stream, which may thus create conditions of increased susceptibility at the periods referred to. Prof. Clarence J. Grieves of Baltimore in a recent paper has further elaborated the same thought and directed attention to the importance of the activities of the ductless gland system in modifying, among other things, the composition of the saliva. Further investigation of this important phase of salivary work is in progress.

Much light has been thrown upon the comparative value of fermentation tests in relation to the soluble carbohydrate content of the saliva by the observations of Dr. Percy R. Howe of Boston. In a paper entitled "The Accelerating and Inhibiting Agents in the Oral Secretions" (DENTAL COSMOS, May 1912), Dr. Howe states his "experiments were carried out in an endeavor to ascertain the action of certain salts upon carbohydrate fermentation":

> **The object of the work was to establish some connection between salivary composition and tooth decay.**
>
> **The method employed consisted of adding the salts to standardized sugar and starch**

solutions, infecting them with saliva or lactic bacteria, and incubating them. The resulting lactic acid formed was estimated by titrating aliquot parts against N/100 NaOH, using phenol-phthalein as an indicator. A comparison was made with controls.

The salts were some of those whose presence had been determined, or which we had physiological reasons to believe were to be found in the saliva during systemic phases. They consisted of di-ammonium phosphate, di-potassium phosphate, di- and mono-sodium phosphate, sodium and ammonium phosphate, potassium, sodium, and ammonium chlorids.

The sugars, maltose, levulose, dextrose, fructose, and various food starches were employed to furnish the fermentable media.

This work disclosed the fact that the phosphates cause an increase of from 200 to 800 per cent. in the lactic acid formation as compared with controls. The period of incubation was from fifteen to twenty-four hours. It is further to be seen that not only is a greater amount of acid formed, but that it is formed in a much shorter time and in a rapidly increasing ratio.

A comparison of the action of the different phosphates shows that di-ammonium phosphate produces the greatest acceleration and virulency of growth as calculated from the lactic acid formed.

The difference in effect between mono- and di-basic sodium phosphate is instructive. The di-basic produces the more acid and with more rapidity. With respect to the chlorids it is demonstrated that they slightly inhibit the bacterial action, reducing it by one-half, in the strength used, so that the action is practically *nil*, and is in no degree augmenting. Ammonium chlorid forms an exception to the rule and augments the growth. In this connection the action of carbonates may be mentioned. These salts, so far as I have determined, do not interfere with the bacterial fermentation of sugars and starches. Analysis shows that they lose their degree of alkalinity and that CO_2 is evolved, signifying acid production. It may be reasonably concluded from these experiments that the phosphates furnish a stimulant for bacterial nutrition, as they do for higher forms of flora. This opinion is further strengthened by the action of the di-ammonium phosphate, for from this salt not only is the augmenting action of the phosphates evident, but an additional source of bacterial nutrient material is shown by the greater degree of acid formed. This is to be accounted for by its ability to furnish nitrogen, which is absolutely essential to bacterial life. Even as the salt of a stronger acid, this base acts to supply the nitrogen for bacterial proliferation, as is here demonstrated in the case of ammonium chlorid.

The effect of $H+$ and $-OH$ ions (indicative of acidity or alkalinity) upon bacterial growth is to be distinguished in the comparison of the action between mono- and di-basic sodium phosphate. The greater amount of lactic acid is produced in the presence of the di-basic salt. The base of this salt replaces more of the $H+$ ions of the phosphoric acid, and is therefore the more alkaline in reaction. We have here further evidence in support of the opinion that bacterial life progresses more favorably in an alkaline medium than in an acid medium.

Other accelerating agents include the albumin and globulins of the saliva, or the glyco-proteid mucin, when they have been subjected to the action on proteolytic bacteria, as they then afford nitrogen.

By adding amino-acids to cultures, I have found the acid production to be greatly increased.

Local infective processes of the gums, tonsils, sinuses, and nasal passages, adenoids, inflammations of the pillars of the fauces and uvula, or catarrhal conditions in which the colloids of the mouth show evidences of alterations or liquefaction by bacteria, are distinct aids to lactic acid forming organisms through affording available nitrogen, as I have shown by experimentation.

Dr. Howe has conducted an important series of observations upon the variability in composition of the saliva and the relationship of this variability to metabolism and semeiology.

In his study of "Dietetics with Relation to Salivary Composition" (Dental Cosmos, January 1911), he says:

> In the conduct of the work, notes were made upon the character and amount of food taken by the subject under examination. Clinical observations were recorded of his physiological condition and his anatomical characteristics. This was supplemented by some very general salivary analyses. Inquiry was made as to—
>
> > The amount of food—for comparison with the standards of intake and output that have been evolved in the laboratories at Yale University, viz, 60 grams protein, and 1500 to 2500 calories for a normal individual weighing 70 kilos and under ordinary work.

The character of the food—as to its bulk, coarseness, effect upon digestive secretions (stimulant or depressant), and its fermentability as opposed to its putrescence. The bearing of this is extremely important in regard to intestinal toxemias, to digestive activity or to stasis.

Habits of life, sedentary or active. Exercise in the open air—with reference to the complete oxidation of foods.

Nervousness—with respect to the perfection of the physiological process concerned with metabolism.

General appearance—for the detection of pathological states and for perfection of anatomical formation. My studies compel me to believe that the narrow protruded arch, adenoid and tonsillar affections, are indicative of nutritional defects. (Compare cretins and cases of osteomalacia.)

This work shows that salivary composition is markedly influenced by these factors. In the case of intestinal crises I have many times found indican in the saliva. During toxemias, sialorrhea is a very constant accompaniment, as well as during some febrile states when it comes on in an effort on the part of the system to eliminate the toxins.

It is not difficult to see that when the dietetic principles become distorted to such an extent that pathological conditions ensue, then caries is most active.

Further experimentation was carried out to show the connection between dietetics and salivary composition by dieting several individuals for a number of days, first on a considerable excess of protein, and later on an excess of carbohydrate material. Analysis of the saliva was made with a view to ascertaining if imperfect or partially oxidized metabolites were present.

In the case of excessive protein feeding, the general alkalinity of the saliva was lowered. The reaction of the saliva which was allowed to ferment was alkaline, with the formation of ill-smelling gases. This indicated sulfates and ammoniacal products. In certain cases urea was shown to be present by the Doremus test.

In the case of excessive carbohydrate feeding, the general alkalinity of the saliva was also lowered. In some cases it was acid after boiling. Certain cases gave evidence of sugar or its homologs by causing reductions, with mirror formation, as shown by Tollen's test. These salivas fermented, became acid, or became reduced to an alcohol as shown by the iodoform test. This is still further proof of the presence of fermentable carbohydrate material. This saliva showed no signs of putrescence after it had been kept for weeks.

It is concluded, then, that the lessened alkalinity of these salivas is indicative of impeded oxidations throughout the system; for complete oxidations mean CO_2 in the case of carbohydrates, and CO_2 and ammonia in the case of proteins.

It is further concluded that food substances when taken in excess of physiological requirements become excretory products and are to be found in one form or another in the saliva.

In another series of experiments I have emphasized and demonstrated the fact that the salivary glands are secretory channels by taking *per os* many medicinal substances in capsules, and have shown that these substances are to be detected in the saliva in from fifteen to twenty minutes. Their presence is to be detected for about fifteen hours. Bromids, iodids, iron, KCNS, salicylic acid, and other substances, are to be included in the list of medicaments tried.

Pathological substances formed within the system are excreted in the same way, as has been already stated. So that it may be seen how elements for or against bacterial proliferation find their way into the mouth from other parts of the system.

Dr. Howe has also contributed an important communication upon the devices and tests used in his salivary work. (DENTAL COSMOS, January 1913.) I add here his report upon that phase of the subject as follows:

The refinement of analytical work upon the saliva has created a demand for an equipment adapted to the work.

First as to suitable apparatus, and next as to appropriate volumetric tests.

One of the most indispensable things that I have originated and use in my work is an apparatus for collecting saliva directly from the several glands. Illustrations of these instruments are to be found in the DENTAL COSMOS, although since their publication I have improved and added to the appliances.

One consists of a glass aspirator, with a bell-shaped mouthpiece to inclose the orifice of the duct from the parotid gland and a reservoir for holding the saliva. The aspiration is controlled by a rubber bulb. In use this is placed over Steno's duct, just enough aspiration produced to hold the instrument in place, and food eaten to incite the flow. The rate of flow is noted, and the saliva collected absolutely uncontaminated with extraneous material.

A similar device is used on the duct of Wharton. Here both duct outlets are covered with the bell on account of the close proximity of the two ducts.

Still another collector with a suitable piece of soft rubber is used, covering as closely as possible the entire glandular outlets of the sublingual glands as well as those of the submaxillary glands.

Other devices such as are to be found in any well-equipped laboratory I have had made smaller or altered for the work in hand, such as pycnometers, suction filters, funnels, Gooch filters, extraction and distillation apparatus, viscosimeters, and many other similar things.

The tests I employ are such as are used in the best physiological laboratories, and that are appropriate for work upon the saliva and capable of detecting very small quantities of the substance sought.

Dr. Howe has furnished me for this report the following record of the conclusions he has reached from his own investigations of the saliva thus far, which seem to be quite in accord with the views and conclusions reached by the late Joseph Porter Michaels of Paris:

The saliva is individual in character. It reflects the physiological actions of the system, and its constituents are controlled by the same set of organs, by the same nerve centers, and by the same metabolic principles that control these elements throughout the body. Alterations in its character occur only in accordance with definite physiological principles.

Under stimulation its character is changed, depending upon alterations that occur in the O and CO_2 relations with the gland, as shown by Barcroft, and set forth in Starling ("Physiology of Digestion").

Pain causes a very alkaline saliva.

Even under stimulation, the saliva maintains its individuality as may readily be seen by using the same stimulus to incite the flow and making comparative analyses.

The constituents of the saliva maintain a definite relation to one another—the Na to the K, the Ca to the Mg, the albumin to the globulin in parotid saliva. From the few analyses that I have made in cases of systemic derangement, I feel that these proportions are subject to the same alteration that occurs in other parts of the body during the same derangement.

Morbid and excretory products are to be found in the saliva—for example, indican may be readily found during crises of intestinal fermentation. Urea, sulfates, KCNS, may be classed among the excretory substances. Such substances as iodids, bromids, iron, KCNS, taken in capsules by way of the stomach can be detected in the saliva in fifteen minutes after taking.

During feeding experiments in which carbohydrates were taken for a number of days in excess of physiological requirements, evidences of imperfectly oxidized metabolites were to be obtained, and during an induced glycosuria marked reduction action occurred with Tollen's test, indicative of the presence of glucose, or an aldehyd.

Evidences were obtained of imperfect oxidation of protein substances in experiments in which excessive protein diet was maintained for some days. Other substances that I have been able to determine by positive tests are creatinin and cholestrol.

So that it may be seen that excretory substances, morbid substances, and partially oxidized metabolites are thrown directly into the mouth by way of the saliva.

From many estimations and some balances carried out, it may be generally stated that the saliva is composed of—

Carbonate and phosphate of calcium and magnesium.
Chlorids of sodium and potassium.
Phosphates " " "
Mucin.
Serum and albumin and globulin.
Lecithin.
Other fats.

One other property of the saliva is its colloidal absorption property, and its effect on holding in solution the calcium salts beyond the usual solubility point, even after the removal of the CO_2.

Dr. Henry C. Ferris, of New York, who has for years given sympathetic attention to the study of the physical and chemical characteristics of the saliva, has furnished me with a *résumé* of his own work, as follows:

Desiring to study the pathological condition of the oral cavity, I was impressed with the small amount of technical information upon which to proceed, and a further lack of information as to the normal physiological properties of the salivary secretion. Before studying the pathological field, therefore, it was necessary to develop a technique that might establish the normal within physiological limits.

In an effort to develop a technique that would be practical for diagnosis, my first obstacle arose from the fact that 20 cc. was all that could be delivered by an individual within a reasonable time; therefore, instruments had to be constructed that would give readings with a small quantity of specimen. This was experimented upon until I was able to report twenty findings with this quantity of specimen, namely: Quantity of flow per minute, specific gravity, viscidity, enzymic index, proteolytic test, oxydase, free acidity to phenol-phthalein, combined acidity to phenol-phthalein and aldehyd, alkalinity to methyl orange, amino-acids as ammonia, centrifuged precipitates, globulin, Purdy albumin, thiocyanates, chlorin, urea, potassium base, sodium base, total solids and ash.

The technique adopted for determining the length of time for delivery needed careful consideration of the psychic influences and the reflexes due to the excitation of the optic, auditory, and olfactory centers, as reported by Professor Pavlov, in his work on "The Secretory Glands," recently published; therefore the patient was given a book to read and placed by himself in a room which was moderately illuminated, and free from any disturbing noises or odor of cooking food, and then instructed to expectorate (without exercise of the muscles of mastication or contact of the teeth) 20 cc. into a white porcelain cup, as fast as the saliva flowed. An opaque cup was found to be necessary owing to the effects upon the sensibility of some patients of observing the specimen in a clear glass vessel, which had the effect of retarding the flow of these sensitive individuals.

The time of delivery of 20 cc. at a given hour in the day, bears a relation to the consumption of water or the fluidity of the blood, "within physiological limits," as a varying diet will have an influence upon this finding, but with control of the diet I have found this factor to be of diagnostic value, particularly in acute pathological conditions.

In determining the specific gravity, it was found that a modification of a Soxhlet hydrometer was the most practical instrument, as the specific gravity of 2½ cc. could be attained. This was particularly valuable in the analysis of specimens of children under four years of age, when 4 cc. was all that could be obtained, and also in diabetic patients.

The viscidity is difficult to obtain, and the findings are the least accurate of any that are secured in this technical procedure, owing to the fact that the atmospheric conditions have a great influence over this property, as well as the enzymes and the bacteria when the specimen is exposed to the air. In want of a perfect instrument, a crude method, as illustrated in the report of the National Dental Association of America in 1911, was found to be as satisfactory for diagnostic purposes as any. The viscidity varied greatly in the time of day that the specimen was delivered, but seemed at 11 A.M. to be the most constant in the normal subject. The early hours gave the highest findings with a decreasing scale.

It is my belief that more complete information upon the physiological properties of this material and the effect of the nerve reflexes, is of the greatest importance in the solving of this problem.

To determine the enzymic index I adopted the method proposed by Glinski and Walther, as being considered by Professor Pavlov to be the most accurate method of determining the value of this enzyme, and it has proved to be very valuable in determining the ability of the patient to digest starch, and seemed to bear a relation to the total acidity of the specimen, also to the functioning ability of the teeth.

The proteolytic ferments, while appearing in small quantities, were yet proved to be markedly present in the normal specimen, particularly those patients who were large consumers of meat.

While there is a ferment oxydase present in the normal specimen, its presence is detectable only by color reaction, and is very delicate. It is minus in cases with lesions of the oral cavity or general febrile conditions.

In determining the acidity by titration with phenol-phthalein as an indicator, we find this latter to be sensitive to CO_2, and as the gas in the exhaled breath has been shown to vary from 5.3 to 5.7 per cent. we may reasonably feel that these findings are inaccurate as representing true acidity, but repeated tests from the same subject in the same day, and again in successive days at the same hour, show variations within physiological limits and prove to be of value in diagnosing general disorders, and bear a relation to the enzymic value, particularly when the total acidity is taken. When amino-acids are calculated as ammonia, they seem to bear a relation to the chlorin; when the former is high the latter is low, and *vice versa*.

I have used a centrifuge method for determining the precipitates; this, according to some writers in the biological field, is obsolete, but I find it to be helpful in determining the general physical condition of the system. Specimens free from food particles give very

uniform readings, and when Purdy albumin is present are diagnostic of pathological states.

The thiocyanate content of the saliva, over which considerable controversy has occurred, I believe to be important, and from my records such presence is indicative of normal states.

The presence of urea in large quantities is decidedly diagnostic, as it is in the urine.

Potassium and sodium bases, when compared, will often assist the physician when directing diet and in the administration of drugs.

In closing, I can say that by this means I have been able in a number of cases to aid physicians in constitutional treatment, which has resulted in cures—when other methods of diagnosis have failed, and I am firmly convinced that this active fluid or secretion of the body, so easily obtained, will eventually be proved to give more diagnostic information to the student of pathology than is now obtained from the analysis of the excreta or waste products of the body.

The republication in America of the contributions made by the late Dr. Joseph Porter Michaels of Paris, aroused a widespread interest in America in the study of the saliva. The pioneer work of Miller, Leon Williams, and Black on the subject of dental caries had already justified the conclusion that the causes which originate dental caries were to be sought in the environment of the teeth and not in the teeth themselves. The emphasis which the work of Michaels placed upon the idea that the saliva was of constantly varying composition, not only as between individuals, but variable in composition in the same individual at different times, strongly suggested that light upon the unsolved problem of immunity and susceptibility to dental caries could be most hopefully sought for in an investigation of the relationship of the salivary fluids to the etiology of dental caries. Moreover, the dictum of Michaels that salivary composition is a reflex of metabolism at a given time, and therefore an index of the bodily state of even greater significance than the composition of the blood or urine, has aroused a general interest in the subject of saliva study and stimulated research to a degree which is most encouraging, and which will doubtless continue until satisfactory results have been obtained.

Without minimizing the importance of the work already accomplished both as to results and magnitude of labor involved, it is evident that what has been accomplished is but meager in comparison with that which needs to be done. But it is equally true that what has been accomplished furnishes abundant evidence of the extreme importance of the general question of salivary composition, and it cannot be doubted that the recognition of that fact is ample guarantee that the work of salivary investigation will proceed with increasing enthusiasm and larger results in the future.

RELATIONS OF DENTAL AND RHINOLOGIC WORK.

By R. R. DALY, M.D., Atlanta, Ga.

THE physical connection between the fields of dentistry and rhinology is so close as to need no description; nevertheless we have dissociated the two areas involved by the use of the words until we find ourselves thinking absurdly about their related functions.

Terminology, after all, is a decisive factor, and our concepts of the relations of the ailments which the dentist and the rhinologist respectively treat are qualified by even greater separation than possibly the distance between their offices.

THE PUBLIC'S ATTITUDE TOWARD THE DENTIST AND THE RHINOLOGIST RESPECTIVELY.

In the minds of many of the intelligent laity, these two sets of workers are hardly acquainted with each other, and they can never come close enough to clash. There is one bond uniting us, and yet we resent it. Some of our best patrons, when we attempt to secure histories from them or to advise them as to general hygiene, decline to answer or to be advised, because the speaker is "only a dentist," or "only a throat specialist." They do not realize that, as doctors, we are teachers, and teachers for their own good.

My diploma is written in Latin, unfortunately. It is very impressive on that account to some of my patients, but it is not convincing that I am a *doctor* in the true sense. We all, therefore, are classed among the "onlys"; our *ex cathedra* utterances, no matter how solemn, are never accorded their full meed of respect, and they are often received with so many grains of salt as to make them seem almost salacious.

Fortunately, we are accustomed to standing upon our feet, and to having the world below us. We can see and enjoy its humor, and make the most of its foibles.

CO-OPERATION ESSENTIAL.

We can smile indulgently upon the surprise manifested at the wisdom we display, for gradually we are becoming leaders in the great art of healing, and the people are learning to turn for advice to those men who make a study of the diseases of the head and neck. The vast majority of the diseases that burden humanity, leaving aside the venereal, have their origin in or gain entrance through the facial openings, and we are showing that when these orifices and the organs directly within them are put in good order and kept so, the longevity of the race is increased and much is added to the stock of human happiness.

This should and does make us content to get together and do our work, every group correlating its special endeavor with that of every other, and each yielding mutual assistance.

IMPORTANCE OF ORAL HYGIENE IN THE TREATMENT OF TUBERCULOSIS.

My experience with the treatment of tuberculosis in the public clinic of Atlanta proves beyond a peradventure that a cure of this disease cannot be effected unless the teeth are in good order. I have treated case after case of tubercular laryngitis, with apparent success so far as the ulcers were concerned, only to have recurrences almost as rapidly as the patient could return, when the crux of the matter was the foul teeth. A thorough cleansing of the teeth removed the filth so familiar to all of us, changed the character of the buccal secretions from being irritating solutions to such as were nearly normal, and permitted the laryngo-mucous membranes to fight their battle unhandicapped. Moreover, cases in which the foci were all in the lung, and in which supremacy in the battle for life hung upon the aid obtainable from nourishing food, died when the teeth were bad, or recovered when the food was subjected to normal mastication and entered the stomach unpoisoned and in a condition fit for digestion.

I would no more attempt to treat tuberculosis today without the aid of a dentist than without the assistance of good food and fresh air. A set of dirty teeth, even if there is no pyorrhea present, will undo or prevent all the gain the other methods will induce. On the other hand, when the teeth are in bad condition, and nutrition is manifestly interfered with, the observing dentist is in a position to warn the patient as to the dangers threatened by numerous infections, tuberculosis included. Just how this disease is contracted is not definitely proved. We are taught to believe that it is almost entirely an inhalation disease; yet such an able investigator as Dr. Thrash of Atlanta has attracted wide attention to his thesis, which seeks to show that it is primarily through the

alimentary tract that the germs find their way. But whatever may be the avenue, the disease progresses or subsides according to the amount of bodily resistance which it meets. A foul mouth means lowered resistance.

This is true, of course, of any infectious disease, but tuberculosis is the one scourge which is always with us, and constantly presents new problems for us to solve.

NORMAL BREATHING AND THE SHAPE OF THE PALATAL ARCH.

The problems of normal breathing and the shape of the palatal arch present themselves to us simultaneously. The dentist has children come to him with high arches and beginning curvature of the nasal septa, tonsils and adenoids interfering with nasal breathing so as to prevent the tongue from exerting its normal pressure upon the developing arch. The rhinologist has patients presenting themselves who have twisted septa with high arches that he cannot reduce, and others who continue to be mouth-breathers after the respiratory passages are clear, because the jaws do not occlude properly. It does not do for the practitioner of either profession to say to the parents that he has done his part, and that if the child does not breathe well it is not the rhinologist's or the dentist's fault. The child came in the first instance to be cured and be restored to normal, so that it would grow to strong adult life. It is the child and the child alone who is to be considered, and we must see to it that we work together to bring about this result.

It is a waste of time in this day of great mechanical skill to tell parents to let the child outgrow any deformity. There never was a deformity outgrown yet. I defy any man to show me one case where nature unaided has corrected it. It is for us to judge among ourselves after an intelligent combined study of cases as to how much aid is needed.

Will the little septum which is beginning to deviate and to obstruct a nostril so that the child cannot use one side of the nose to its functional limit—will that septum become straight if the upper jaws are pressed apart? Or must we operate early upon the septum itself in order to prevent asthma and lack of nutrition? There is no question that the nares should be free and open so that the turbinates may do their work; but who is to perform the operation, the dentist or the laryngologist? How can we find out, unless we are in closest touch and working together? There are thousands of children in town, and some of them seem to be in the way, but there is not one to be treated thoughtlessly, not one upon whom an unnecessary operation should be performed.

When, after removal of tonsils and adenoids and a careful clearance of the breathing tract, the mouth continues to stay open at night because the jaws still do not occlude accurately, or because the arch is high, who shall say what is to be done but the man who knows whether the increased pressure of the released tongue will adjust those jaws, or whether apparatus must be introduced?

I can never feel satisfied with such cases until they have been examined by the dentist. I cannot induce them all to go, because the people are not yet educated as to this important matter, but I am trying in every case to have the benefit of expert opinion, and to give the child all the chances which we as the custodians of science have to offer.

CHRONIC OR RECURRENT PHARYNGITIS.

This disease or symptom is a common one among adults in our practice, and its cause is often difficult to find; it may be due to troubles situated higher in the breathing tract, or to smoking or chewing. Among the poorer people it is often due to snuff. But more than all else, in my experience, it is due to diseased teeth and gums. This disease may appear in what seem to be the cleanest of mouths, but whenever bridge work or crowns of any character are present, I begin to hunt for troubles in the saliva. This may sound like a wholesale indictment of all such work. I do not mean to

condemn such work, but the dentist knows best himself what may occur at the cervical margin of a crown which cannot, in the nature of things, be fitted absolutely correctly to the abutment, or what may occur beneath a bridge where the dental floss will not reach.

POSSIBLE SOURCES OF FETID BREATH.

Food lodges and decays there, producing an acid reaction, until the saliva is so changed that it irritates the oral tissue, causes more or less foul breath, and produces a pharyngeal condition which attracts the attention of the wrong man. It is a dental proposition pure and simple. This all may sound elementary, and I would not speak of such conditions were they not presented to me so frequently as to warrant attention. No one of us is sufficiently expert always to see all that he is looking at. It is the little things, the things that we think we ought to know as a matter of course, that we really overlook while we are searching for the abstruse or that which only the specially trained eye can see.

One little factor that comes to my assistance is empiric, but it is accurate enough for its purpose, and that is the odor of the saliva. I get it on my tongue depressor, and from it I judge largely what to look for. This odor indicates to me the presence of decayed food and of pus, and it is quite different from that of acute infection of the pharynx. It tells me whether I have to consider the need of dental assistance, and whether the fetor of the breath is of gastric, pharyngeal, or dental origin.

Incidentally, it is well to remember that any instrument used in the mouth and allowed to lie on the table for two or three minutes while another instrument is being used, will have a bad odor even from clean saliva. When a mirror is warmed in a flame or over a lamp, as with laryngologists, the odor will go far to cause gagging, unless all the saliva has been removed. Incidentally, there is only one good method of removing saliva or any other dirt from instruments, and that is the use of soap and running water. I do not like a tray of antiseptic or of boiling water too close at hand. The cooked or the poisoned germs may not be so very harmful, but I do not like the idea of having them put in my mouth or in that of any patient.

THE MAXILLARY ANTRUM, AND ITS TREATMENT.

The antrum is our bugbear, and in serious conditions thereof we have our decided differences of opinion and method of procedure.

In the great majority of my own cases diseased conditions of the antrum are serious because they are a bugbear. In my judgment antral disease is not a dental problem at all. Of course there are exceptional cases in which the whole alveolus has been injured, or malignant disease exists, but these do not concern us at present. The accidental perforation of the antrum in ordinary dental work is of little consequence, if it is allowed to heal promptly and without attention. Even if there is antral irritation, it should be allowed to heal, and the buccal opening should be closed. I have never seen a case of antral trouble get well when there was communication with the mouth. Antral sinusitis is a nasal proposition, and drainage through the nose is the only successful method of treatment.

Barring malignant disease, if reasonable drainage through the nose is established, and the antrum is kept free from irritating fluids—such as saliva and a lot of antiseptics—it will recover. I have several cases of recovery to my credit in which I have done nothing in the way of treatment. The defenceless mucous membrane lining the antrum was simply crying out for a rest, and its real needs had not been recognized.

I am not even making as many punctures underneath the inferior turbinate as I used to. Since I have learned to pack the nares with soft pledgets saturated with argyrol, I have found that I can apply enough of the gentle antiseptic to remain for two or three days,

these dressings being inserted over the normal opening without pain or distress. The proof that the antiseptic reached the antrum lies in the fact that it continues to come out and stain the handkerchief on the third day.

The dentist is to determine whether a tooth is causing the pain that radiates through the side of the face, or whether this pain is due to some other cause. Then the rhinologist is to ascertain whether there is indication of primary antral inflammation. A little combined observation sets both these observers on the right track, and the patient gets the benefit of speedy relief without experimentation in each instance. Will not our credit as good workers increase enough to pay us for the trouble?

CONJUNCTIVITIS.

The subject of conjunctivitis takes us at a leap into a new field, but my experience shows that it is correlated to the mouth and naso-pharynx.

I have had children suffering with persistent conjunctivitis which seemed to be a constantly recurring infection rather than a chronic condition. It took me a long time to learn to see what I was looking at, and realize that the source of infection was a dirty mouth. We have learned to associate conjunctivitis with tonsillitis in children because they often occur together, possibly owing to the same extraneous infection, possibly because of the lowered resistance, and possibly owing to infection which the fingers carry from the mouth to the eye. I have learned that when a dirty mouth and continuous conjunctivitis are associated, the mouth must be cleaned before the eyes will get well.

HEADACHE.

Perhaps the most troublesome cases come to us for the relief of headache. The people have learned that headache often indicates eye-strain and come to us on that account. That is easy to determine, but in a large percentage of cases some other cause must be looked for. It is our duty, then, to determine the etiology of the trouble. But here again I often meet with the public's reluctant attitude spoken of before. For when I begin to make further search into the disturbed physiology of the patient, I am met with rebuff until I have translated my Latin diploma and perhaps shown my registration certificate. The wonder is that we do not lose patience, but the problem is interesting, and the sufferer is there for relief, not for words or labels.

A TYPICAL CASE.

I will relate one case which shows the complexity of interrelations. Headache was the first symptom complained of; it was not due to the eyes. Then there was complaint of stomach pains, loss of appetite, etc. This was followed by pains in the joints, sleeplessness, bad dreams, bad breath, ideas of poisoned food, and a dozen other indications of hypochondria or manic-depressive insanity. Perhaps it would have been well to stop after this diagnosis, and let the label carry the responsibility to someone else, but no relief had been granted, and that was sought.

The combination of these symptoms pointed to the mouth, and there the search was made. The saliva had a bad odor, especially when the least heat was applied. There were several crowns and considerable bridge work, all seemingly well done. To the ordinary observer the gums looked fairly healthy, and the patient was manifestly tidy with the brush.

But expert examination showed pyorrhea alveolaris in over a dozen teeth, and dental care was at once instituted as the only means of relief. The urine was loaded with indican, and there was a general toxic condition that accounted for all the other symptoms. Subsequent recovery relieved us from further search.

TUBE TEETH AND PORCELAIN RODS: THEIR USES AND ADAPTATIONS IN PROSTHETIC DENTISTRY.

By JOHN GIRDWOOD, D.D.S.Univ.Pa., L.D.S.Edin., Edinburgh, Scotland.

(Continued from vol. lvi, page 1344.)

(IX.)

CHAPTER XI.—The Use of Tube Teeth in Plate Work.

In dealing with this subject no consideration will be given to the construction of metal plates, but attention directed at once to the fitting of tube teeth, and it is to be understood that struck plates are here referred to.

Assuming the case to be that of an upper where the third molars and canines alone are left standing, and that the amount of absorption is such that the case could be satisfactorily dealt with by the use of plain teeth, suitable teeth should be chosen for the incisors, care being taken that they are long enough and of the right width to fill the space. The color, however, is the most important matter, as it will be seen from what has already been said in connection with the subject of shaping and grinding, that teeth of whatever size, provided they are large enough and of the right color, can be shaped to the requirements of any case. The first step after having chosen the teeth is to rough-fit the two central incisors to the plate, and having removed all débris from the tubes and melted a thin layer of wax on to the front of the plate, the two incisors should be slightly heated and carefully stuck in position (Fig. 153); the marker (Fig. 154) should then be passed down the tube of each tooth in turn, and the point pressed into the plate, while the instrument is being rotated. While doing so the teeth should be firmly held in place with the forefinger and thumb of the left hand, so as to steady them and prevent their position from being altered. Another way of marking the pins is to touch the end of a marker with vermilion paint, and for this purpose a piece of pin-wire tapered and rounded at the point answers well. This should be passed down through the tube, where of course it will show a red point on the plate. The operator being satisfied that the position of each pin has been duly marked, the teeth should be removed from the plate by slightly heating it over a Bunsen flame and clearing away all traces of wax from plate and teeth. Having replaced the plate upon the model, hold it firmly in position with the left hand, while resting the model against the bench-block, and with the graver deepen the marks previously made. The holes for the pins should next be drilled, and in order to do this use a drill a size smaller than the pin wire. Pliers are sold for the purpose of punching these holes, but they should not be used, especially by the inexperienced, as their use involves a danger of bending the plate. When the pinhole has to be made on a steeply sloping part of the plate and not on the top of the ridge, considerable care and skill are required to prevent fixing the position of the pin too far down on the slope. In order to avoid this a good plan is to use a small drill, and afterward enlarge the hole for

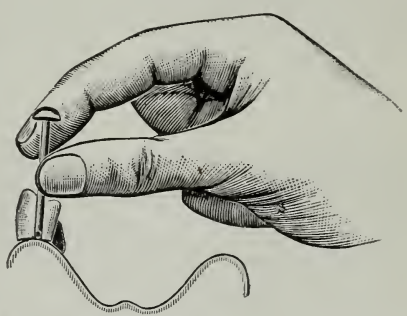
the pin by means of the broach, using the tooth as a guide. The broach used should be either a size smaller at its thickest part than the pin wire, or have a mark made on it to indicate the point beyond which it cannot be used without danger of making the hole too large or of splitting the tooth. The bur made by the drill and broach should be removed by the scraper or graver, and the pinhole slightly countersunk on the palatal surface. A length of pin wire is now taken

Fig. 153.

Shows centrals stuck on plate, ready for position of pins to be marked.

and passed through the tooth, and a piece a little longer than the tube cut off with the cutting pliers. Next grasp the pin with a pair of roughing pliers, file the end of it to a three or four-sided shape, and slightly taper it to enable it to hold firmly in the hole during the soldering process. All pins should be prepared in this way and placed on the bench, each one opposite its corresponding tooth. The pinholes are now painted with borax, as well as the pins. Grasp each pin with the roughing pliers, and firmly force it into the pinhole in the plate, taking care to give it the right direction—and until much experience has been gained it is best to solder not more than two to four pins at one time, but the experienced workman will have little difficulty in soldering as many pins as may be required at once. Having satisfactorily fixed the pins in place, proceed to solder them in the following way: Place a small piece of solder on the plate, touching each pin; then place the plate on the soldering block, or on a good-sized piece of asbestos fiber, where it will rest steadily, taking care that the pin or pins to be soldered are in a vertical position. Now heat up the plate

Fig. 154.



Method of marking position of each tooth.

carefully and slowly with the blowpipe, so that the borax in fusing does not displace the solder. The plate must be heated-up until the solder flows, and should it be found on examination of the palatal surface that the solder has not flowed through, heat up the plate thoroughly, center the flame on to the ends of the pins on the palatal surface, and carefully draw the solder through. In soldering the pins to the plate, a lower grade of solder may be employed than has been used in any other part of the work, because this is usually the last soldering that requires to be done, except the case is one in which flat teeth have been used, when they are generally soldered last, and pins for the tube teeth are protected by investment. It is a matter of considerable importance to have the pieces of solder of the right size. Too much solder will interfere with letting the tooth down over it, and have to be cut away, while too little will leave the attachment of the pins to

the plate too weak. The correct amount should be sufficient to solder the pin to the plate and surround it on its lingual surface with a slightly beveled collar, which will add to its strength. The beginner invariably errs in using too much rather than too little solder.

The plate should now be boiled in pickle to remove the borax, and any excess of solder or slight projection of the pin on the palatal surface should be cut off with a half-round graver, or ground off with a small stone so that the plate may go home to place on the model. The teeth should now be tried on the pins to insure that their direction is right, as

Fig. 155.

Central fitted to gum with plate cut away.

during the soldering process this may have been slightly altered. But if that end of the pin attached to the plate is right, any alteration which may have taken place in the soldering can only affect its direction, and this may be rectified by grasping the pin with the pin-bender or a pair of pliers close to the surface of the plate, while it is held firmly on the model, so bending it into line.

There are other methods employed of uniting the pins to the plate, such as investing and then soldering, or tying them to place with binding wire. The method given is, however, the simplest, and yields entirely satisfactory results.

Having got the pins soldered, the teeth are to be tried until it has been ascertained that they are correctly placed. Slight bending may be required to adjust them satisfactorily. Their free ends may now be cut down to the bite, and any excess of solder around the base of the pins which might prevent the teeth from getting home should be cut away, but if the correct quantity of solder has been used this will not be necessary. The steel countersink may now be used to countersink the base of the platinum tube tooth, or this may be done with a Butler's point in the case of a non-platinum tube tooth. The two tube centrals should now be let farther down to fit the plate, and the lateral incisors treated in precisely the same way as the centrals. If the teeth are to be set on the gum and not on the plate, the latter should be cut away as in Fig. 155, allowing the porcelain to project about one-sixteenth of an inch beyond the edge of the gold. Unless the teeth are too narrow in the base, this will not interfere with the strength of the attachment between the pin and the plate. The teeth should be ground in the manner described in connection with fitting tube crowns, until they accurately fit the plate, and their cervico-labial margins are adapted in like manner to the model, the operator taking care in doing so to note that they are left of a proper length and made to conform to the bite, while the pins are at the same time filed or ground flush with the lingual surface of the teeth. The teeth cannot be considered as fitted until there is not the slightest visible space between them and the plate. In fact, the gold should appear as if it were cast on to the tooth. Accuracy with regard to the fit of the teeth to the plate not only shows workmanlike skill, but has the practical advantage of lessening the risk of the rotary motion of the jaw loosening the teeth, a possible accident which might occur if they are not steady on the pins.

After the pins have been soldered to the plate, and the fitting of the teeth is being proceeded with, one or more of them may be found to "bind" as they touch each other, and this will necessitate a little of the contour being ground off; or the reverse may be the case, and some of the teeth may not touch, and

adjustment of the pins will be required to obtain points of contact.

Having fine-fitted the teeth to the plate, their ground edges will be a little rough, and these should be smoothed off

FIG. 156.

Model showing case suitable for bridge, while patient preferred plate. Canine devitalized; cap and tube shown in place. Molar with gold inlay hollowed out to accommodate spur on plate.

by slightly touching them against the sides of a fine and fast-running wheel.

The fitting of the grinding teeth should be carried out in the same manner as already described in connection with

FIG. 157.

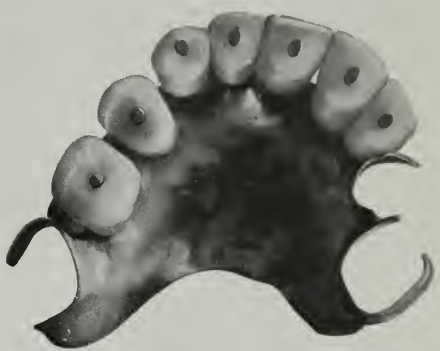
Small gold plate with three tube bicuspids, pin attached to plate to enter canine tube. (Pin not shown in illustration.)

the incisors, but some operators prefer to have them touch along their approximal surface from the plate to the grinding surface, as thereby particles of food do not easily lodge between them, and there is much to be said in favor of this method.

FIG. 158.

Partial upper gold plate with tube teeth; labial view.

FIG. 159.



Lingual view of plate in preceding illustration.

FIG. 160.

Partial lower gold plate.

When a tube tooth has to be fitted against a clasp, it is well to reduce it to nearly its proper length before grinding off the side to fit the clasp, and only

about half of what will require to be ground off should be removed before the pin is soldered to the plate. Further, in marking the position for the pin, the base of the tooth should be held close up to the clasp at its neck, unless it be a type of tube tooth much contracted at the neck, as some tube bicuspids are. This will incline the tooth a little away from the clasped one. After the pin has been soldered to the plate, the former should be bent slightly toward the clasped tooth, when it will be found that the tooth will not go home to place, but press against the clasp. Mark where it rests, and grind carefully away, taking care not to grind away from the neck of the tooth but toward it. Bend the post still farther toward the clasped tooth, and repeat the process of grinding and bending the post until the tooth is in proper line, when it will be found to lie closely against the clasp. (Figs. 156 to 160.)

Double-tubed Rods.

The use of double-tubed rods has been dealt with in treating of crown work, and the advantages claimed for them in that connection apply also in certain cases of plate work. The class of case most suitable for their use is where the bite is abnormally close. The method of fitting them is in all respects similar to that already described in connection with single-tube teeth or tube rods, and the only point which calls for special mention is the method of fixing the pins to the plate. There are two methods whereby this may be done, and that which calls for the least amount of skill and which yields the desired results with very little labor will be first described. After the block has been fitted and cut off to the required length, it should be fixed in position on the plate by means of sticky-wax, the position of the pin determined as before described, the hole drilled, and the pin soldered, the pin nearest the front being the first to be soldered. If by chance the position of the porcelain block should be found to be a trifle too far away from the tooth anterior to it after the post has been soldered, this can easily be remedied by cutting off the pin and resoldering a fresh one. If, on the other hand, it should be a trifle too close to the adjoining tooth or space, sufficient of the excess can be ground off; but with ordinary care such a mishap should be impossible. Special care should be observed to make certain that the direction of the first pin is correct, and that it has been given the necessary inclination toward the center line in the case of the upper, and in the lower placed vertically, as it is important that no subsequent bending of the pin should be necessary. Having now fixed the first pin satisfactorily, the second or posterior pin is adjusted, as in the case of a single tooth.

The second method is to adjust and solder both pins at once, and while this is very easily done, it requires more care and skill than the method already described. The block is to be fixed as before, and the position of both pins carefully marked on the plate. The pin for the first should be firmly fixed by forcing it to place with the roughing-pliers, or a temporary pin employed, and the hole for the second one enlarged with the broach passed through the tube, which thus acts as a guide. Having prepared the posts and their sockets, adjust them so that the block can be slipped off and on readily, then solder them without investing.

The subsequent steps are the same as those already described in crown work.

Repairs in Plate Work.

The repairing of a gold plate with tube teeth is an easier matter than where the teeth are soldered, as the teeth, being usually fixed on with sulfur, can be easily removed,* and in consequence the danger of fracture while soldering is obviated, while at the same time the investment can be much more quickly heated up, and in certain cases can be dispensed with altogether. In cases of

* This subject will be dealt with in a subsequent paper.

close bite and where there are several detached teeth, tube teeth are peculiarly well suited, for the above reasons, as well as for others stated elsewhere.

In the case of replacement of a broken tooth only, the procedure is similar to that of fitting a tube tooth as described in "Crown Work," Chapter IX.

apparent to those who have followed the arguments advanced in their favor, and it is therefore unnecessary to elaborate these further, though additional confirmation may be obtained from the accompanying illustrations.

With regard to the selection of suitable teeth, this presents fewer difficulties

FIG. 161.

CHAPTER XII.—THE USE OF TUBE TEETH, GUM TUBE TEETH, AND SECTIONS IN VULCANITE WORK.

In dealing with this subject the writer proposes to describe briefly the use of the above-named teeth in connection with vulcanite as a base, as well as combination dentures, which include metal plates —usually gold—with vulcanite attachments, vulcanite plates with metal linings, etc. The suitability of these teeth for use in the above manner will be

than in the case of ordinary plain teeth, or indeed of teeth of any other type, for various reasons, one of which is that the method of attachment permits of much greater amount being ground off without the danger of impairing or destroying the anchorage.

The method employed in arranging tube teeth is similar to that followed in connection with other forms. They have, however, this advantage, that they allow of greater freedom in the matter of arrangement than plain teeth, for the

reason that they can be set at a greater angle to one another without the risk of showing vulcanite, and so obtain the advantage possessed by teeth which do not require a vulcanite or metal backing (Fig. 161), their closest rivals in this respect being countersunk teeth. The teeth are set up in the usual way, but before the case is flasked the tubes should be filled with wax, in order to prevent plaster from flowing into them while the case is being invested. Fig. 162 shows an upper case ready for packing, and before doing so suitable posts (Fig. 163), such as those supplied by

Fig. 162.

Upper case ready for packing.

Messrs. Ash of London,* should be cut to the proper length and fitted to the tubes. Before fixing them in place small pieces of rubber should be packed into the tubes and the posts slightly heated, and pressed home to place: this insures the posts being covered with rubber, and a secure attachment being obtained.

The foregoing is the method employed in most cases, but certain conditions may exist which will necessitate modification. If, for instance, it is seen when the teeth are being set up that there is apparently too little room for the heated posts between the base of the teeth and the model, sufficient space may be obtained by hollowing out the base of the teeth, which should be set up with the pins in place, before investing. In certain partial cases the teeth cannot be brought away in the upper half of the flask, but must be covered by the investment in the lower half. Here a difficulty may arise with regard to the rubber not flowing around the posts in the tubes. This may be overcome by filing a little off one side of each of the posts to allow the rubber to fill the tubes, or by filling the tubes and surrounding the heads of the posts with rubber before investing, as already described, when most or all of the rubber surrounding the heads of the pins may be removed and replaced by fresh rubber while the case is being packed; or the teeth may be removed before the case is

Fig. 163.

Ash's aluminum alloy post, roughened.

invested, and in order to facilitate their removal without altering the position of the posts, the base of the teeth should be oiled to prevent the wax from sticking to them. The case should then be invested without the teeth, the pins being securely held in the investment, and after being vulcanized the plate should be finished in the usual way, the teeth being either cemented to place before the case is finished or stuck on temporarily with hard wax during the finishing process, otherwise the edges of the vulcanite sockets may be too much rounded in finishing.

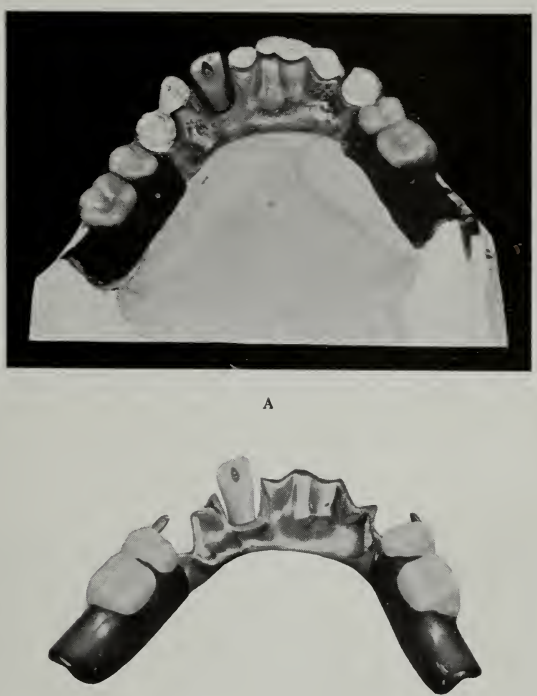
Another method is to coat the pins and interior of the tubes with plaster or whiting, and thus prevent the rubber from flowing into the tube, and after vulcanizing—but before finally finishing the plate—remove the teeth, and afterward fix them on with cement.

Combination plates of gold or other metal wherein vulcanite is employed as

* These posts are made of an aluminum alloy, which does not oxidize during the vulcanizing process.

a means of attaching the teeth to the plate, as well as vulcanite plates with gold or wire strengtheners, afford equal opportunities for employing tube teeth or gum tube teeth or sections, while in addition they permit of their use in certain cases whereby their peculiar advantages are made available; Fig. 164 shows a partial lower combination plate where plain teeth with vulcanite attachments have been used to supply the grinding teeth, while the missing lateral is supplied by a tube tooth. Here the advantage of the tube tooth is apparent, and for several reasons. Owing to the canine having moved backward, a space has been left between the canine and central, too small to permit of the use of two normal sized teeth, yet too large for one, without the risk of showing the metal backing or vulcanite attachment. Moreover, the probability of having to replace such a tooth owing to fracture, shortening of the tooth due to the sinking of the plate, etc., is greatest where an isolated tooth is concerned. By employing a tube tooth we insure easy replacement, without the necessity of soldering or vulcanizing, while at the same time there is the advantage to be derived from an all-porcelain tooth, and the peculiar advantages which result from the employment of the tube form. Where one or more tube teeth are used in the manner described, the attachment should be by means of cement or sulfur, but where the whole of the gold is covered with vulcanite, the attachment may be carried out by its means, although generally speaking it is best to cement the teeth

FIG. 164.



A

B

Partial gold and vulcanite plate. A, On model. B, With isolated tube teeth.

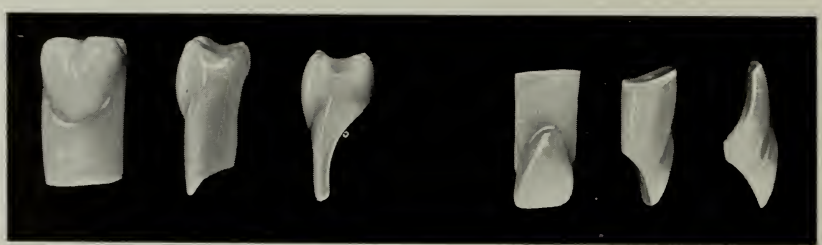
on to the pins after the case is vulcanized. Instead of pins depending upon vulcanite for their anchorage, pins cast with the gold plate or soldered on to it may be used. This method necessitates the use of a face bite, in order to obtain the correct position of the pins, which may

Fig. 165.

Tube teeth with cone-shaped base.

be of gold or dental alloy. The pin should be roughened to afford a hold for the cementing medium, but the porcelain tubes are rough enough to afford the necessary hold. In the case of the grinding teeth, it is an advantage to make them slightly cone-shaped (Fig. 165), as thereby there is less risk of undermining them—particularly on their lingual surface during the finishing process—than when their surfaces are parallel or nearly so. The vulcanite should always be carried up about a sixteenth of an inch from the base of the teeth on their lingual surface. This furnishes a socket and permits of a better finish being obtained. When the plate is of gold and vulcanite, the provision for attachment of the vulcanite to the gold may be by means of catches in the ordinary way, or the pins for the teeth or sections may be soldered to the plate, when the surfaces to be covered by the vulcanite need only be roughened by means of a graver, as the pins and teeth will afford ample hold. Wire strengtheners may also be used to carry one or more teeth in a similar manner to that suggested in connection with gold plates or strengtheners, and experience of individual cases will decide as to the advisability or otherwise of employing a combination of soldered and detached pins. When it is intended to remove the teeth after vulcanizing, and set them with cement, the pins should not be roughened until after the plate has been finished. The removal of the teeth may be readily effected by heating them slightly, when by means of a pair of forceps, the blades of which are covered with lead in order to avoid the danger of damaging the teeth, they may be readily detached without danger of disturbing the pins, if reasonable care is exercised. In fact, the teeth can often be dislodged without heating if the precaution has been taken to coat the interior of the tube with plaster or whiting before vulcanizing.

Fig. 166.



A B C A B C

Single-gum tube molar and central. A, Front view. B, Side view. C, Tooth cut away for vulcanite attachment.

The application of single gum tube teeth or gum tube sections is carried

out on the same lines as in the case of single tube teeth, and the jointing of the various sections is done in the same manner as with ordinary gum sections. There is this difference, however, in connection with their preparation for the purpose of using them in connection with vulcanite only, or with a metal plate with vulcanite attachment, that ordinarily a certain amount must be ground away from the base of the lingual surface to permit of a sufficient amount of vulcanite underneath the blocks (Fig. 166), and for metal catches when a metal base or strengthener is employed. Instead of the ordinary form of catches, some of the pins may be soldered, and these will serve to anchor the vulcanite to the plate, as already pointed out, or the pins may be of the ordinary headed variety, and these will serve to anchor the sections to the vulcanite. The amount of vulcanite need seldom be so great as in the case of ordinary gum sections.

In cases of accident, necessitating repair or renewal of one or more teeth or sections this may be carried out without the necessity for vulcanizing.

Replacement of a tube tooth or gum tube section is usually a much more simple matter than in the case of plain teeth, or ordinary gum sections, for the reason that the tooth, or what remains of it, provided it has been fractured, may be easily removed, and a new tooth or section fitted and cemented to place.

In the event of the post being broken, a new post will require to be vulcanized in its place. It seems almost superfluous to remark that tube teeth and sections may be used along with all other forms of teeth or sections.

(To be continued.)

ORAL PROPHYLAXIS AS TAUGHT AT THE FONES SCHOOL.

By Mrs. T. A. GANUNG, Bridgeport, Conn.

(Read before the New Hampshire Dental Society, at its annual meeting, at Weirs, N. H., on June 18, 1914.)

IT has been my privilege to be a member of the first class that has ever been formed, I believe, for the study of Dental Hygiene. Dr. A. C. Fones of Bridgeport formed this class. Dr. Fones has had this subject deeply at heart for many years, and this past winter has given much time and personal effort and has gone to great expense to offer thirty-two women the opportunity of taking a practical course in dental hygiene, including a series of notable lectures, which are to be the subject-matter of a text-book, and about eight weeks of practical work. The lecturers included such well-known men as—

Prof. R. C. Osborn of Barnard College: Anatomy.
Dr. A. M. Prince of Yale: Physiology.
Prof. L. F. Rettger of Yale: Bacteriology.
Dr. R. H. W. Strang of Bridgeport: Special Anatomy of the Head and Jaws.
Dr. G. M. McKee of New York: Dermatology.
Dr. E. C. Kirk of Pennsylvania: Oral Secretions and The Psychology of Handling Children.
Dr. Miner of Harvard: Inflammation.
Dr. E. H. Smith of Harvard: Dental Caries.
Dr. M. L. Rhein of New York: Alveolar Abscess.
Dr. R. J. Hutchinson of New York: Pyorrhea Alveolaris.
Dr. R. Ottolengui of New York: Orthodontia.
Dr. C. R. Turner of Pennsylvania: The Teeth as a Masticating Machine.
Dr. R. H. Chittenden of Yale: The Chemistry of Food.
Dr. M. I. Schamberg of New York: Oral Surgery that Might Have Been Prevented by the Dental Hygienist.

Dr. E. S. Chayes of New York: The Sanitary Aspect of Dental Operations.
Prof. C. W. Crampton of New York: Personal Hygiene.
Prof. I. Fisher of Yale: Posture and Fresh Air.
Dr. W. G. Anderson of Yale: Lengthening the Life of the Resistive Forces of the Body.
Dr. T. Hyatt of New York: Teaching Dental Hygiene to Children.

And last but not least, Dr. A. C. Fones, who gave us five very instructive lectures on Dental Prophylaxis, and who personally instructed each woman in the practical work and gave each the benefit at all times of his broad experience in dental prophylaxis.

RANGE OF LECTURE COURSE.

These lecturers, wherever possible, illustrated their lectures with pictures to bring out the specific points, and vividly presented the clinical phenomena of alveolar abscess, pyorrhea alveolaris, malocclusion, etc. The impressions left with the pupils by Professor Crampton of New York and Dr. Anderson and Professor Fisher of Yale were very pleasing, making them anxious to take advantage of nature's gifts, *i.e.* fresh air and water, correct posture, breathing exercises, sleeping out of doors, etc. Professor Anderson of Yale, after his talk, took the class out on the gymnasium floor at Yale and instructed the pupils in some valuable exercises. One might say, What has posture, breathing, exercising, sleeping out of doors, etc., to do with dental hygiene? Yet all these factors affect the blood supply, and good blood supply is certainly necessary for healthy gum tissue and a generally healthy mouth.

PRACTICAL ROUTINE PROPHYLAXIS.

Our big aim in dental hygiene is prophylaxis, *i.e.* prevention of caries and disease resulting from caries and unclean mouth conditions. We are anxious to help our patients to an understanding of the importance of cleanliness of the mouth at all times, by the aid of prophylactic treatment and proper brushing of the teeth. By proper brushing we mean a thorough brushing of the teeth and gums; emphasis is to be laid on the gums, because if the gum tissue is kept clean we are fairly sure of keeping the teeth clean also. By artificially increasing the blood supply to the gum tissues, we also increase the blood supply around the roots of the teeth. This artificial stimulation means perfect oxidation, thorough removal of waste material, and increased resistance of these tissues; therefore gum brushing is considered to be exceedingly important. This brushing is to be done according to instructions given individually to all patients, requesting them to brush their teeth so that the prophylactist may observe and criticize. This exercise is repeated at least four times a day, and *every* day, the brushing to be followed by the use of dental floss at least twice a day, rinsing of the mouth with lime-water, and finally rinsing with plain water. The use of dental floss and lime-water is especially urged in conjunction with the brushing before retiring, as the sleeping period is the ideal time for the microorganisms to do their destructive work, an unclean mouth being an ideal incubator for germ growth, presenting as it does, decayed food, darkness, heat, and moisture.

We hope and expect that when children are brought to the dentist for prophylaxis early in life, even at the early age of four years—according to health conditions and temperament—before dental caries starts, and when these children obey instructions as to the home care of the mouth, we may be able to prevent at least 90 per cent. of dental caries, do away with the fear of the dental chair, and make prophylactic treatment no more to be dreaded than a shampoo or a haircut, with this difference—that the prophylaxis is vastly more important to general health.

TESTS REGARDING THE VALUE OF DENTAL HYGIENE.

Experiments and tests have been made in institutions and schools, notably in

St. Vincent's orphan asylum in Boston, and one of the grade schools in Cleveland, as to the value of dental hygiene. One of the most striking features of the St. Vincent's orphan asylum test was that, while there had previously been annually from eighty to one hundred cases of sickness among the children due to infectious disease, after the children had their mouths put in order and kept under monthly dental inspection and treatment, the sick list was reduced to six cases of measles and one of diphtheria in the eighteen months ending in December 1913. These cases occurred in children who had been recently admitted and had contracted the disease outside. On examination, these children were all found to have very bad mouth conditions.

Miss O'Neill, principal of the Cleveland school mentioned, gave a lecture before the Fones class on the wonderful results obtained in her school. Thirty dull, backward, unhealthy children were selected, their mouths put in good condition, and monthly dental inspection and treatment instituted, these children fully obeying instructions as to brushing and home care of the teeth. By this test it was proved beyond a doubt that constant attention to mouth conditions is of the greatest possible benefit to general health and happiness. In both these test cases mentioned, the improvement amounted to from 60 to 99 per cent. in general condition and studying ability; the children became more self-respecting and took pleasure in helping other children; bad boys were changed to good boys, dullards into good students. Dr. White of the New York State department of Health, has carried out experiments along this line, and has noted in all cases an improvement of from 60 to 90 per cent. in general condition. If after their mouths have been put into healthy condition, and are kept so, children acquire from 60 to 90 per cent. more efficiency in school work, it would seem as if free school clinics would have to be established for the sake of economy.

Aside from the children, adults come in for their full share of instruction and help to better ways. The mouth is the gateway to the human body, and if we will but reason out that passing food through unclean and decayed teeth means passing poison to the stomach, where it is absorbed and carried through the entire system, we readily see the need for insisting on clean teeth and prevention of caries. We all know people to whom we would like to say that "A man is known by the teeth he keeps." Dr. Neff, an authority on tuberculosis, defies anyone to cure or improve a case of tuberculosis if the patient has decayed teeth. In the lectures this past winter, the pupils of the Fones class have been shown many cases of ill health which were all traced to bad mouth conditions, pyorrhea alveolaris, alveolar abscess, etc.

PRACTICAL COURSE IN MOUTH SANITATION.

After finishing the lecture course, practical work was commenced by first using manikins with rubber cheeks and tongue, two full sets of teeth, and movable jaws. By a couple of weeks of daily practice on manikins the pupils became familiar with handling the instruments and the patient properly. The pupils were taught a system of going over the teeth with instruments and porte-polishers, the correct position of holding instruments, the best fulcrum points, and the sequence of the teeth to be cleaned. For first practice, the manikin teeth were thoroughly pencil-marked, which gave the pupil practice in polishing with an orange-wood stick. For the next exercise, the teeth were covered with deposits, which were to be removed, so as to give the pupil instrument practice. Each pupil had to pass an examination in every stage of the work. The next step consisted in cleaning children's teeth. The class cleaned between seven and eight hundred children's teeth, each child receiving thorough instructions as to brushing, and demonstrating with his brush that he had understood the instructions given. When the children brought no brushes

with them, Dr. Fones furnished them therewith.

Some very amusing and some rather pathetic incidents occurred. One day a boy presented his appointment card, and it proved to be dated for the day before. When asked about this, he replied, "Well, I'm not Billy Jones, but Billy didn't have to give up his ticket yesterday, and we thought I might get my teeth cleaned on it too." Needless to say, his teeth were cleaned. I asked one of my little patients one day if he had his tooth-brush with him, whereupon he produced from his pocket a rather hard-looking brush, well worn and far from clean. I started giving him instructions in brushing, while his brush was soaking. Conscience apparently bothered him, for he finally stammered, "Eh! that isn't *my* brush; it's my uncle's, but he lets me use it." He was then given a brush for his exclusive use upon the promise that he would keep it as his own property. In practically every case the children were anxious to learn to care for their mouths, and we hope that we drilled them sufficiently in brushing so that at least a large percentage of them will be greatly benefited.

The practical work was finished by cleaning adults' mouths, and many advanced cases of tartar deposits, pyorrhea alveolaris, etc., were found.

In this training the pupils are taught to attempt nothing beyond prophylactic treatment, *i.e.* cleaning, but these cleanings are to be most thorough, not a hasty running over the teeth with a rubber cup in the engine, but a thorough removal of all tartar and stains by careful instrumentation, followed by a thorough polishing of the tooth surfaces, labially, bucally, lingually, above and below the gum margin, with an orange-wood stick dipped in fine powdered pumice and hydrogen dioxid, taking care to reach the approximal surfaces, then using dental floss dipped in pumice for reaching approximal surfaces difficult of access, and finishing up the grooves and fissures of the occlusal surface with the bristle brush in the engine.

After finishing a prophylactic treatment, improper conditions, such as poor crown and bridge work, pyorrhea conditions, and suspicious points where trouble might arise, are to be carefully noted, and all such cases are to be reported to the principal for his attention. The Fones pupils hope and expect that by conscientiously following the principles of their training they will be of good service to both the dentist and mankind generally.

On June 5th the class formed the Connecticut Dental Hygienists' Association, and on the same day fitting graduation exercises were held in the Fones schoolroom, which on less festive occasions presents the appearance of an interesting operating room fully equipped with sixteen chairs, lights, sterilizing equipment, etc. Many of the lecturers were present on this occasion to wish every good fortune and success to the first class in Dental Hygiene, which extended to Dr. Fones sincerest thanks for his untiring efforts in helping them to a very interesting and beneficial course.

BACTERIA OF THE MOUTH, AND THEIR RELATION TO SYSTEMIC DISEASE.

By F. E. STEWART, Ph.G., M.D., Philadelphia, Pa.,
PROFESSOR OF MATERIA MEDICA, DEPARTMENT OF PHARMACY AND CHEMISTRY, MEDICO-CHIRURGICAL COLLEGE, PHILADELPHIA.

(Read before the Susquehanna Dental Association of Pennsylvania, at its annual meeting, Delaware Water Gap, May 26, 1914.)

THIS paper is not intended to be an original contribution to knowledge, neither does it present my personal views or opinions. It is a compilation of the results of many observers concerning the origin of oral sepsis, its effects on the health, its prevention, and brief reference to its bacterin treatment.

THE CONSTANT PRESENCE OF BACTERIA IN THE MOUTH.

It is said that thirty kinds of bacteria have been found in the oral cavity. In fact, Miller,* in his book published over twenty years ago, claimed to have isolated "more than one hundred different kinds of bacteria from the juices and deposits in the mouth." The staphylococcus and streptococcus are permanent residents; the pneumococcus is found in about ninety per cent. of persons examined; and other germs are so frequently present as guests, that to find them there is not at all surprising.

As a rule, these bacteria do us no harm. They live with us as commensals or messmates, deriving their sustenance, like dogs, from the crumbs which fall from the master's table. But, like dogs, they sometimes turn and bite the hand that fed them.

As already stated, the mouths of ninety per cent. of healthy persons examined showed the presence of the pneumococcus. This organism lives on particles of food, cast-off epithelial cells, etc., and usually does no harm; yet it may become the causative factor of pneumonia, may take part in producing pulmonary phthisis, is one of the invaders in pyorrhea alveolaris, and one of the important factors in the production of rheumatic symptoms.

EXPLANATIONS FOR THE PATHOGENICITY OF BACTERIA.

The streptococcus, also ordinarily a harmless saprophyte, may cause oral sepsis, erysipelas, puerperal fever and septicemia or blood poisoning, streptococcic sore throat, acute rheumatic arthritis, endocarditis, and many other affections.

These facts are significant. Why should these apparently harmless microorganisms become under certain circumstances the deadly foe of man? The answer to this question is very important to the health and life of the community, and of special interest to the practitioner of dentistry, because the mouth is a place where these organisms may learn to become parasites, and be changed from useful servants to deadly enemies. Streptococci are useful servants when they aid in giving flavor to butter and cheese, but when they are transmuted into pathogenic or disease-producing bacteria they are indeed dangerous to health and life. E. C. Rosenow* has been able to convert hemo-

* Miller, "Micro-organisms of the Human Mouth," 1890.

* E. C. Rosenow, *Journ. Infect. Diseases*, 1914, xiv, 1.

lytic streptococci into streptococcus viridans and other forms, and to change these about almost at will. Possibly every kind of bacteria started as a harmless saprophyte and owes its pathogenic form to transmutation occurring in the animal body.

Most bacteria, if placed upon living tissue, are unable to attack it, and soon die; but if they are placed upon the same tissue after it is dead, they feed upon it readily. Most bacteria are therefore saprophytes or feeders on dead organic matter.

Bacteria live, grow, and multiply by converting the organic matter upon which they feed into bacterial tissue. This they are able to do because the protoplasm of which they are composed has inherent within it the power of ingesting, digesting, and assimilating food.

Prof. Randle C. Rosenberger* of the Jefferson Medical College, Philadelphia, believes that it is the number of the bacteria and not their types that bring about a condition of sepsis in the mouth. If the mouth is not properly attended to, food particles and desquamated cells tend to increase, and this makes an exceedingly rich pabulum for the multiplication of bacteria. As a result, products of decomposition and fermentation are formed, and perhaps minute erosions or ulcerations make their appearance, thus giving the bacteria an opportunity to obtain a foothold and grow in the mucous membrane or dental tissues. It would seem to me that it is the character of the bacteria, as well as the number of bacteria, that makes them dangerous. A bacterium—the tubercle bacillus, for example—that learns how to digest living human tissue at once becomes a man-eater, like the tiger that has tasted human blood.

Having become a man-eater, the bacterium greedily devours the tissues upon which it is placed, and except for the defensive powers with which the tissues are endowed, this destructive process would rapidly continue until the entire body of the infected individual would be consumed.

The tissues have the power of defending themselves against bacteria by producing enzymes and so-called anti-bodies (amboceptors, opsonins, bacteriolysins, etc.) which digest and destroy the bacteria. These enzymes are produced in response to the stimulating action of the bacterial split products upon the body cells of the infected individual.

VAUGHAN'S EXPLANATION OF BACTERIAL SPLIT PRODUCTS.

What do we mean by "bacterial split products?" Let us turn to Prof. Victor C. Vaughan for an explanation.

Vaughan* calls attention to the fact that bacteria and tissue cells are living proteins, and the digestive action of one on the other is a proteolytic digestion. The breaking-up of the proteins by enzyme action splits the protein molecule into two or more portions, one of which is a poison. This poison is set free to a greater or less extent, and to the extent that the poisonous portion of the bacterial protein is set free by tissue-cell digestion the infected person is poisoned. In this way he accounts for the toxemia of the infectious diseases.

This poison, however, is not specific. It is the same in relation to all proteins. The specificity of the digestion lies in the secondary portion of the protein molecule.

It is well known that a state of immunity frequently exists in those who have recovered from certain infectious diseases. According to Vaughan, when the protein molecule is undergoing digestion by the body cells, a new and powerful specific proteolytic enzyme is produced which has the power of destroying the kind of bacteria causing the infection. The power acquired by certain body cells to produce promptly this proteolytic

* Victor C. Vaughan, M.D., LL.D., "Protein Split Products in Relation to Immunity and Disease."

enzyme on re-exposure to the disease accounts for the immunity against subsequent attacks.

THE PATHOGENICITY OF BACTERIA IN THE MOUTH.

Let us apply these facts to the subject before us.

I have called attention to the mouth as a place where bacteria may learn how to become parasites, *i.e.* learn to grow and multiply in the tissues of the animal body. These bacteria find conditions of life very satisfactory in a dirty mouth. They are provided with a warm habitation and plenty to eat and drink, and thrive luxuriantly. As long as the mouth tissues maintain their vigor, or the accumulation of bacteria is not so great as to overcome their resisting power, no opportunity is given for the bacteria to become parasites. But lowered vitality in some spot or a rupture in continuity may occur, and thus afford favorable opportunity for local infection. The germ, having learned how to subsist on living tissue, may not only do irreparable damage to the tissue originally infected, but also infect a nearby tonsil. Rosenow sees in the tonsil a place where streptococci acquire the peculiar property necessary to produce the disease known as rheumatism, with its involvement of the joints, affections of the heart and other concurrent phenomena. From the tonsil or other focal infection the germ may find its way into the circulation and give rise to infection of some other organ.

Rosenberger says:

> Personally, I believe that the ingress of bacteria into the blood stream does not very often occur from decayed teeth or diseased gums. What does occur far more frequently is absorption of the products of the bacteria. . . . In other words, it is to the toxicogenic bacteria that most symptoms are due —or auto-intoxication. The headache, the flushes of heat, pain referable to the eyeballs, sometimes slight or pronounced fever, malaise and other vague symptoms, chills or pronounced rigors, can very easily be traced in some cases to the conditions of the teeth and mouth. The gastric disturbances, the intestinal disorders, with apparently no cause from errors of diet, can be due to the continual swallowing of the products of putrefaction and decomposition going on in the mouth as a result of accumulated bacteria and their products. Apart from the symptoms referable to the stomach and intestines, it seems reasonable to suppose that other viscera may suffer from the intoxication. It is well known that Hunter, our English colleague, believes that Bright's disease, mucous colitis, and even sclerosis of the spinal cord and joint affections, may occur from oral sepsis, as well as many instances of general malnutrition. In some instances of profound anemia, resembling in its blood picture pernicious anemia, symptoms referable to the stomach and intestines are very common. It is possible that the condition of the mouth with its products of decomposition plays a part in the alteration of digestive ferments, and thus brings about improperly prepared and improperly masticated food for gastric digestion.

THE BACTERIA IN PYORRHEA ALVEOLARIS.

Examination by Dr. C. P. Brown,* of the Mulford laboratories, of the pus from the pus pockets of pyorrhea alveolaris secured by Dr. Joseph Head of Philadelphia, demonstrated the almost universal and continual presence of six kinds of bacteria, namely, bacillus influenzæ, the streptococcus, staphylococcus, pneumococcus, micrococcus catarrhalis and diphtheroid bacilli. Goadby found in the early stages of pyorrhea alveolaris, micrococcus catarrhalis, bacillus septus, micrococcus pneumoniæ, bacillus necrodentalis (Goadby), streptococcus brevis, and micrococcus citreus granulatus (Freud). In the later stages of the disease he found micrococcus catarrhalis and streptococci of various types, and also the streptobacillus (Goadby). Allen† considers that the spirochetes and spirilla found in the mouth are connected with, if not responsible for, the severe anemia which is sometimes met with in cases of pyorrhea alveolaris.

* C. P. Brown, "The Bacteriology of Pyorrhea Alveolaris," *N. Y. Med. Journal*, December 20, 1913.

† Allen. "Vaccine Therapy, Its Theory and Practice." Blakiston, Philadelphia, 1913.

Cummins* considers the streptococci and the streptobacilli to be the germs usually immediately concerned in the arthritic and other auto-intoxication processes sometimes connected with the pyorrheal infection. Rosenberger found on the mucous membrane pneumococci, streptococci, staphylococci, and various bacilli, and around or in decayed teeth organisms which belong to the class of the ray fungus (actinomyces). According to the same authority, yeasts and molds may also be present, as well as the micrococcus catarrhalis. Spirilla are not uncommonly found, especially when decayed teeth are present.

IMMUNITY AGAINST BACTERIAL INVASION.

Assuming some one or more of the bacteria mentioned in the above list to have penetrated the natural defenses of the body and started a colony in the mucous membrane of the mouth, stomach, or intestine, or in some one of the viscera, what happens? The tissue cells and the leucocytes commence to digest the invading bacteria with their enzymes, and split up the bacterial protein into two or more portions in the manner described by Vaughan. If the protein is effectively digested, very little if any of the poisonous portion of the protein molecule is set free and no toxic symptoms appear. The secondary group of the protein molecule split off during the digestion stimulates the body cells to produce Vaughan's specific proteolytic ferment which aids in destroying the colony of bacteria, and a certain amount of immunity is produced against further attacks. Each colony of bacteria started in various parts of the body may have a similar history. The patient may be immunized by dose after dose of bacteria. Immunity thus produced is probably sufficient in most instances to keep the body from being seriously infected. But after a time the "mechanism" of immunity partially breaks down, and then follows the train of symptoms already described which occur as the result of the growth and multiplication of the infecting organism in the part of the body invaded.

The theory of immunity produced in the manner just described is well exemplified in the following statement by Dr. Chas. E. Woodruff,* lieut.-col. U. S. Medical Corps (retired). In discussing the subject of tuberculosis before the annual meeting of the Medical Association of the Greater City of New York, January 19, 1914, Woodruff called attention to the present belief that every child is born free of tuberculosis, but soon acquires it, and that in everyone the lesions become active sooner or later. He says that it is probable that all civilized people are tuberculous and undergoing constant auto-vaccination, causing an effective immunity. No one was ever infected in adult life. If incipient tuberculosis develops in an individual, it is, according to this authority, because something has interfered with his manufacture of anti-bodies.

Cummins in his interesting paper on Oral Sepsis, classifies the results of this invasion according to the system involved, as follows: (1) Alimentary system. (2) Arthritic system. (3) Nervous system. (4) Circulatory system. (5) Cutaneous system. (6) Respiratory system. (7) Primary affections taking place in the mouth and its immediate neighborhood. He states:

> The conditions which lead up to the involvement of the alimentary tract are easily understood. An enormous number of bacteria are swallowed in a case of pyorrhea alveolaris. They are received into the stomach both during and between meals, at all times of the day and night. There is no doubt that the gastric juice possesses inhibitory and bactericidal power upon these organisms. But the continued abuse of this defense can only lead to its destruction. Dyspepsia, flatulence, and indigestion with all their varied symp-

* Dr. Chas. E. Woodruff, *N. Y. Med. Journal*, May 16, 1914, p. 1007.

toms follow, and the general health is undermined; septic gastritis and gastric ulcer occur.

Dr. Wm. H. Haskin* of New York City does not agree with Cummins concerning the bacterial power of the gastric juice. He says:

The old theory that all bacteria are killed by the acid of the gastric secretion becomes clearly absurd when we realize that this acid is only found during the active period of digestion of solid foods. It requires some time for the stomach to provide enough of this free acid to have any effect on the bacteria which have in the meantime escaped into the smaller intestine with its alkaline secretions. Every mouthful of fluid, even the saliva, is contaminated, and these bacteria are not even subjected to any possible effect of the acid, as the secretion is not stimulated except by solid food.

Goadby† has demonstrated the identity of the infecting organisms in certain cases of coexistent pyorrhea alveolaris and articular rheumatism, and it is now quite generally conceded that focal infections in various parts of the body and by different kinds of micro-organisms may cause so-called rheumatic symptoms.

NERVOUS DERANGEMENT DUE TO ORAL SEPSIS.

The various nervous affections attributed to oral sepsis include toxic neuritis, the nervous symptoms of anemia, etc. Prof. Lewis M. Ferman‡ of Leland Stanford University says that—

Bad teeth may cause nervousness either indirectly by causing malnutrition or directly from the reflex irritation which aching or crowded teeth produce. Motor automatisms sometimes result and moral self-control may become impossible. Even choreiform movements and epileptiform seizures may occur. Dr. Jessen examined the teeth of thirty-one stammerers and stutterers and found nearly twice the usual amount of defectiveness. Another investigator examined fifty-eight persons with the skiagraph (an instrument for recording irregularities of the teeth), and found that all who suffered impaction showed signs of nervous disorder. The symptoms ranged from headaches and restlessness to epilepsy, and from mild insomnia to dementia præcox. The same author reports that six out of eight such cases recovered upon relief of the impaction. It is significant that in no case was there any local pain, and in only a few, pain of any kind. Holmes describes an interesting case of moral delinquency and nervous instability which appeared to be the result of impacted teeth. The boy became irritable, nervous, and restless, gradually developing incorrigibility and habits of lying and stealing. He was brought before the juvenile court, treated for adenoids, etc., to no avail. Finally a dental examination was made which disclosed an extraordinary condition of impacted teeth. Treatment was followed by return to nervous control and complete moral reform.

CIRCULATORY AND RESPIRATORY DISEASES DUE TO ORAL SEPSIS.

The circulatory diseases include inflammatory affections of the endocardium and the arteries. Among the cutaneous effects are erythema, urticaria, purpura hemorrhagica, acne, eczema, seborrhea, alopecia areata, herpes, etc. The respiratory effects include septic tonsillitis, acute and chronic bronchitis, etc. The condition of the lungs brought about by the infecting organisms may pave the way for tuberculosis, and the infecting germs may become the factor in the mixed infection of phthisis. Knopf has written extensively on the question of diseased teeth and their effect on tuberculosis, and shows the possibility of their being one of the chief causes of infection. He also says that it is almost impossible to cure tuberculous patients who have bad teeth. Oral sepsis is also

said to be responsible for cases of pharyngeal abscess, septicemia, acute, subacute and chronic, also for diseases of the ear, including mastoid disease, diseases of the Eustachian tube, etc.

FAR-REACHING INFLUENCE OF ORAL SEPSIS IN APPARENTLY HEALTHY PERSONS.

It has been urged against the oral sepsis theory of infection that the majority of people of fifty years have pyorrhea alveolaris, and comparatively few people manifest symptoms of intoxication. Indeed, many individuals have been found in which oral sepsis is severe, and yet no marked symptoms of ill health appear to exist.

However, Cummins says that examination in many cases of pyorrhea alveolaris not showing any special symptoms of intoxication has demonstrated continued mild intoxication, manifested by depression, dyspeptic symptoms, and indigestion; and in course of time the indigestion results in anemia and diminished resistance to bacterial invasion. He says that such cases may develop duodenal ulcer, gastro-enteritis, catarrhal conditions of the gall-duct, inflammation of the appendix, chronic diarrhea, and intestinal stasis. Rosenow has proved that gastric ulcer may be caused by streptococcic infection due to oral sepsis, the bacteria causing the ulcer being derived from blind alveolar abscesses. He has also proved the same source of infection to have caused endocarditis and other diseases.

SERIOUS RESULTS OF NEGLECT OF CHILDREN'S TEETH.

The serious results of neglecting the teeth of children are strongly emphasized by Professor Ferman in his book recently issued, in which he calls attention to Dr. Wm. Osler's belief that more physical degeneracy can be traced to neglect of the teeth than to the abuse of alcohol. It certainly affects directly many more people. This author states that—

Examinations of thousands of school children in divers parts of the world have shown that fewer than 10 per cent. of our school children are free from diseased teeth or gums, dental caries (decay of teeth) being the most common defect. The average school child has from three to five decaying teeth. Many investigations report as many as 20 to 30 per cent. of all the teeth as affected. In New York City, 61 per cent. of 266,426 children examined had defective teeth, but less than one-fourth had ever entered a dentist's office. The Dental Association in Cleveland found 15,061 cavities in the teeth of 2677 children, or an average of 5.6 per child. Boston reports 33,575 school children as in need of dental services, and Brookline 77 per cent. Of 500 New York children who in 1909 applied for certificates permitting them to leave school to go to work 486 had 2808 decayed teeth; only 5 per cent. had ever visited a dentist except for an extraction, and there was not one "decently clean" mouth in the 500. Smaller cities have given similar results. Superintendent Johnson reports dental caries in 96.9 per cent. of 497 children of Andover, Mass., and 31.4 per cent. of all the teeth, as affected; 22.5 per cent. of the children had suffered from toothache within the previous week. Superintendent Reavis examined 407 children in Oakland City, Ind., and found only 53 with satisfactory teeth; 210 children had from 1 to 4 decayed, and 133 from 5 to 10; 44 children had all four of the six-year molars in a carious condition.

CHILD-FEEDING AND FOOD HABITS RESPONSIBLE FOR THE INCREASE OF DENTAL CARIES.

The main cause of infantile malnutrition, according to Ferman, is artificial feeding. He says:

Michael investigated the relation of dental caries to infant feeding in 11,762 children. Those who had been suckled ten months or more had only 9 per cent. of their teeth carious; those fed on cow's milk, 22 per cent., those whose principal diet was oatmeal-water, 27 per cent. Children suckled six months had teeth correspondingly inferior to those suckled ten months. Röse's study of 157,000 children shows the same thing. Even the mother's milk is sometimes inferior, due to worry, overwork, alcoholism, specific disease, etc. Jewish children, who as a rule are breast-fed and otherwise well cared for, are much less subject to dental caries than other chil-

dren. It has not been demonstrated that the difference is one of racial heredity. From an examination of many skulls, Underwood shows that dental caries is ten times as prevalent in western Europe today as it was a hundred years ago. European skulls of the eighteenth century average about one decayed tooth each; those of today about ten. Smith examined over 50,000 Egyptian skulls, and found practical immunity up as far as 4000 B.C.; after that a rapid increase. Of 500 "aristocratic" skulls dating from the pyramid epoch only a fifth were free.

It hardly seems possible that actual racial degeneracy as regards the power of the teeth to resist decay could establish itself so universally in a few generations. Nor is it necessary to assume such degeneration. Underwood, who has made the most extensive researches in this field, holds that the facts are readily explained in terms of changed food habits. Cooked, mushy, and sticky foods have replaced foods that were resistant and fibrous. The consumption of sweets has been multiplied many times. Mastication can more easily be slighted. This tends to produce irregularities of the teeth and maldevelopment of the jaws. Babies are less often nourished in the natural way, and all through childhood there is a deficiency of the sunlight, air, and activity necessary to healthy growth. The disease is a disease of civilization. For these and other reasons the prevention of dental caries is becoming a more difficult problem than ever before. If the disease is not arrested, micro-organisms will soon score their first complete victory.

Appropriate preventive treatment during childhood would probably insure good teeth to a majority of adults. Preventive measures should include especially cleanliness, thorough mastication, suitable food, the care of the temporary teeth, nutrition during infancy and childhood, the prevention of decay, the prevention of irregularity and the repair of defects as rapidly as they appear. To this end the school can make two contributions of the greatest importance: It can instruct children more thoroughly than it now does in the essentials of mouth hgyiene; and it can undertake preventive and curative treatment in school dental clinics. In fact, there is no other matter of health where the proverbial ounce of prevention will go so far.

IMPORTANCE OF ORAL HYGIENE.

Haskin says, "There is not one single thing more important to the public in the whole range of hygiene than the hygiene of the mouth." J. B. Murphy, Hunter,* Collins, Eyre and Payne,† Colyer,‡ and many other authors lay stress upon the danger of infection from septic conditions of the oral cavity. This vast amount of evidence accumulated by the experience of competent observers is sufficient to warrant the verdict that a septic mouth is a serious menace to health.

VACCINE TREATMENT OF PYORRHEA ALVEOLARIS.

The treatment of pyorrhea alveolaris and the infections caused by it is a phase of the subject of too much importance for detailed consideration in such a short paper as this. However, brief reference to the treatment of this affection with bacterial vaccines is in line with the object of my paper, which is to bring the subject before you from the bacteriological viewpoint.

Referring to vaccine treatment, Prof. Rosenberger, from whose paper I have already quoted, says:

> Vaccine treatment—mostly autogenous vaccines—has been used with great success by a number of men in the treatment of pyorrhea alveolaris. Whether this is a permanent cure or not remains to be seen, but where gouty or rheumatic diathesis are the undermining causes, it does not seem that we have yet found *the* remedy for this affection. My personal views upon this affection are that the constant formation of pus and discharge which is for the most part swallowed by patients, is deleterious to health. The disease or condition is a progressive one and usually results in loosening and loss of the teeth, so why not advise extraction and substitute false teeth? The looseness of the teeth lessens the proper mastication of food, and this in itself is sufficient for gastric or intestinal indigestion or both. As the organisms most commonly present in the discharge are pyogenic ones, it seems reasonable to suppose that even

---

† Eyre and Payne, "Vaccine Treatment of Pyorrhea Alveolaris," *Proc. Roy. Soc. Medicine*, 1910, vol. iii, Odont. Sec., pp. 29–61.

‡ Colyer, "Dental Surgery and Pathology."

stock vaccines may exert some beneficial results, but it appears that the ordinary bacterial flora, which are not easily cultivable, increase in this disease so that the pyogenic cocci vaccine does not seem in itself sufficient to overcome the process. If a vaccine were made from *all* the bacteria that are found in this process without trying to isolate the predominant ones, this mixed vaccine might alleviate or even cure the condition. Where in other pyogenic processes there is mixed infection, cures or improvement occur where mixed vaccines are used, and not where the most common organisms alone are used for this purpose.

A "bacterin" or bacterial vaccine is a suspension of bacteria, either killed or so modified as to prevent the bacteria from growing and multiplying in the body, while preserving the property of stimulating the body cells to produce antibacterial substances, when injected into the body.

The suspension is usually made in normal physiological salt solution. The bacterin is standardized by bacterial count, and as a rule preserved by an antiseptic; one-half of one per cent. of tricresol is generally employed for the purpose.

When a bacterin containing the same kind of bacteria as that causing a certain infectious disease against which the individual is to be immunized is introduced into the healthy body, its digestion by the body cells splits the protein molecule of the bacteria contained in the bacterin into two or more groups of atoms in the same manner as already explained in reference to the invading living bacteria causing an infectious disease. If the digestion of the bacterial protein is efficient, very little of its poisonous group is set free and reaction is reduced to a minimum. The immunizing group of the protein molecule set free by the digestion stimulates the body cells to elaborate the specific proteolytic ferment or enzyme to which the immunity to disease is due. Therefore more or less immunity to an attack of the disease is secured by the injection.

When a bacterin is used for the treatment of an infectious disease, the bacterin selected must contain the same kind of micro-organisms as those causing the attack. Injection of the bacterin is followed by the digestion of the bacterial protein in the manner above described. If the digestion is efficient, a minimum of the poisonous group is set free and no untoward reaction occurs. The immunizing group stimulates the body cells to form antibacterial substances which are taken into the circulation, carried to the infected area, and there aid the tissue cells and phagocytes in their battle against the invading disease germs.

Sometimes a marked reaction follows a dose of bacterial vaccines. This reaction is manifested by local soreness, also by systemic phenomena, such as fever, feeling of malaise, and possibly, but rarely, a cutaneous eruption. Vaughan teaches that these reaction symptoms are due to the inefficient digestion of the protein molecule, the symptoms being caused by the toxic action of the poisonous group, which is set free in large amounts under such circumstances. The importance of securing proper digestion of the bacterial protein injected is therefore apparent.

SENSITIZED VACCINES.

In 1902, Besredka,* a noted French scientist, devised a plan for increasing the digestibility of the bacterial protein, and thus to largely overcome the reaction due to the setting free of the poisonous group of the protein molecule. This he accomplished by macerating the bacteria in homologous immune serum, that is, serum from the blood of an animal immunized against the disease of the same kind as that produced by the living bacteria. What occurs when bacteria are macerated in homologous immune serum it is necessary for us to know, in order

* A. Besredka, "Concerning Vaccination with Sensitized Virus; Vaccination by Means of Sensitized Vaccines," also "Besredka's Sensitized Vaccines," by F. E. Stewart, M.D., Ph.G.; read before the Seaboard Medical Society, Norfolk, Va., December 1913, and published in the *New York Med. Journal*, Feb. 14, 1914.

to understand what is accomplished by this method.

All enzymes or digestive ferments, according to Vaughan, are composed of amboceptor and complement. The function of the amboceptor is to sensitize the protein substance to be digested, thus rendering it susceptible to the lytic or dissolving action of the complement. Normal blood serum has the property of digesting and destroying both living and dead protein substances. This property is possessed only to a limited degree. When an animal is immunized against a certain protein by the injecting of the same into its tissues or in other ways introducing it into the animal's body, it is found that the power of digesting said protein has been enormously increased. Examination of the blood serum now discloses the fact that this increase is due to the production of a specific amboceptor in large amounts, no increase having occurred in the complement. Now let us apply these facts to the subject before us.

When a bacterin is macerated in homologous immune serum for some hours, the amboceptor contained in the serum combines with the bacterial protein, thus rendering it susceptible to immediate and efficient digestion by the body cells when used either for prophylactic or therapeutic application. In other words, when the bacterial protein is presensitized, by macerating with the immune serum, it is prepared for the immediate action of the complement contained in the blood of the individual when it is injected into the body. The digestion by the body cells is immediate, efficient, and complete. Only a minimum of poisonous substance is set free by the digestion, and toxic symptoms are rarely manifested. The immunizing group of atoms set free by the disruption of the protein molecule stimulates the body cells to produce a large excess of specific amboceptor, which is at once taken into the circulation, and, when the bacterin is used for the treatment of the disease, sensitizes the invading bacteria and thus enables the complement in the patient's blood to act upon and destroy them speedily.

Pyorrhea alveolaris is a mixed infection, as we have already noted. In most cases, it is due to the presence of one or more of five or six principal types of bacteria. The object of treating pyorrhea alveolaris with bacterial vaccines is to stimulate the body cells to form substances antagonistic to the invading bacteria. For that purpose either an autogenous vaccine is employed containing the various germs found in the pus pockets, or a mixed polyvalent stock vaccine is used, which for reasons just given may preferably be a sensitized vaccine made according to the method of Besredka.

CONCLUSION.

In conclusion, I wish to again call your attention to the fact that this paper is a compilation containing the views of a large number of observers, for none of whom I am sponsor. I am presenting the paper for your discussion, not for the purpose of advocating any special theory of immunity or any special method of treatment. The bacterin treatment of pyorrhea to which I have called special attention because of its recent introduction and importance, is now undergoing investigation by leading members of the medical and dental professions. My paper is now before you for consideration, and I hope you will feel perfectly free to discuss its contents impartially.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

CORRESPONDENCE.

THE EUROPEAN WAR AND THE DENTAL SURGEON.

To the Editor of the Dental Cosmos:

Sir,—At a time when all Americans are watching the developments of the great war now raging in Europe, it is interesting to note what part our profession is called upon to take. Many, no doubt, are familiar with the work being done by many of our prominent *confrères* in the English, French, and German hospitals, where they are sharing with the medical staff the care of the wounded; but it remained for the *Deutsche Medizinische Wochenschrift* to emphasize the great value of the services of the dental surgeon in properly preparing the soldier for the hardships of active military service.

To quote from that journal. "—— insists that the teeth of the soldiers should be put in good condition before they are sent to the front. All broken-off roots should be pulled, even if they are not causing disturbance. The tissues around are seldom quite normal, and although there is no trouble under ordinary conditions, chilling, wetting, and trauma are liable to set up mischief in the old roots at any moment." He even goes back of the reservist to the children—the soldiers of the future—and emphasizes the necessity of systematic training in oral hygiene of children in school as a vital factor in building up the health of the rising generation, and reducing dental trouble in the land and sea forces. Dental prosthesis is of the greatest importance in cases of wounds of the jaw, as fracture of the jaw is of more vital consequence, he declares, than fracture of any other bone, perhaps. The Japanese army in time of war is supplied with ready-made adjustable splints for fractured jaws, and they restore the functional use of the jaw.

Also we note in the *Presse Medicale,* Paris, October 15, 1914, that Drs. Martinier and Roy, in an article on "Dental Prosthesis in Military Surgery," say: "The collaboration of the dentist is thus indispensable to the army surgeon for early assistance in treating wounds, not only of the jaws, but of the skull, while his aid is of paramount importance in the later treatment of wounds leaving defects of the jaws, nose, and ears."

It is gratifying to know that the United States army has had for nearly fourteen years a dental corps—very inadequate and insufficient in numbers, it is true, but yet it *has* this dental department, and it is very important that the dental profession see to it that this corps within the military arm is maintained upon the most efficient standing. Of course this is hardly possible under the present rate of advancement; that is, from the contract basis to the—one and final—grade of commissioned first lieutenant. In order to attract high-grade men, and more of them, to the corps, it is imperative that Congress be impressed with the necessity of increasing the grades within the corps to include the relative ranks of captain, major, and colonel. The few good men of the old original corps hang on from year to year, hoping that the dental profession can persuade Congress to

grant them the increase in rank which they justly deserve. And each year it becomes more and more difficult to obtain the best type of the young dentist to fill the vacancies made by the resignations of those who can see no chance of advancement.

And, further, the law now provides for only one dentist to each one thousand men: at some future date this should be increased to two dentists to each one thousand men, but for the present the dental profession should bend its every effort to obtaining the increase in the grades, and thus place the dental corps on an equal basis with other corps—such as the medical, signal, quartermaster, chaplains, etc.—the members of which far outrank the members of the dental corps.

Wm. C. Fisher,

Pres. Assoc. Milit. Dent. Surgeons.

New York, N. Y., December 1, 1914.

ANALGESIA BY MEANS OF $N_2O + O$.

To the Editor of the Dental Cosmos:

Sir,—In the report of the forty-sixth annual meeting of the Dental Society of the State of New York, contained in your November number, I have noticed that some of the most eminent members of our profession expressed themselves as being very skeptical as to the possibility of getting satisfactory results in analgesia by the use of nitrous oxid and oxygen in any considerable percentage of cases, and did not approve of the method, even though it could be used to enable one to relieve one's patients of much nerve-racking, which we all know must leave its permanent traces both physically and mentally.

The expression of such opinions by men of the exalted standing of those to whom I refer must carry great weight, and the said opinions are obviously, at least to one who has successfully used N_2O and O, not based on fair observation.

Therefore I trust I may be pardoned for my forwardness in offering you this report of my experience as one of the class who are accused of having made patients harder for the man to work on who has not mastered N_2O and O. There is no doubt in my mind that 5 per cent. of success is a good average for the man who is learning the technique of administration. It would appear that the principal reason why so many condemn analgesia is that they do not give themselves time to master it, but base their opinions on their own results while they are still unskilled, and discard the practice. There is, I feel sure, no anesthetic in use which requires more care and skill to get the best results than N_2O and O, but the dentist who will devote the time and thought necessary to master it, if he be adapted to the work, will be fully repaid for his trouble. I have been using N_2O and O for both analgesia and anesthesia continually and extensively for about three years, and would not care to continue the practice of dentistry if I had to go back to the old painful work. For some months my results were far from satisfactory, on the whole, but I assure you I am conservative when I say that I am now having at least 85 per cent. of my cases go

through perfectly satisfactorily both to myself and patients.

In conclusion I will say that I have yet to see a single case in which there was any evidence of injury, mental or physical, and I doubt if any dentist who has been in practice any length of time can say as much in regard to the old method of subjecting one's patients to unmitigated pain.

Very truly yours,

J. NEALES.

PROVIDENCE, R. I., November 11, 1914.

THE ARMY DENTAL SURGEONS CORPS.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—From time to time, and again in the December number of the DENTAL COSMOS, I find references to the army dental corps. Can you tell me or ascertain for me what attracts men to service in the army dental corps? What is the exact nature of the services they are called upon to render? Do you find men who have been several years in practice entering the army dental corps as acting dental surgeons? Last April, I believe, there was a competitive examination for acting dental surgeon in the United States army; if I remember correctly, there were about twenty-eight vacancies. How many were filled? and how much practical experience individually have the successful candidates had before the time of their examination?

I think the answers to questions like these will go far toward explaining the position or status of the army dental surgeon, and at the same time will enlighten many dentists who may have had or have a desire to join the army dental corps.

Yours truly,

PHILIP SCHEIMAN, D.D.S.

NEW YORK, December 7, 1914.

PROCEEDINGS OF SOCIETIES.

PENNSYLVANIA STATE DENTAL SOCIETY.

Forty-sixth Annual Meeting, Philadelphia, June 30, July 1 and 2, 1914.

TUESDAY—*Morning Session.*

THE forty-sixth annual meeting of the Pennsylvania State Dental Society was called to order on Tuesday morning, June 30, 1914, at 10 o'clock, in the Clover Room of the Bellevue-Stratford Hotel, Philadelphia, by the president, Dr. H. S. Seip, Allentown.

Rev. EDWIN HOWARD ROMIG, Philadelphia, Pa., invoked divine blessings on the deliberations of the association.

Dr. RICHARD HARTE, director of public health, welcomed the association to the city of Philadelphia.

Dr. EDWIN T. DARBY, Philadelphia, responded to the address of welcome on behalf of the society.

Dr. S. P. Cameron, Philadelphia, was called to the chair, while the president, Dr. SEIP, read his annual address, as follows:

President's Address.

By H. S. SEIP, D.D.S., Allentown.

I bid you welcome to this, the forty-sixth annual meeting of the Pennsylvania State Dental Society, and take this opportunity to express to you my deep appreciation of the great honor you have conferred on me by making me your president.

THE MEETING'S PROGRAM.

In this age, when everything is gaged by efficiency, I shall confine myself to the things that pertain to our State Society. I certainly voice the sentiment of every member present when I express to the chairmen of the program, clinic, local arrangements, and exhibit committees, and the members thereof, our heartfelt thanks and appreciation of their labors in our behalf, as evidenced by the splendid program they present to us for this meeting.

I wish to say as an explanation to the society that, by our special request, the papers on "The Vaccine Therapy in the Elimination of Mouth Infection" will of necessity be long, because we particularly asked that the essayists should go into every detail, so that every dentist might be in a position to understand what this new movement really means.

In the light of our newer knowledge concerning the effects of mouth infection as a cause of systemic disease, the auto-infection caused by toxemia of the intestines must pale into insignificance. In fact, there is now no room for doubt that the elimination of pyorrhea from the gums will add many years of life and happiness to every man, woman, and child in the community.

PROPOSED CHANGE IN DATE OF MEETING.

This brings me to the first recommendation I have to submit to your consideration. I fully realize that it will require the change of our charter—but what of that, if it is within the line of progress?—that is, to change the time of our meeting to some other period of the year. We meet too near to the time of the National Dental Association's meeting, which renders it difficult for your committees to secure papers and

clinics. The month of June is a very busy month for the colleges, and we certainly want the benefit of the presence of all the faculties of our dental colleges, and it comes just when every dental practitioner is busiest getting his patients ready to go away for their vacations.

CHANGE IN NOMINATION OF OFFICERS PROPOSED.

My observation has led me to the conclusion that the operation of the machinery of the Pennsylvania State Dental Society is wofully defective. Men who have rendered comparatively no services to the society are advanced to positions of trust, and others, who have given years of faithful and efficient service, are passed by or kept on our committees continually, which is all wrong, and does not make for efficiency, the cry of the age. This is due to our governmental system—the Councils who nominate the officers and appoint the committees. They meet between sessions, and consequently the time is limited, when much time should often be given to certain subjects—and they even often delay the regular session. The greatest delay occurs when the nominations must be made. In order that we may overcome this difficulty, and bring our component societies into closer touch with the State Society, I would recommend that the Councils shall put in nomination for the state board of dental examiners the presidents of the different component societies of the state; that the State Society put in nomination for members of Council the secretaries of the different component societies of the state; that the Council then appoint the committees of the State Society from the officers of the different component societies of the state. Thus we will have all the officers in continual touch with each component society, and they will be able to keep up and increase our membership. This may require a change in our constitution and by-laws, but if we consider it in regard to efficiency, it is our duty to make the change. I would recommend that the secretary be elected for five years, at a salary of $700 per year, to attend to the interests of the society and the enforcement of the dental law, and that he be provided with a stenographer at a salary of $500 per year, to assist him and the chairmen of all the committees of the society in the furtherance of their work and the preparing of the program for each meeting. It is no longer feasible or practical or conducive to efficiency to expect a man in active practice to give of his valuable time to serve either on the program, the clinic, or the exhibit committee without some assistance, which such a stenographer could very ably render after having once gone through the work. There is considerable money expended each year by the various committees which would practically provide the salary of the stenographer.

THE EXHIBITORS.

We have been justly proud of the exhibitors' display at our Pennsylvania meetings. The exhibits are truly an educational feature, as they show us everything new in the way of office equipment, and all dentists who are progressive want to see the latest things the manufacturer has. This feature should be conducted on business principles, which would be fair both to the society and the exhibitor. I would recommend that a definite part of the expense of each meeting should be borne by the exhibitors, viz, the expense of the hall and meeting-room and fifty per cent. of the expense of the clinicians and essayists. Twenty per cent. of the amount decided on by the society to be expended in advertising the meeting should be used in favor of the exhibitors. If the meeting is held east, notices should be sent to every dentist in eastern Pennsylvania, New Jersey, Delaware, and eastern Maryland; when it is held west, notices should be sent to every dentist in western Pennsylvania, eastern Ohio, western New York and West Virginia. This would be done to reimburse the exhibitors for being charged a definite share of the expenses of the meeting.

PUBLICITY COMMITTEE PROPOSED.

I would recommend that the duties of a publicity committee be added to that of the local arrangements committee; that they shall communicate with every component society of the Pennsylvania State Dental Society, and secure a true list of every ethical practitioner in the state, and that stencils be provided for the secretary's addressing machine, and that a certain amount of our literature be sent to every ethical dental practitioner in the state. This will aid in increasing our membership.

The *Bulletin* should be sent monthly, beginning with October, and contain a reprint of one of the papers read at our previous meeting, and other matters of interest. This should go only to the members, thus gradually helping to bring in to the State Society all the ethical dentists of the state.

It should be the duty of this publicity committee to bring to the attention of the public the facts emphasized in our program this year—for only by the education of the general public in the things pertaining to dentistry, and by publication of what we are doing, can we hope to bring the people to the full realization of the importance of their giving attention to dentistry, and thus making themselves more efficient.

NECESSITY OF ORAL HYGIENE SERVICE.

It is conceded that a dentist can comfortably take care of four hundred patients in a year. There are 18,009,891 school children in the United States; ninety per cent. of these children's teeth are neglected. There are 41,117 dentists in the United States, whose entire time could be taken up by the neglected school children's teeth, leaving the balance of 82,000,000 population entirely without the possibilty of any dental attention! Fellow members of the Pennsylvania State Dental Society, these figures are simply staggering from an economy and efficiency standpoint. Our responsibilities to the state in regard to education and work are appalling, for upon our shoulders rests all the care of this generation, and it is our duty to make the state see this, and realize the loss in efficiency in the cases which are not reached.

ORAL HYGIENE IN GIRARD COLLEGE.

We in Pennsylvania can be justly proud that through the efficient presidency of Dr. Cheesman A. Herrick, Girard College, one of the magnificent charities in our midst, has established dental, medical, and rhinology departments—the dental department under the splendid management of the chairman of our Program Committee, Dr. S. P. Cameron, who with two assistants and a mechanical assistant is rendering the very best dental services to his wards. There is probably no other institution in the world that is doing for its wards from an orthodontic and operative and preventive dental standpoint what Girard College is accomplishing. Since their mouths have been put in a healthy condition, the general health of the boys has improved wonderfully.

DENTAL NURSES.

Owing to the mighty movement of oral hygiene, and the foregoing statistics as to the inability of the dental profession to take care of the pressing necessity for the treatment of dental caries and irregularities, I recommend a change of our dental laws, so as to provide for the licensing of dental nurses, whose province it shall be to assist the dentist, and who shall be permitted to give prophylactic or surface treatment of the teeth, etc. Suitable courses of instruction could be provided by our dental colleges, and the services of these nurses utilized while they are taking the course at the chair and clinic, as are the services of the medical nurses at our different hospitals. We could then utilize them in our public school work, as suggested by Dr. Alfred C. Fones in his report as chairman of the Oral Hygiene Committee of the National Dental Association—"The source of unclean mouths and decayed teeth is found in the first five grades of our public schools; how are we going to check it?"

The work of instructing these children as to the use of the brush and the surface treatment of the teeth once a month could be taken up by these nurses under the direction of competent dentists in each school district, systematized as the doctor suggests. Each set of nurses would advance with each grade of pupils, and the new nurses would take the first grade each time, until the five grades were supplied with dental nurses. This would insure for each child the proper care of his teeth and proper education regarding cleanliness and hygiene for the first five years of school life, which is the period when the teeth are most susceptible to caries.

EXAMINATION OF SCHOOL CHILDREN'S MOUTHS BY DENTISTS.

This brings me to a recommendation which will require a change in our school code, and that is the request of the Lehigh Valley Dental Society to the State Dental Society, that it endeavor to have our school code so changed that a competent ethical dentist be employed to examine the teeth of our school children—the good effects of which will be patent to all of you without further comments on my part. But while this effort is made, we should endeavor to have the employment of the dental nurse also incorporated. It would result in the betterment of the children, and there would be a smaller percentage of children compelled to review their grades, and the saving to the state would far outbalance the added expense to each school district. If all the facts were brought to the attention of the proper parties, there ought be no difficulty in accomplishing our object.

CONTROL OF PROPRIETARY PREPARATIONS IN SCHOOLS.

At the suggestion of the Nestor of our profession in Reading, Dr. W. H. Scholl, I would call your attention to the various proprietary materials on the market, which are advertised by free distribution in our schools, etc., and to the fact that we do not always know whether they are beneficial or not, and while we are educating the public as to oral hygiene it is our duty to see that they are properly informed in this respect. I would therefore recommend that a committee be appointed to make proper investigation, with the aid of a chemist if necessary, and a report be made at our next meeting as to their findings.

LENGTHENING OF THE DENTAL COURSE PROPOSED.

I am constrained to make my next recommendation because of the fact that the general public and the medical profession, owing to the demonstrated relationship which mouth infections bear to general bodily diseases, which we will have so ably demonstrated at this meeting, demand that we, as a profession, give them relief from these conditions. This means that a larger educational preparation must be provided. I shall not go into detail, as time will not permit, but when we realize that the dental schools are already assigning 1200 hours per year, when the available hours of eight-hour days, Saturday afternoons excepted, is only 1400 hours, and that the academic student's maximum is only 600 hours per year, engineer's not over 700 hours, medical student's about 1100 hours, it can be readily seen that the dental course is at the breaking-point. We all concede that the present course cannot be curtailed, consequently the only conclusion left us is a lengthening of the course; and I would recommend a change of our dental law, to read: "The degree of Doctor of Dental Surgery, or other established dental degree from a reputable educational institution maintaining a *four* years' course in dentistry." I am convinced that many a man who goes through his dental course fails before the board because he has too much crowded into too short a time in his course. The object of education should be not to reach the quick and smart boys, but those who, though they be not as quick, if given the proper attention will make just as useful men in the profession. The present trend in all education is to crowd too much

into too short a time. True, it eliminates the weak, but is that not, after all, the object of education—if we wish to contribute to the general uplift of all classes?

MEMBERSHIP IN NATIONAL DENTAL ASSOCIATION.

It is a matter of regret, when we consider the position which the Pennsylvania State Dental Society holds among the states of the Union—this state having always held the foremost place in dentistry—that we should have but 390 of a total number of practitioners of over 1000 who have voluntarily become members of the National Dental Association. I would therefore recommend that an amendment to our by-laws be presented at this session making each member of this society a member of the National Dental Association.

DENTAL RELIEF AND SCIENTIFIC FOUNDATION FUNDS.

I especially commend to you the Dental Relief Fund, and the Scientific Foundation Fund of the National Dental Association, and would say that the subscription to the latter fund from the State of Pennsylvania is far below our quota. I shall take special pleasure in allowing Dr. Grieves, one of our essayists and a member of the commission of the National Dental Association, to present the cause of this foundation before one of our sessions.

In bringing these remarks to a close, I can find no more fitting words to urge us on in our endeavor to work out the great problems before us, and to emphasize the need of conscientious endeavor in serving the present generation in our chosen calling, than the lines of the poet:

When Earth's last picture is painted, and the tubes are twisted and dried,
When the oldest colors have faded, and the youngest critic has died,
We shall rest—and, faith, we shall need it!—lie down for an æon or two,
Till the Master of all Good Workmen shall put us to work anew!

And those that were good shall be happy; they shall sit in a golden chair;
They shall splash a ten-league canvas with brushes of comets' hair;
They shall find real saints to draw from—Magdalene, Peter, and Paul;
They shall work for an age at a sitting, and never be tired at all!

And only the Master shall praise us, and only the Master shall blame;
And no one shall work for money, and no one shall work for fame,
But each for the joy of working, and each, in his separate star,
Shall draw the Thing as he sees it, for the God of Things As They Are!

Dr. Cameron appointed the following Committee on the President's address: Drs. W. D. DeLong, H. E. Friesell, and F. D. Gardiner.

Motion was then made and carried to adjourn until the afternoon session.

TUESDAY—*Afternoon Session.*

The meeting was called to order by the president, Dr. Seip, at 2.30 o'clock Tuesday afternoon.

The President announced as the first item on the program for the afternoon session, the reading of a paper by Dr. A. PARKER HITCHENS, M.D., Glenolden, Pa., entitled "Rationale of the Use of Bacterial Vaccines in Pyorrhea Alveolaris."

[This paper is printed in full at page 1 of the present issue of the COSMOS.]

Dr. JOSEPH HEAD then read a paper entitled "Vaccine Therapy in the Elimination of Mouth Infection."

Discussion.

Dr. ARTHUR H. MERRITT, New York, N. Y. I feel not a little embarrassed in appearing before you this afternoon, for I observe that I am to speak to you about "The Uses of Vaccines in the Treatment of Pyorrhea," when, as a matter of fact, I am not going to talk about their use, but about their *uselessness.*

I am further embarrassed because I

find myself in complete disagreement with my friends Dr. Head and Dr. Hitchens, both of whom I hold in the highest esteem. They may be right in their observations, and I may be wrong in mine, but there is one thing in which we are all equally interested, and that is, in arriving at the truth.

The therapeutic value of vaccine therapy in the treatment and prevention of certain infections is beyond question, notwithstanding the fact, conceded by those best qualified to judge, that its failures are more numerous than its successes.

Like every great discovery, vaccine therapy has had its enthusiastic advocates whose use of it has not always been as discriminating as it should have been. There is nothing strange in this, since this is the history of every discovery made in medical science. There are always sure to be those who will make a fad of any innovation. This has been especially true of vaccine therapy; there is something in the psychology of germ inoculation which strongly appeals to physician and patient alike. In short, it has become fashionable, with the result that the wide use which is being made of it is in part due to the forcing of the physician's hands by his patients. There can be no doubt that a large amount of vaccine therapy is, in consequence, of the most discursive and slipshod kind; so desultory and unsystematized is it that it can have no place in estimating the value of the method in the treatment of disease. I believe a warning should be sounded in every place where medical and dental men gather against this indiscriminate use.

A fact which should never be forgotten is that, while the principle of vaccine therapy is correct, it is not a panacea for every ill; in reality, it has only a very limited application. As has been said by a recent writer, "It is as though one wandered up and down a long passage into which many locked doors opened, carrying a key, and trying the doors with it. Many refuse to open; the key does not fit. Then there comes one where the key turns smoothly, and the door opens easily. This accurate fitting of lock and key illustrates the specific stimulus and response of a vaccine given in a successful case." The lesson to be learned from this is that the key does not always fit; in fact, more often it does not.

My own use of vaccine has been limited to the treatment of pyorrhea, begun in 1907 with high hopes that it would prove a valuable adjunct in the treatment of this most chronic of localized infections. I have always used it experimentally—*i.e.* in selected cases—and under varying conditions, with a view to ascertaining just what place, if any, it had in the treatment of pyorrhea. I accordingly used it prior to the usual local treatment, during such treatment, and after treatment had been discontinued. As a result I have seen the subjective symptoms clear up, with some improvement in the disease itself, and this independently of other treatment. In no single instance have I seen more than this; there has never been any permanent improvement. When combined with local treatment, I have not been able to see that it appreciably influenced results. As a post-operative treatment it is unnecessary so far as the disease itself is concerned, if the local treatment has been thorough, and it will avail nothing if it has not been so, as I will show later.

I frankly confess to being disappointed, not because my preconceived notions have not been realized, but because an expected aid has not been forthcoming.

This is not surprising, however, when we realize that the success of vaccine therapy depends upon the isolation and employment of the germ causing the disease. So far as is at present known, pyorrhea is not caused by a specific germ; the infection which takes place is a secondary one, without doubt a serious complication, giving to the disease its characteristic symptom of pus discharge, and being largely responsible for its unfortunate influence upon the health and well-being of the patient. To treat such a disease with vaccines would therefore consist in the treatment

of symptoms, justifiable no doubt under certain conditions—and in that instance explaining the improvement in symptoms, but explaining also its inefficiency as a curative agent. In spite, therefore, of the high hopes with which I began the use of vaccines seven years ago, and with which I have continued it in selected cases to the present time, I am forced to the conclusion that it has a very limited place in the treatment of pyorrhea.

Without entering into the question, at this time, as to whether pyorrhea is or is not a purely local disease, the fact remains that it can be cured by local treatment, though the question of diet, elimination, hygiene, etc., should in every case be considered. Where this has been done, and the surgical work has been thorough, there can be little need of vaccines, and to subject a patient to such inoculations before it has been proved that the usual surgical treatment is unavailing, is in my opinion unwise.

When, as a result of a long-standing pyorrhea, there is evidence of a general toxemia, or when for example there is a chronic arthritis, vaccines may prove valuable, though it is surprising how often these systemic expressions of pyorrhea clear up of themselves by the removal of the original focus; a fact which may be explained not only by the removal of the cause, but by the auto-inoculation which undoubtedly takes place through local treatment, whereby the patient's resistance to infection is increased. The use of vaccines in such cases would therefore apply to the elimination of diseases produced by the original focus rather than to the pyorrhea itself.

In all that has been said and written about pyorrhea and its treatment, there are a few facts which should not be overlooked in any effort to arrive at the truth:

(1) That pyorrhea can be and is being cured by surgical methods alone —the first essential being thoroughness.

(2) That the most enthusiastic advocates of vaccine therapy do not claim that it will of itself cure pyorrhea.

(3) That there is not a vestige of proof that pyorrhea which has not yielded to surgical treatment can be cured by vaccines.

(4) That the claim which is frequently made by the advocates of vaccine therapy that its use will prevent recurrence is only an assumption. There is no proof that this is so.

In an article which appeared in the *Lancet* for February 7, 1914, by H. D. Rolleston, entitled "Vaccines from the Standpoint of the Physician," the following statement is made—which very clearly expresses the attitude of the conservative physician regarding vaccine therapy:*

> Curative vaccine treatment must be admitted to have disappointed the high hopes with which it began, and in this respect its history resembles that of most remedies. The problem of immunity is so complex that it is highly probable that the technique or practice rather than the principle of vaccine therapy is at fault, and that in time this may be so perfected as to establish the position of vaccines as a reliable remedy. The determination of the infecting micro-organisms is exposed to well-known fallacies and may be very difficult. Even with all due precautions a wrong vaccine may be given and do harm. . . . Possibly the conditions of culture on artificial media may so modify the products of the micro-organisms of which the vaccine is composed as to render artificial inoculation far inferior to auto-inoculation. It has therefore been suggested that vaccines should be made from organisms grown on blood or other natural media. . . .
>
> In chronic local infection of various kinds, such as arthritis and colitis, in which gradual improvement follows vaccine therapy, it is very hard to decide whether the credit is due to the treatment or to nature unassisted.

At the present time, the results of vaccines are so uncertain that their use appears to be justified only when other and more trustworthy therapeutic methods have failed, or do not exist.

Dr. C. P. Brown, Philadelphia. There is one point to which I wish to call particular attention. Most bacteri-

* I am indebted to Dr. A. M. Nodine and Dr. William R. Williams for calling my attention to this article.

ologists who have investigated this disease have used either plain agar or Loeffler's blood serum. Goadby used nothing but plain agar, and was successful in isolating practically nothing but streptococci, staphylococci, and yeasts. Medalia of Boston used plain agar and Loeffler's blood serum for his first isolations; he used blood agar only to ascertain whether or not a streptococcus produced hemolysis; he isolated staphylococci and pneumococci. So many micro-organisms fail to grow on plain agar and blood serum that these media are insufficient for work of this kind. In the study which Dr. Head and I reported in the Section of Stomatology at the meeting of the American Medical Association in Minneapolis, we used blood-agar plates for every case. Our results show clearly that certain organisms are nearly always present in pyorrhea.

Dr. J. C. Hertz, Easton, Pa. I would like to ask if anyone experienced in the use of vaccines has found any rise in the bodily temperature in the reactions to the various injections.

Dr. C. S. Tuttle, Philadelphia. It has been a great pleasure to me to listen to Dr. Hitchens and Dr. Head, as I have only recently become interested in the treatment of pyorrhea by the vaccine method. In telling of one success I had, among several others, I will relate a story that can be verified by Dr. Head, because he saw the beginning and the ending of the case. The patient, a man of the alcoholic type and good physique, presented himself for the treatment of four teeth which served as abutments for bridges and which were affected with pyorrhea. After having treated him locally in a manner which I considered thorough, and having opened the gums so that two abscesses could discharge, I had entire failure.

Dr. Head. How long was the case treated locally?

Dr. Tuttle. It was treated locally for six years, and I barely managed to keep the abutments in position during that period. Then I became interested in vaccine therapy through the patient himself, who had been acquainted with a man who was doing a great deal of this work, a physician, however, and one who had not had a great deal of experience with vaccine therapy as far as dentistry is concerned. In considering the advisability of treating the case by means of vaccine therapy, I felt, because of the fact that I have no medical degree, that I would like to place the responsibility of the inoculation upon a physician. The patient suggested Dr. R. V. Patterson, who said to me, "Before we take up the work: If this case is cured, and you would consider it cured, and other men who understand this work would consider it cured, will you attribute the cure to the vaccine?" I said I would. I had arrived at the point of extracting the teeth, and was on the verge of sending the man to an exodontia specialist, and would have considered my conscience clear if the teeth had been extracted. We, however, decided to try the vaccine treatment, and the first thing to do was to remove the bridge; the removal of the bridge was indicated, as there was a large swelling suggesting an alveolar abscess. I drilled into the pulp chamber expecting to find a dead pulp, but found a vital one, which showed that it certainly was a clear case of pyorrhea.

Someone asked about blood pressure. We took the blood pressure in this case at various times during the treatment. We started with a ten million inoculation, and the dose was gradually increased until the patient received the maximum of twenty-one millions, and at no time did his temperature go up, and at no time was there a change of more than two points in blood pressure. Taking into consideration that the blood pressure varies on different days and at different times of the day, even this could not be attributed directly to the inoculation. This patient took twelve or fourteen inoculations, and in spite of the fact that he continues the use of alcoholics and has no regular hour for retiring, these bridges have remained firm since they were replaced.

Dr. Joseph Head, Philadelphia. I

wish to state that I do not know of any man in the whole profession for whom I have greater respect in regard to his scientific ability and general ability as a dentist than Dr. Merritt; but now we have come to a point where I believe that I am rather optimistic, while he is pessimistic. Perhaps my optimism may be turned into pessimism as time goes on. I can only say that, for over ten years, I strove to treat pyorrhea and did it successfully, and was of the opinion that pyorrhea could be cured, if one calls controlling a cure, but Dr. Merritt says that by six weeks' treatment he is able to cure pyorrhea cases so that there will be no recurrence. Now, I am going to say that Dr. Merritt has shown me several cases, particularly the one case cited in which the tooth was exposed almost to the tip and abscessed—and in that case I should have opened the tooth and extirpated the pulp. I cannot get rid of abscesses without taking out infected pulps, but he does not seem to have had that difficulty. He is able to cure these cases in six weeks or two months with apparently infected pulps remaining in the teeth. I will say, however, that in my cases which I have striven to bring under control, and in which I was unable to do anything after treatment for two or three years, I have with vaccine treatment in the course of six months seen most profound improvement, more than I had had at any time previous. It has also been my experience that after the use of vaccines for from three to six months to a year sometimes there is a general improvement in the condition of the tissues of the mouth. In patients whose gums are easily inflamed and have an apparently slight hold on the teeth, without any other treatment there has been a tremendous increase in the tightening and healing of the gums. This is my feeling; I may be wrong, and Dr. Merritt may be right. Before I began using the vaccine treatment, I treated many cases surgically, and in many cases had a fair amount of success and was considered to be a pretty good dentist by some. But I can only say that, since I have been treating these cases by vaccine treatment, I have been able to make people comfortable where it could not possibly be done before, and I am convinced that proper surgical treatment aided by vaccine therapy—but in contact with the tissues around the teeth—gives a result that is impossible without the vaccine treatment, no matter how careful and how valuable that local treatment may be.

Dr. Hitchens (closing the discussion). It has been a great privilege to listen to Dr. Merritt this afternoon. Those of us who are incarcerated in the laboratory most of the time and are consequently not so familiar with the application of the things in which we are so much interested, are always anxious to hear the clinical side of the question.

Dr. Merritt's experience coincides so exactly with what our theories would lead us to expect that what he has said would be difficult to discuss, were it not for the fact that I am inclined to draw slightly different deductions. If, as Dr. Merritt has reported, systemic improvement follows treatment with bacterial vaccines, we must believe that the systemic condition was due to bacteria; and the improvement must have depended upon some influence antagonistic to the bacteria. That is to say, the bacteria involved in the process of infection so located that they could be readily acted upon by the ferments were destroyed. Those bacteria ensconced in the tissues, as I have indicated in my paper, could not be reached by the specific ferments, and therefore were probably not affected—only their products could be influenced in any way. The only way these protected bacteria can be reached is by the method Dr. Merritt used. He cut directly down upon the infected area, as I understand it; if there was infected tissue he removed it; any foreign material that might complicate healing or assist the infecting bacteria was removed. Dr. Merritt treats pyorrhea according to the principles of vaccine therapy. Bacteria that cannot be reached by specific ferments resulting from vaccine treatment

should, whenever feasible, be removed surgically.

As to Dr. Merritt's disappointment in the general system of vaccine treatment, there are certain points in his method of procedure that the bacteriologist would like to be assured upon. Of course, he did not go into the bacteriological aspect of the subject, but it seems to me that if there has been any systemic improvement it is a testimonial in favor of vaccine, and if there has been any improvement from the local treatment, I would wonder if it did not come about as a result of the influence of the treatment upon bacteria that were present locally. As I said in my paper, if bacterial vaccines are injected, they form specific ferments, and if these specific ferments are brought in contact with the infected area, improvement results. Of course that is where the whole trouble lies; in conditions like this, the bacteria cannot be reached without surgical interference.

The meeting then adjourned until the evening session.

TUESDAY—*Evening Session.*

The meeting was called to order on Tuesday evening at 8 o'clock by the president, Dr. Seip.

The first item on the program, as announced by the President, was the reading of a paper by Dr. J. CLARENCE GRIEVES, Baltimore, Md., entitled "The Relation of Dental Septic Conditions to General Disease."

[This paper is in substance the same as the paper by Dr. Grieves which appeared in the DENTAL COSMOS for January 1914, vol. lvi, page 52.]

The next paper on the program was one by Dr. W. J. ROE, Philadelphia, entitled "Surgical Lesions Due to Oral Sepsis, and Their Treatment."

[This paper will be published in a later issue of the DENTAL COSMOS.]

The next item on the program was a lantern lecture by Dr. A. H. MERRITT, New York, on "Pyorrhea Cases and Root Amputation in Cases of Blind Abscess."

The next order of business was the reading of a paper by Dr. M. T. BARRETT, Philadelphia, entitled "The Protozoa of the Mouth in Relation to Pyorrhea Alveolaris."

[This paper was printed in full in the August 1914 issue of the DENTAL COSMOS, vol. lvi, page 948.]

Discussion.

Dr. A. W. STRECKER, Philadelphia. I have been treating pyorrhea for about ten years, following the system advocated by Dr. D. D. Smith, and have obtained some very good results. A few days ago Dr. Sausser called me on the phone and asked if I could not send a case to Dr. Barrett for treatment. I sent a case to Dr. Barrett, and he treated it three times, and I must say that the results were remarkable. The tissues at once cleared up in a manner that I was unable to bring about in any other way.

Dr. E. R. SAUSSER, Philadelphia. I wish to corroborate some of Dr. Barrett's clinical observations in the treatment of this suppurative condition. A few weeks ago, Dr. Barrett told me that he had found a parasitic micro-organism in pyorrhea cases, and I immediately became interested and offered to co-operate with him and send him a few cases for treatment in which I had failed to produce a cure. I selected five cases—three of the anemic, underfed class, with no assimilation whatever, and of the chronic toxic type. In all these cases Dr. Barrett found the amœba. One of the other cases was that of a robust woman who had pyorrhea; this had been under control, so we thought, for about twenty years, but the amœba was found present. The fifth case was that of a man suffering with a lesion of the liver, no doubt, with attacks once a month, and in his case amœbæ of gigantic proportions were found. The last case I treated myself, following the ordinary cleansing procedure, and then drying the pockets thoroughly and putting a

one-half of one per cent. solution of emetin hydrochlorid into the bottom of the sockets of the lower anterior teeth, which were mostly affected, and allowing that solution to remain under the protection of cotton rolls for a few minutes, following this application with thorough massage. I saw the case two days afterward, and I can testify that macroscopically there was no pus present, although this case had been showing a suppurative condition from the first treatment. Of the three cases which Dr. Barrett treated, one was especially interesting in that the patient had suffered with pyorrhea for about fifteen years, and her mouth was a picture so far as exquisite oral toilet is concerned, she being continually under the care of a dentist who kept her mouth clean; but there had always been a flow of pus, although I could never find any deposits of any kind that I could identify as serumal or salivary, but a sort of mushy deposit which we possibly do not know anything about at the present time. In that case, twelve teeth were extracted, and pyorrhea still persisted, pus flowing from the gums. The upper left lateral was treated five times, and after the third treatment that livid tendency of the tissue disappeared, the pockets disappeared, the flow of pus diminished, and the tissue cleared up satisfactorily; but there is still a little pus. However, that is not to be wondered at, considering the long-standing and insidious nature of the case. It has been very interesting to me to see that mushy pus clear up, and I fully believe that Dr. Barrett will succeed in reducing the condition to a satisfactory status, if the present progress continues.

In the case of the robust woman who had been having her teeth treated for about twenty years, the patient was most enthusiastic over the treatment. Previously she complained very much of the treatment, and did not recover from it for three or four days afterward. Just the mere massaging of the gums would cause considerable pain around the necks of the teeth. Her statement after the first treatment was, "My teeth have been feeling different since I had that treatment." She said that she could bite much better than before, which to my mind was an indication of improvement in the peridental tissue.

Whether or not emetin is a specific, or whether or not the amœba is the vital cause or a secondary condition in pyorrhea, it is most interesting to us to see these destructive conditions clear up after such short treatment.

Dr. Allen J. Smith, Philadelphia. My personal interest in the work presented by Dr. Barrett has been primarily from the standpoint of parasitology, and were I to follow my inclinations, my remarks would cover more fully the description and mode of identification of the organisms which we meet in these oral lesions. But realizing that your members are more likely at this time to wish for general comments, particularly in the matter of treatment, I will forego for the present any technical zoölogical references.

Probably many of my hearers recall the fact that Dr. James Truman advocated and used with effect local applications of quinin in pyorrheal pockets. Like emetin, quinin is, perhaps in a minor degree, an amœbicide, and has been used not infrequently in rectal injections in the treatment of amœbic dysentery. While perhaps Dr. Truman did not at the time realize its mode of benefiting the lesions, in retrospect we may now feel that quinin did so by directly affecting not the bacteria of the pockets, but the amœbæ present there. It is from the effect exerted by these known amœbicides that we may infer the pathogenic importance of these protozoa. It is impossible, as has been brought out in Dr. Barrett's paper, to declare that these parasitic amœbæ are the sole cause of Riggs' disease, but in my opinion he has offered sufficient evidence to permit at least the declaration that they are pathogenic. By analogy, in amœbic dysentery and in abscess of the liver secondary to amœbic dysentery, the problem of the relative importance of the dysenteric amœbæ and of bacteria has also been proposed, and is still

a matter of discussion; *i.e.* whether the endamœbæ are the essential causative agents or whether they act mainly as conveyers of bacteria which they have ingested, from the surface of the colon into the tissues of its wall to produce the characteristic ulcers, and into the liver to produce the abscess of the latter organ. The recently determined but widely proved fact that emetin destroys the amœbæ and is followed by healing of the lesions does not exclude the associated bacteria from a part in dysentery, but it unquestionably does show that the amœbæ perform an important part in the process. In the same way, from the fact that injection of emetin into pyorrhea pockets is followed by cessation of the suppuration and disappearance—as far as has been determined—of the endamœbæ, I believe we are justified in holding that these protozoa have an important part in the process. Yet from the fact that they carry with them bacteria, it is impossible to say that the latter are not also of etiologic importance; therefore we may well have to deal secondarily with the bacteria, and thus have reason to continue the usual antibacterial measures, including vaccine therapy, in dealing with the whole problem. Doubtless there will be found a number of cases which will not completely respond to the amœbicide, and in such it will be found necessary to use, in addition to the emetin, local antiseptic applications, or complete the treatment by the employment of vaccines. Possibly, too, there are cases in which amœbæ are not the responsible agents. Just as we recognize dysenteries as being of different types from an etiologic standpoint—as amœbic dysenteries, bacillary dysenteries, toxic dysenteries, etc.—there is no reason why we may not find different kinds of pyorrhea; and I would be surprised if, in future experience, Dr. Barrett should find that every case of pyorrhea treated by him responds with the same promptness that these thirteen cases have shown.

Perhaps the dental profession may not appreciate the prediction I am about to make, because of its unfavorable bearing upon the dental practitioner and his earnings. Emetin when used in the treatment of dysentery is usually introduced hypodermically, and the drug injected under the skin of the arm is efficient in killing the endamœbæ of the colon. It will probably prove effective also in cases of pyorrhea if administered hypodermically; and should it become generally accepted that the hypodermatic injection of a quarter of a grain of emetin into the arm will take from the dentist's office patients who have been in attendance, perhaps, for years, the dentist's source of income is likely to be materially impaired. These, however, are apt to be the lines along which progress in treatment will proceed.

This report by Dr. Barrett must be accepted as merely a preliminary statement of the work we have taken up. In brief *résumé,* the facts thus far presented are that in the examination of material from pyorrhea pockets of forty-six persons, endamœbæ have been found in all cases, without a single exception; that in seven cases which were found free from peridental suppuration, no endamœbæ were found anywhere in the mouth after a prolonged microscopic search of scrapings; and that in thirteen cases treated with a known amœbicide in the form of the hydrochlorid of emetin, immediate response has followed the use of this amœbicide.

It would probably be of interest to you to be told that our knowledge of the amœbicidal action of emetin is in a measure due to one who received his medical education in this city. Dr. E. B. Vedder, a surgeon in the United States army, is a graduate of the University of Pennsylvania of whom we should be proud. While stationed in Manila, in the course of study of the old ipecac treatment of dysentery, he found that the success of this treatment coincided with the amount of emetin in the particular sample of ipecac employed, and on trial found that solutions of emetin are highly lethal to cultured endamœbæ *in vitro*—(not to take up the question whether the amœbæ in the culture used were true examples of

parasitic amœbæ or forms of non-parasitic type which had passed through the alimentary canal in an encysted condition). Colonel Rogers of the Indian medical service applied these findings of Vedder's to actual practice, first administering emetin in 1912 to cases of amœbic dysentery; and his happy results in the few cases first subjected to the remedy have rapidly been confirmed over the whole tropical world. Emetin is recognized today as practically a specific in amœbic dysentery and the amœbic complications of the disease. It is said, too, to be of value in other conditions, as in stopping pulmonary hemorrhage, in the treatment of Japanese schistosomiasis, and to have some effect upon syphilis, although much less than "606." The remedy is, if our results be sustained, of great value in pyorrhea, and, as yet a comparatively new agent, will in time probably be found of value in a variety of other pathological conditions.

Dr. C. J. Grieves, Baltimore. I can only thank you for your courtesy this evening. There is one thought which has come to me in connection with this work, and which was suggested to me through the clinical observations reported by Dr. Sellers, who knows of Dr. Vedder's work, and through whom I have heard a little of it. Dr. Sellers mentions the fact that when the first volunteer regiments went to the Philippine Islands, amœbic dysentery and pyorrhea alveolaris had a great deal to do with decimating their ranks, according to the reports of those who came back. Now, whether there is anything in the suggestion that, considering the disturbed metabolism, intoxication, the diet as customary in that country, and the hot climate, the amœba is present in pyorrhea following dysentery, I do not know, but I shall go home and take this matter up with somebody who knows something about the amœba.

Dr. W. J. Roe, Philadelphia. This is a distinct revelation to me, and I am personally indebted to Dr. Barrett and Dr. Smith for their timely revelation. It is apparent to all of us that the only safe mouth is a perfectly healthy mouth, in the true sense of the term, viz, one with no devitalized or diseased teeth or gums. This object the dental profession, the medical profession, and the public should strive to attain, and this is the only condition in which any of us can feel perfectly safe, because, as Dr. Grieves has shown us tonight and on previous occasions, a diseased or devitalized root is a hotbed for not only pus germs but many germs not pus-producing, and many others which we are not able to show, even by methods of cultivation, at the present time; they are sources of toxic infections that are detrimental in a great many ways. I think we are all indebted to Dr. Grieves for the valuable work he has carried on for a number of years.

Dr. Barrett (closing the discussion). There is nothing further that I can add that would be of interest. I feel that Dr. Smith has covered the subject very well; so I thank you.

Motion was then made and carried to adjourn until the Wednesday morning session.

Wednesday—*Morning Session.*

The meeting was called to order on Wednesday morning, July 1, 1914, at 10 o'clock, by the president, Dr. Seip.

The first order of business was the reading of the report of the Council, by the secretary, Dr. L. M. Weaver.

The next order of business was the reports of committees.

Dr. Schlegel moved that the reports of committees be read by title and published in the proceedings. (Motion carried.)

The secretary, Dr. Weaver, read communications from Dr. H. C. Brown, president of the National Dental Association, and from Dr. E. G. Link, chairman of the Local Committee of Arrangements, inviting the members of the society to the annual meeting of the National Dental Association to be held in Rochester in July.

Dr. Seip appointed as auditors Drs. J. C. Hertz, S. B. Luckie, and Geo. F. DeLong.

The next order of business was the reading of the report of the Committee on the President's Address, by Dr. W. D. DeLong, chairman, as follows:

Report of Committee on President's Address.

Mr. Chairman and Members of the Society, —The Committee on the President's Address approves the recommendation for changing the time of meeting, and hereby offers a resolution that the Council be directed to look into the matter of having the charter of the society so altered or amended as to enable our meeting to be held at some more suitable time of the year, and that steps be taken to obtain this relief at the coming session of the Legislature.

In reference to the recommendation to change the manner of electing officers of the society, with the idea of increasing the efficiency of its management, the committee recognizes the need for great improvement in this respect, but does not believe that the suggestions offered in the address would remedy the defect. The committee believes that the fundamental cause of the trouble lies in the present method of electing Council, and that, if provision were made whereby the component societies were permitted to elect one or more members to Council in proportion to their membership, greater efficiency in management, wider interest in the society, and a more representative form of government would result.

The committee does not believe that any change in the present method of handling the exhibits is desirable.

The recommendation that the duties of a publicity committee be added to those of the committee of local arrangements is approved.

In regard to the matter of dental nurses, the committee believes that the subject is one that will demand the serious attention of the dental profession in the next few years, but the present time does not seem opportune for this society to take any definite action.

We heartily indorse the request of the Lehigh Valley Dental Society that the State Society endeavor to have our public school code so changed that a competent ethical dentist be employed to examine the teeth of school children.

We approve the appointment of a committee to report to the State Society in reference to the distribution to school children of samples of proprietary dentifrices and mouth-washes.

The committee recognizes the overcrowded condition of the dental course, and heartily recommends that the society take definite action looking toward a change of the dental law so as to require a four years' course of not less than eight months each year. The committee further recommends that the existing preliminary educational requirements of four years of high-school work shall be demanded without conditions, before the student has entered upon his dental course.

The president's recommendation that the by-laws be changed to require membership in the National Dental Association is approved.

Of the address as a whole, your committee desires to express its highest appreciation, and commends the various important subjects discussed to the thoughtful consideration of the members of the society.

Respectfully submitted,
F. D. Gardiner,
H. E. Friesell,
W. D. DeLong, *Chairman.*

Motion was made and carried that the report be accepted.

Dr. Weaver moved that the Council be instructed to appoint a special committee to frame amendments to the law consistent with the recommendations of the committee, and that the same be referred to the Legislative Committee, recommending favorable action thereon. (Motion carried.)

Election of Officers.

The next order of business was the election of officers, which resulted as follows:

President—J. G. Lane, Philadelphia.
First Vice-president—H. E. Friesell, Pittsburgh.
Second Vice-president—H. B. McFadden, Philadelphia.
Recording Secretary—L. M. Weaver, Philadelphia.
Corresponding Secretary—G. S. Schlegel, Reading.
Treasurer—W. A. Spencer, Carbondale.
Board of Censors—F. W. Allen, C. M. Bordner, Geo. J. DeLong, E. W. Bohn, A. S. Koser.
Board of Examiners—W. D. DeLong, J. D. Whiteman, C. S. Van Horn, and S. P. Cameron.
Members of Council—W. A. McCready, S. P. Cameron, N. C. Heaton.

Motion was made and carried to adjourn until the afternoon session.

(To be continued.)

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA.

Fifty-first Annual Meeting, held at Delaware Water Gap, May 26-28, 1914.

(Continued from vol. lvi, page 1371.)

WEDNESDAY—*Afternoon Session.*

The meeting was called to order on Wednesday afternoon at 3 o'clock, by the president, Dr. Middaugh.

The first order of business for the afternoon was the election of officers for the ensuing year, which resulted as follows:

President—T. W. Thomas, Wilkes-Barre.
First Vice-president—E. J. Donnegan, Scranton.
Second Vice-president—Walter Richards, Slatington.
Recording Secretary—G. C. Knox, Scranton.
Financial Secretary—G. J. DeLong, Allentown.
Treasurer—C. A. Bachman, Emmaus.

Dr. V. S. JONES moved that the president and secretary be authorized to draw orders on the treasurer for the current expenses of the society prior to the annual meeting. (Motion carried.)

The next order of business was the calling of the roll.

The Board of Censors presented the following applicants for membership: Dr. L. J. Morgan of East Stroudsburg and Dr. R. F. Peters of Allentown. Motion was made and carried that they be elected to membership.

Drs. Hoeffer, Heaton, and Scott were appointed as the Auditing Committee to audit the books of the treasurer.

The first paper on the program for the afternoon session was one by Dr. A. P. HITCHENS, Glenolden, Pa., entitled "Rationale of the Use of Bacterial Vaccines in Pyorrhea Alveolaris." [This paper (see page 1) is published in connection with the proceedings of the Pennsylvania State Dental Society.]

The next paper on the program was one by Dr. JOSEPH HEAD, Philadelphia, entitled "The Practical Use of Vaccines in the Treatment of Mouth Infection."

The two papers were discussed by Dr. W. A. Spencer, Carbondale; Dr. Stevens; Dr. F. E. Stewart, Philadelphia; Dr. E. J. Donnegan, Scranton; Dr. R. H. Riethmüller, Philadelphia; the discussion was closed by Drs. Hitchens and Head.

Dr. SEIP moved that a vote of thanks be extended to Drs. Hitchens and Head for their papers. (Motion carried.)

Dr. SEIP further moved that Drs. Hitchens and Head be made corresponding members of the society. (Motion carried.)

The next order of business was the report of the Committee on the President's Address.

Motion was made and carried that the report of the Committee on the President's Address be adopted.

Dr. STRATTON moved that a committee be appointed to draft an amendment to the by-laws changing the time of the meeting.

The motion was carried, and the President appointed the following committee: Drs. Stratton, Seip, and Knox.

The meeting then adjourned until the evening session.

WEDNESDAY—*Evening Session.*

The meeting was called to order by the president, Dr. Middaugh, at 8.30 o'clock Wednesday evening.

The Committee on the Change in By-laws reported as follows: That Art. XIV of the by-laws be amended to read "The annual meeting of this association shall be held in the month of May or October." This amendment was, on motion, laid on the table for further action at the Thursday morning session.

The next order of business was the reading of a paper by Dr. F. E. STEWART, Philadelphia, entitled "Bacteria of the Mouth, and Their Relation to Systemic Disease."

[This paper is printed in full at page 61 of the present issue of the COSMOS.]

Discussion.

Dr. R. M. STRATTON, Scranton. This paper, like those of this afternoon, seems to me to be beyond discussion, owing to the newness of the experiments which are being made in vaccines, and I doubt if there are many men competent to discuss papers of this description.

For many years I have believed that many deaths and diseases are caused by infection from the oral cavity. I know, from personal experience, of two persons who almost died of infection from pyorrhea; one case was that of a man of high degree, the other of a woman who was a lowly servant. The latter patient died from intestinal trouble while I was treating her. I did the instrumentation necessary in such cases, when she was taken with intestinal trouble and died before an operation could be performed. There was some little difference of opinion as to the cause of her death, but apparently it was appendicitis. In the other case, the man absolutely refused to have his mouth treated in any way, and I am satisfied that he died from infection due to oral conditions.

As I said before, I think very few of us are capable of discussing these three papers from a scientific standpoint, but there is much in them to set us thinking, and I firmly believe the time will come when the condition of the oral cavity will enter into all diagnoses by the medical profession.

Dr. JOSEPH HEAD, Philadelphia. There are one or two points in the essayist's paper which I think it would be well to impress on the audience; these are the value of autogenous vaccines and the way in which autogenous vaccines should be prepared. Dr. Hitchens pointed out that an autogenous vaccine is not, of necessity, one which will cure the disease, but may be one which combines with extraneous germs. Therefore it is very important, in getting a vaccine—First, that the method should be studied by which to get rid of the extraneous germs, and that we get the germs which are causing the disease; second, that we should adopt a method by which the germs may be preserved, and not, as many do, merely make a jab at the point of inflammation, stick that on agar, let it grow for forty-eight hours, and then, without any regard to singling out the various germs, simply count them out and take the number of germs present—which are usually staphylococcus, which will crowd out everything else—and then inject that into the tissue in the wild hope that this "autogenous vaccine" will be the means of a cure. Therefore I feel that the chief thing for the dentist to do is to be careful that the necessary precautions are used in procuring the proper vaccine, and when the specimens are sent to the laboratory, be sure that they are sent to one where proper precautions are taken in the development of the vaccine, and then perhaps we have some chance that the real therapeutic effect of the vaccine will be produced.

Dr. A. P. HITCHENS, Glenolden, Pa. It occurred to me after the meeting this afternoon that I might have been more explicit in answering one of the questions asked, viz, that with regard to the recurrence of pyorrhea after it has apparently been cured. The fact that this disease has been made to disappear by the ordinary local treatment is not any

assurance that it may not appear again, and recurrence is by no means an impeachment that the dentist has not done his work thoroughly. To illustrate this, we may refer to the common furuncle. All physicians have successfully treated patients with boils. With the usual methods, it is not at all uncommon for more boils to develop after successful treatment of those which caused the patient to engage the services of a doctor. The recurrence is believed to be due to the peculiar susceptibility of the patient, and not to any lack of thoroughness on the part of the physician. The recurrence is actually due to the fact that the patient is not immune to staphylococcus infection, and, as patients are ordinarily treated, their recovery from boils is not associated with increased resistance to the staphylococcus. The same may be true of pyorrhea. The disease perhaps is cured as a result of local treatment, but the resistance of the patient to the bacteria causing the disease is not in any way increased, and the patient may have another attack of pyorrhea—about the same tooth or about another tooth. The conditions, I think, are identical. We know of persons who have had a hundred or a hundred and fifty boils in succession. The physician has not been blamed for this, but, if the patient had been treated with staphylococcus vaccine, the recurrence of the boils would have ceased. In my opinion, this recovery from infection without subsequent increased resistance is due to the fact that there is a zone of inflammation about the focus of disease which prevents the immunizing part of the bacterial protein from going out into the tissues, where it may stimulate the production of antibodies. The process is very much more complicated in the case of pyorrhea, because we have usually a number of different bacteria at work, and it is further complicated by the fact that there are nearly always foreign bodies present which are difficult to remove. Then, besides, there is a chance of constant reinfection due to the bacteria of the mouth. If we could cut away all the infected gum tissue and alveolar process and polish the tooth and its root perfectly, then make a surgically clean wound, and apply a dressing that would protect it from saliva and other possible means of contamination —if this could be done, pyorrhea could be easily cured. We can do all this with boils, and yet, unless the patient's resistance to the staphylococcus is increased, they continue to recur. But if the chief part of the treatment consists of the administration of staphylococcus vaccine, the boils disappear, and very rarely recur. Furthermore, I have seen on two or three occasions that boils already developing have cleared up, and have not gone through the usual evolution with pus formation. There is reason to believe that the same is true in regard to pyorrhea. With vaccine treatment, a cure should be more lasting than without it. It is of interest to note that following vaccine treatment, the benefits to the patient are not only local but general. Dr. Head has made really surprising observations in this regard. The benefit to the patient seems to be cumulative in its effect; the patient is not only apparently cured, but there is also established an immunity which causes him to increase in health for a considerable period afterward.

Dr. Stewart (closing the discussion). I do not think that I can add anything more. I have had a delightful visit to your meeting, and I wish to thank the members for the courtesies extended to me, and for the pleasure I have had in addressing you.

Dr. Seip moved that a vote of thanks be extended to Dr. Stewart for his paper, and also that Dr. Stewart be made a corresponding member of the society.

The motion was carried.

Motion was made and carried to adjourn.

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

PHILADELPHIA, JANUARY 1915.

EDITORIAL DEPARTMENT.

THE FORSYTH DENTAL INFIRMARY FOR CHILDREN.

ON Tuesday, November 24, 1914, the magnificent structure erected through the liberality of the brothers Forsyth was formally dedicated to its beneficent use. The occasion of the dedication was a notable one, in view of the fact that it marked the launching of an enterprise for which there is no precedent in the history of public benefactions—or, as expressed in the words of its founder, "In the construction of this building we have entered on a new field; no other building of this character is in existence; the problems we have faced have been encountered for the first time."

An examination of the physical condition of the children of the Boston public schools made under the auspices of the Division of Child Hygiene of the Boston Board of Health during the past year, has shown that of something over 118,000 pupils exam-

ined, more than 51,000 had obviously defective teeth. If to that number were added cases of defective nasal breathing, hypertrophied tonsils, defective palate, and diseased cervical glands, all of which conditions are known to be closely associated with and in a large number of instances caused by defects in development of the dental arches and maxillary bones, it would be found that besides the cases of "obviously defective teeth," over 47,000 additional cases having possible, even probable, causal dental relationships could be properly taken into the account in enumerating the total number of defects remediable either wholly or in part by dental and oral treatment.

The figures presented by the foregoing results of the physical examination of Boston public school children do not materially differ in kind or degree from those which have been obtained, or are normally obtainable, from any similar group of public school children. The need, then, for such an institution as the Forsyth Dental Infirmary is not only an obvious but a crying one. It is a universal need to meet which an attempt is being made in various ways and places—by the establishment of public school dental clinics in the larger centers of civilization, and by the attachment to hospitals and eleemosynary institutions—and, in the case of Philadelphia, under municipal supervision—of clinics for the relief of this general source of physical deficiency among school children. It is, however, to the everlasting credit, benevolence, and farsightedness of the Forsyth brothers that this great institution with its unequaled equipment and installation has been dedicated to the single purpose of redeeming the future citizens of Boston from the physical and mental handicap which the existence of this large class of remediable defects necessarily entails.

But the city of Boston will not be the sole beneficiary of this great humanitarian enterprise. As the pioneer of its class it will forever stand as the material expression of the courage, the sound judgment, the farseeing wisdom and faith of its founder in the largeness and reality of the opportunity which has confronted him for doing good to mankind—an opportunity which he has so intelligently and comprehensively embraced. There can be no question as to the success of the undertaking, for the Forsyth Dental Infirmary for Children is the material expression of a great public need efficiently met, and its mission will not have been completed

when it shall have ministered successfully to the needs of the children of the Boston public schools, nor will its success be finally measured in terms of its local usefulness—for, simply as an example of wise practical philanthropy, it must continue to exert an energizing influence in the same direction, and to arouse the spirit of benevolence in other localities to an appreciation of the untold good to humanity that must follow the creation of similar redemptive institutions in other large centers of civilization. The workers in the large field constituting the oral division of the art of healing may well be congratulated on the striking manner in which the service which the art and science of dentistry may render to humanity has been thus practically recognized; and the work and purposes of the Forsyth Dental Infirmary for Children should receive the sympathetic and cordial support of the profession everywhere.

The dedicatory address by Dr. Donald M. Gallie, which we here reproduce in full, presents in larger scope and detail the bearings both public and professional of this important pioneer movement:

Address of DONALD M. GALLIE, D.D.S., of Chicago,

AT THE DEDICATORY EXERCISES OF THE FORSYTH DENTAL INFIRMARY FOR CHILDREN, BOSTON, HELD NOVEMBER 24, 1914.

Mr. Chairman, Mr. Forsyth, Ladies and Gentlemen,—I wonder if there lives an American man or woman who has not had a great desire to visit Boston? Her colonial history, the part she played in the founding of these United States, the prominence of her sons in war, statecraft, letters, and philanthropy, the pre-eminence of her educational institutions, the architectural beauty of her buildings, the acknowledged culture of her people, and her great interest in humanity's betterment, make this city a shrine that every American should visit. I assure you I deem it the greatest privilege and honor to be the representative of the profession which is to profit so greatly by the ceremonies of today.

This magnificent gift and the dedication of this splendid infirmary mark an epoch in the history of dentistry. That history, unlike that of law, divinity, politics, and medicine, is comparatively recent. It is true that some of the early Egyptian, Greek, and Chinese writers made mention of the care of the teeth, and we have in some of the museums of Europe evidence of early dental operations. It was not until about the first quarter of the eighteenth century that anything worth mentioning was written. About this time Pierre Fauchard, a skilful and learned Frenchman, wrote extensively on the art and science of dentistry. Possessing some social prestige and extensive acquaintance with the learned men of other professions, he obtained for dentistry a recognition heretofore unknown.

To the French we owe much for the development and progress of dentistry; and this is especially true of early American dentistry, for it was Lemaire and Gardette, two Frenchmen, members of the Lafayette army, who started dentistry on a secure foundation in this new land. Boston has always played an important part in dental advancement. It was here that John Baker, one of the first of the English dentists, located, and had as an apprentice Paul Revere of revolutionary fame. It was here that Isaac Greenwood and Josiah Flagg, the two first native American dentists, studied and practiced, and from revolutionary days to the present time Boston has been a generous contributor to our profession.

The names of John Randall, Josiah Foster Flagg, Nathan Cooley Keep, Daniel Harwood, Josiah Tucker, Thos. Henderson Chandler, and Luther D. Shepard graced the roll of honor of American dentists. It was in Boston that Horace Wells, humanity's benefactor, the discoverer of anesthesia, studied and for a time practiced. Here also practiced Dr. William F. G. Morton, the discoverer of the anesthetic effect of ether. Sharing with Boston as a center of dental activity was Baltimore. Here a coterie of brilliant men, led by Horace H. Hayden, and later joined by Chapin A. Harris, did splendid service in gaining for dentistry its proper recognition as one of the professions. Through their zeal and efforts, in 1839 the first dental college was organized, the Baltimore College of Dental Surgery, with Chapin A. Harris as dean. Not satisfied with providing means of educating dentists for the future, these men realized that the education of the men of their time was also necessary—so in 1840 the first dental journal was published, known as the *American Journal of Dental Science*. This was immediately followed by the organizing of the first dental society in the world, the American Society of Dental Surgeons, the outgrowth of which is the National Dental Association, which I have the honor to represent today. Close upon these important events came the first dental law introduced and enforced, in the State of Alabama. It was the first law for the regulation of the practice of dentistry in any country. The starting of a dental college, journal, society, and laws placed America far in advance of other countries in everything that pertained to the knowledge and practice of dentistry; and this leadership I am pleased to say we still retain, although in other countries remarkable progress is evident. Since that time colleges have increased until today we have over fifty in the United States and Canada. The dental journals and the literature of the profession have increased accordingly. Dental societies are to be found in every state, city—yes, and in some sections every county—throughout the country. Every state and territory has laws regulating practice. Every effort is being made to raise the standard of efficiency—higher educational qualifications for college matriculation, extension of the college course, subjects taught that a graduate of a few years ago would hardly recognize as part of a dental curriculum; yet with this wonderful advancement, reaching almost perfection in manipulative skill and craftsmanship, in spite of our improved curriculum, we find ourselves unable to keep pace with the ravages of the most prevalent of all diseases, dental caries and oral sepsis. We know positively that the school children in all highly civilized countries show an alarming percentage of diseased mouths, in some sections as high as 90 per cent. We realized long ago that it was impossible to combat this condition by reparative means; we knew that our only hope was in getting at the cause; but how? Only a small percentage could be reached through the dental office; the influence through the home was limited. We knew the only

way to reach the masses and start our campaign of education was through the channel that all child education and instruction is obtained—namely, the public and parochial school. We urged, first, dental inspection, then class instruction in the care of the teeth, and lectures on oral hygiene. But these suggestions met with strong opposition, not only from the laity, school boards, and municipal officials, but in many cases from the medical profession. It was not until epidemics broke out in schools throughout the country, and the carrier of contagion was traced to the mouth, teeth, and tonsils, that the people and our medical teachers realized the importance of our campaign. In addition, a scientific and practical test was made in the Marion school of Cleveland, which demonstrated conclusively that the mental, moral, and physical condition of school children was greatly improved by dental inspection, instruction, and care.

In 1911, when preparing the annual message for the Illinois State Dental Society, I wrote the president of the school board and the commissioner of health of every city in the United States and Canada, having a population of over 35,000—of which there are about 130—asking them the following questions:

(1) Are the children of the public and parochial schools of your city instructed in the care of the teeth and surrounding tissues?

(2) Are the teeth of these children examined by a dentist?

(3) Have you any free dental clinic in your city where the teeth of the poor are cared for?

I received 65 answers.

To question (1) No, 40. Yes, 25.
" (2) No, 52. Yes, 13.
" (3) No, 42. Yes, 23.

In answer to question 3, the twenty-three answering yes were practically all from cities having dental colleges. Today, but three years later, if we were to send out this inquiry we would find that not only in practically all the large cities, but also in scores of the much smaller cities or towns they have inaugurated dental inspection, class instruction, and in many cases some means of caring for the unfortunate. In many of the large cities provision has been made for from five to fifteen clinics, and appropriations for this purpose run as high as $20,000 a year. Surely this is making progress; yet, gratifying as it is, how inadequate when we consider the tremendous demand and need! Fortunate indeed is the city of Boston, and blessed are the children of this great city, that they have such a citizen and such a benefactor as Mr. Forsyth, who has given this magnificent infirmary.

Not only have the mouth and teeth been the carriers of contagion and disease to children, but also the cause of many diseases the origin of which was until recently unknown. Hunter, the eminent English physician, claims that a diseased mouth is the most prolific cause for much of the chronic infections, diseased glands, intestinal disorders, nephritis, arthritis, pulmonary affections, and heart lesions. Before sixteen hundred physicians and dentists in Chicago a short time since, Dr. Charles Mayo read a paper entitled "The Mouth as a Focus of Infection." He closed in this manner: "The next great step in preventive medicine must be taken by the dental profession. Will they take it?"

In answer to that question, our profession from border to border and from coast to coast is attempting it, but we must creep before we walk.

We have not at present the many advantages that our medical colleagues enjoy. We have no hospital internship, no center of dental thought and instruction in Vienna, Berlin, Paris, London, and Edinburgh, no great post-graduate schools; at the present time no Rockefeller Foundation for Dental Research, no Carnegie Institute, no Johns Hopkins, with their unequaled equipment and unlimited resources. However, we have an army of earnest workers fully conscious of the great responsibilities placed upon them, who are making every effort to equip themselves for the great work, who are forming study-clubs and postgraduate classes in very many of the large cities, where scientific apparatus and laboratory facilities are available. We have state and local societies engaging eminent scientists to carry on special research. We have a National Dental Association which has grown from 900 two years ago to 14,000 today, and which has as component bodies the state and territory society of every state and territory in the Union; and these state and territorial societies have as component bodies all local, district, or county societies within the state, so that today the dentist in the remotest hamlet is in touch with the progress of the profession. We have in the National Dental Association a Scientific Foundation and Research Commission composed of twenty-four of our best thinkers and workers, who are doing excellent work, and who have already made valuable contributions to our science, and who fully expect within the next year to have a fund of $200,000 for research purposes. And today we have another great aid—the Forsyth Dental Infirmary, which I am sure will prove a great stimulus and inspiration to other good men, who, in the near future, will build and endow similar institutions in other great cities of this country.

Today, I feel that our profession is contributing a full measure to the great movement which is going on toward child welfare, race betterment, and human uplift.

Mr. Forsyth,—In behalf of the dental profession and in behalf of our little patients, I offer you our thanks and wish you God's blessing.

Bibliographical.

A Manual of Practical Hygiene for Students, Physicians, and Health Officers. By Charles Harrington, M.D., late Professor of Hygiene in the Medical School of Harvard University. Fifth Edition, Revised and Enlarged by Mark Wyman Richardson, M.D., Secretary of the State Board of Health of Massachusetts. Octavo, 933 pages, with 125 engravings, and 24 plates in colors and monochrome. Cloth, $5.00, net. Philadelphia and New York: Lea & Febiger. 1914.

The reviser, recognizing the growth and importance of the subject, has secured the collaboration of several of his associates in the Massachusetts State Board of Health; thus the book may be taken as an exposition of the views and practices of that body. The work in general has been well done, and in most instances is complete and up to date, though there are a few rather important omissions.

The section on Foods, as in previous editions, is given too much space for a general work, and has been added to by the inclusion of more statistical tables. Reference is made to Dr. Wiley's work on the effects of boric acid and the borates and benzoic acid and benzoates as preservatives, and to his controversy with the Bureau of Chemistry in regard to the latter, but no definite stand is taken on either side.

The section on Water has been somewhat condensed, and it would have been as well if as good judgment had been shown in that on Foods. A few new tests have been included, as those for iron and copper and the use of permanent standards for color determinations. Not sufficient emphasis is laid on the value of storage and sedimentation in water purification, either alone or as a preliminary to filtration, and no mention is made of the use of liquid chlorin in place of hypochlorite, either alone or as an added precaution after filtration, as advised by Major Darnell in 1911 and employed successfully for some months in Philadelphia and elsewhere. The statement that methods of formaldehyd disinfection by spraying have fallen into disuse is rather strange, considering that two of the largest cities in the country, Chicago and Philadelphia, are using spray methods regularly in house disinfection and find that when correctly employed they give decidedly the best results.

Surprisingly little change has been made in the sections on Sewage and Garbage Disposal. Under Disinfectants and Disinfection, reference is made to the U. S. P. H. methods for standardizing disinfectants, but no details are given and no credit is given to Rideal and Walker for their original work in this line. The use of paper sputum-cups for consumptives is emphasized, and a very practical method is given of increasing the efficiency of calcium oxid as a disinfectant for excreta by slaking the lime in hot water in the presence of the excreta, thus combining the chemical

action with the effect of the heat generated. Much emphasis is given to the views of Chapin of Providence and the Massachusetts Board on the uselessness of terminal disinfection after contagious diseases. While there is undoubtedly strong ground for this, many men doubt the advisability of adopting the practice in all cases in private houses, with the present lack of appreciation of sanitation and asepsis by the general housekeeper.

Under Military Hygiene—of especial interest at present—the principal additions are new data and photographs of army tents, and the inclusion of the U. S. A. rules for disinfection and the use of disinfectants.

Under Infection and Immunity, diphtheria immunization is well handled, and reference made to the use of the toxin-antitoxin mixture for this purpose. The advantages of prophylactic typhoid vaccination are dwelt upon, and mention is made of the curative use of the same, but no reference is made to the employment of sensitized vaccines. While their use may still be considered in the experimental stage, it may yet prove to be a decided advance.

Under Quarantine and Administrative Control of Communicable Diseases the new regulations forbidding the use of common drinking-cups in trains, depots, etc., are given, but no reference is made to the common towel or to the control of restaurants or barber shops. The articles on typhoid, tuberculosis, and ophthalmia neonatorum are excellent.

The section on Occupational Hygiene is entirely new and is excellent throughout, with a number of well-chosen photographic illustrations. Special emphasis is placed on the effects of dusts, fumes, and gases and their amelioration.

There is a new section on School Hygiene, excellent as far as it goes, with emphasis on the value of the school nurse and the importance of follow-up work, but not sufficient detail as to the routine examinations by the school physician for the detection of physical defects and their correction. The corrective application of eye-glasses is dwelt upon, as is the value of examinations of the teeth and free dental work by regularly employed school dentists. No reference is made to the care of the teeth in the section on Personal Hygiene.

The section on Insects is much revised, the references to malarial, yellow fever, and filarial transmission by mosquitos being excellent, but the louse as a carrier of typhus fever is not mentioned. References to ticks, bed-bugs, and flies are rather meager, and no reference is made to the breeding-places of the common house-fly—or "typhoid fly" as christened by Dr. Howard—and no mention of methods of destroying flies and preventing their development.

The other sections remain unaltered. The rearrangement and tabulation of the table of contents is a decided improvement.

H. F. S.

A Laboratory Manual of Qualitative Chemical Analysis. By A. R. Bliss, Jr., M.D., Ph.G., Professor of Chemistry and Pharmacy in the Birmingham Medical College. Octavo, 244 pages, with working tables. Cloth, $2.00 net. Philadelphia and London: W. B. Saunders Company. 1914.

A careful examination of this work fails to reveal any large justification for its publication. It is apparently "just another Qualitative Analysis book"

setting forth the same tests that one finds in scores of others. The directions for manipulation are a little fuller than usual, and the lists of alloys and pharmaceutical preparations which follow each group introduce some information which is sometimes desired. The author has changed the recognized group divisions of the elements by calling the acid members of group II "group III," and calling groups III and IV "group IV," but this has also been done by a number of other writers on the same subject. There is nothing in the work apparently to especially commend or to condemn. It is another materialization of the personal point of view which seems to lead each teacher to think that he must have a book of his own compilation.

THE SCIENCE AND PRACTICE OF DENTAL SURGERY. Edited by NORMAN G. BENNETT, M.A., M.B., B.C.(Cantab.), L.D.S.(Eng.), Dental Surgeon to St. George's Hospital and the Royal Dental Hospital, London; Member of the Board of Examiners in Dental Surgery, Royal College of Surgeons of England. With an Appendix on DENTAL JURISPRUDENCE, by P. B. HENDERSON, B.A.(Oxon.), Solicitor to the Supreme Court. With 993 text illustrations; 786 pages. New York: William Wood & Co. 1914.

The title-page of the above handsome volume hardly conveys, to those who have not yet seen it, the intelligence that Mr. Norman Bennett, in addition to his own share in treating certain sections of the book, has essayed the difficult task of editing the work and writings of thirty of his dental colleagues in Great Britain, Canada, and New Zealand; but this knowledge is soon gained by glancing at the pages which immediately precede the first chapter, where it is found that the number of contributors first mentioned is increased by three, two being the names of medical men, the other of a distinguished lawyer.

The publication in one volume of the latest observations of many eminent dental practitioners, each an acknowledged expert in his subject, is a novel event of unusual literary interest and scientific importance in the dental world. It is of interest because this is the first occasion, we believe, in Great Britain, in which several dental authors and authorities have contributed to the making of one volume; it is of importance because, by this contribution the practice of dentistry now takes a closer place with relation to the practice of medicine and surgery, inasmuch as many books, dealing with these subjects, written through the combined effort of an assemblage of experts, have already appeared. This plan of co-operation is not new in this country, but, as has occurred before in similarly constructed treatises, this one, while offering to the reader the most recent scientific methods of treatment of the various subspecialties in the science and art of dental surgery, seems to possess the somewhat serious disadvantages of lack of co-ordination, of a deficiency and incongruity of literary style, of absence of methodical and systematic arrangement, and of a general sense of incompleteness, which are as frequently apparent in our own publications as in the volume before us. It is impossible for an editor to infuse into his army of contributors an identical vein of thought. He can take steps to this end, as is evident here, but the result is not just the same as if the whole were the outcome of his own pen. In short, a collection of essays, no

matter how good they may be individually, is not one with a finished homogeneous literary composition.

Taking the foregoing into consideration, therefore, it may be noted at once that the book is a marked advance on any other British dental work, and as such should be eagerly perused by students and dentists of other nationalities for information with regard to the trend of thought in practical and scientific dental matters in England.

While the choice of subjects has not included our ideas of what constitutes the science and art of dental surgery, the book very creditably achieves its object, which is "to combine the scientific with the practical, for neither is of much value to the practitioner without the other, . . . an effort having been made to include everything in pathology or practice . . . . that might be of value to the modern practitioner."

Of the 786 pages which comprise the volume, nearly two hundred are occupied by contributions with regard to the irregularities in position of the teeth, and the pathological development of their associated parts. The subject is very complete, being dealt with from the points of view of occlusion, growth of the jaws, the influences of heredity, environment, and pathological conditions acting as causative agents, classifications, studies of different types, general objects of treatment, methods of estimation of the size and configuration of the dental arches, comparison between surgical and mechanical treatment, and age best suited for the latter. The principles of retention, mechanics, and physiology of tooth movement, the technique of orthodontics, and the construction of appliances, are fully entered into and described; and this section of the book concludes with descriptions of the correction of individual concrete cases. Throughout these chapters we observe with satisfaction the great influence that American authors and practitioners of oral surgery have had in reducing the study of orthodontics to a scientific proposition, and while not entirely agreeing with the writers, we consider that in these pages the reader has placed before him fair unbiased statements and collections of facts and theories which will be of real service to the average dental surgeon when brought up sometimes against perplexing and difficult situations. It may be that the importance of the mechanics of these problems is a little too much enforced, and we are of the opinion that it is quite easy to lay too great a weight upon the hypothetical mathematical aspect of a condition which, after all, is one of nature's making and therefore hard to reduce to any known precise dogma or formula. The book will, however, probably be chiefly read and remembered for these chapters, and those who have many children in their *clientèle* will be benefited very much by becoming thoroughly conversant with them.

The titles of the other chapters are as follows: Development of the Jaws and Teeth, before and after birth; Affections Associated with the Third Molar and Due to Diseased Teeth; Abnormalities in size, number, form, and structure; Saliva and Calculus; Oral Bacteria; Etiology and Pathology of Dental Caries; Erosion, Abrasion, and Attrition; Oral Hygiene; Treatment of Cavities by Filling; Antiseptic Technique and Dental Surgery; Diagnosis of Cause of Pain; Treatment of Children's Teeth; Diseases of the Periodontal Membrane; Dental Electro-Therapeu-

tics; Injuries and Fractures; Bridge Work; Crown Work; Extraction of Teeth; Local Anesthesia; Oral Sepsis; Empyema of the Maxillary Sinus (exclusively from the rhinological and not as it should be, from the dental aspect); Dental Radiography; Odontomes; Actinomycosis, and Dental Jurisprudence.

Of these, strictly speaking, it seems to us that the articles describing the "Development of the Jaws Before Birth," "The Dental Operating Room: Its Appointments and Hygiene," "Odontomes," "Actinomycosis," and "Oral Sepsis," are unnecessary, if not out of place, in a volume of this kind. While the last-named essay is very readable, it must be remembered that the whole subject of so-called oral sepsis—or "dental" sepsis, as we note some would prefer to call it—so little understood, is nevertheless inclined to be over-elaborated, not to say even embroidered, with the result that many dogmatic and doctrinal *ex parte* statements connected with it must be greatly discounted, and time must be allowed to show the valency or otherwise of somewhat prejudiced views.

With regard to further changes in nomenclature, we cannot think that, as shown on page vi of the preface, the substitution of "inferior alveolar canal" for "inferior dental canal," "inferior alveolar nerve" for "inferior dental nerve," and "auditory tube" for "Eustachian tube," is anatomically correct or desirable. The terms "mandibular canal" and "mandibular nerve" are surely to be preferred.

A useful feature of each chapter—with the exception of five—is the addition of a complete list of references to papers and text-books dealing with each subject, and a particularly complete index concludes the volume.

The work has been well published. It is singularly free from typographical or other errors, but each page should bear on the top some indication of the character of the text beneath. With a rearrangement of the parts, the omission of some, the fusion of others—as, for instance, chapters XVIII and XLVI—the "heading" of individual pages, and the replacement of a few illustrations which are old-fashioned and should be either redrawn or excluded, the second edition should enjoy even a larger circulation than will evidently be the case with the first. We can thoroughly recommend the book.

Review of Current Dental Literature.

THE TONSILS AS A HABITAT OF ORAL ENDAMŒBÆ. POSSIBILITY OF SYSTEMIC COMPLICATIONS OF ORAL ENDAMŒBIASIS. By Allen J. Smith, M.D., W. S. Middleton, M.D., and M. T. Barrett, D.D.S.

[*American Journal of Clinical Medicine*, Chicago, November 1914.]

HAS PYORRHEA BEEN MASTERED AT LAST? Editorial.

In continuation of their important and most promising studies on the endamœbæ, Smith and Barrett* have now been able to prove that these parasites at times involve the tonsils also. Believing that from their proximity to pyorrhea pockets, which these investigators hold to be the analogs of the ulcerous excavations found in the mucosa and submucosa of the colon in amœbic dysentery, and from their favoring anatomic structure, the tonsils might be invaded and form another habitat for these endamœbæ, they have made a number of examinations of tonsils to determine their occurrence in these organs. Of seventeen cases of excised tonsils, five showed the motile amœbæ of the type of endamœba buccalis Prowazek. The tonsils of the five persons in whom these organisms were demonstrated were all large, with pouting crypts, and were removed from young persons presenting the usual local and general symptoms of chronic tonsillitis with irregularly occurring exacerbations. A fully satisfactory method for collecting the cryptal contents of tonsils *in situ* still remains to be worked out.

Pyorrhea alveolaris has for years been suspected of primary relationship to various systemic disturbances, including particularly certain chronic or recurrent arthritic affections, and possibly, too, some of the anemias of obscure origin and degenerative lesions of various parenchymatous organs; and even greater suspicion, amounting almost to certainty, has attached to tonsillar affections in relation to such systemic complications. Thus of six cases of chronic arthritis, four exhibited endamœbæ in material obtained from the tonsils. In several instances of cases treated for pyorrhea by Dr. Barrett, the disappearance of symptoms of gastric and intestinal disorders simultaneously with the cure of the pyorrhea was noted.

In another case of pyorrhea and associated obscure anemia, the local administration of emetin hydrochlorid for the pyorrhea was promptly followed by a remarkable gain in weight and improvement in general condition, which suggests the possibility that some of the obscure anemias, especially those suspected of being of hemolytic origin, might find their explanation in oral endamœbiasis. In the gums of three other cases regarded as pernicious anemia endamœba buccalis was found, and in one of these also in the tonsils. Though no definite conclusions could be made, as other remedies were applied conjointly, emetin applied locally and hypodermatically produced notable improvement.

The writers freely acknowledge that the scant data here presented can in no wise be interpreted as proving that oral endamœbiasis is surely a factor of generalized intoxication in the production of arthritis and anemia. The positive finding of the parasitism, however, and the favorable results of emetin therapy in the few cases reported, are sufficiently suggestive to warrant further trial. Whatever the relations may be between the amœbæ and the accompanying vegetable micro-organisms, one may be certain that the amœbæ feed largely on the latter, and in this bacterial phagocytic action they doubtless set free from this and that organism different

* Dental Cosmos for August 1914, vol. lvi, p. 948; also December 1914, vol. lvi, p. 1345.

endotoxins, and the end-results of toxic absorption are sure to vary, now manifesting as hemolysis, now as cellular degenerations or necroses of fixed tissues, now as inflammatory changes, as of synovial and serous membranes.

The *American Journal of Clinical Medicine*, commenting on Barrett and Smith's discovery, hails it as promising to be the most important therapeutic discovery since Ehrlich put out salvarsan, and reprints in full the editorial comment of the *New Orleans Medical and Surgical Journal* of October 1914 on the findings of amœbæ in pyorrhea alveolaris by Dr. C. C. Bass and F. M. Johns, of the Tulane College of Medicine, presented in a paper read before the Orleans Medical Society meeting held on September 14, 1914. These investigators, who have been prominent in the study of malarial organisms, demonstrated the endamœba buccalis in the mouth lesions of 85 out of 87 cases, and in all stages of pyorrhea. They further announced having obtained most remarkable and gratifying results from treatment with emetin hydrochlorid, administered hypodermatically. They have experimented considerably, with the object of determining the proper dosage of emetin for this purpose, also to ascertain the proper interval between doses and the necessary duration of the treatment. They have not reached final conclusions, and are emphatic in stating that further experience and experiments now under way are likely to modify the present routine.

The dosage suggested is ½ grain of emetin hydrochlorid dissolved in one cc. of water, given hypodermatically in the arm—or other part of the body—each day for three successive days. A similar dose should follow every fourth to seventh day, until the gums are entirely healed and the loosened teeth have been tightened in their places. The degree of peridental membrane destruction will determine the length of treatment, which may be only a few days or may need months.

The object of the repeated doses of emetin after the first few days' treatment is to destroy any amœbæ which may have escaped the previous treatment, and to prevent the reinfection likely to occur before the gums have had a chance to heal and the root sockets to resume normal condition.

Infection with this particular amœba is widespread, and the authors suggest that brushing the teeth with a few drops of fluid extract of ipecac on a wet brush may be prophylactic in mild or early cases of the disease. Bass and Johns express the belief that the treatment submitted by them is specific for pyorrhea alveolaris, but that it cannot be expected to replace the physical damage done by the disease. The usual dental care of the mouth must be practiced, and the treatment of gums and mouth is necessary just as if there were no such infection.

The *American Journal of Clinical Medicine* considers Barrett and Smith's treatment of filling the gingival pockets and their walls with a 1 per cent. solution of emetin hydrochlorid as more logical, and suggests that the ideal method of treatment would apparently be the conjoint use of hypodermatic injections and local applications.

[*Zahnaerztliche Rundschau*, Berlin, November 8, 1914.]

STATISTICAL OBSERVATIONS ON DIABETES AND PYORRHEA ALVEOLARIS.

By Dr. Juljan Zilz.

The writer's extremely valuable statistics have been collected during the months of May and June 1914 in the First Medical Clinic of Vienna, in one hundred diabetics belonging mostly to the working class, who had enjoyed dental treatment in but few instances. Seventy-one of these one hundred diabetics were suffering with pyorrhea alveolaris, the women being more generally affected than the men. In regard to the synchronism of diabetes and pyorrhea, it was ascertained that in 47.8 per cent. the pyorrhea had preceded the diabetes, which fact speaks strongly in favor of those observers who maintain that every pyorrhea patient is a suspect of diabetes. In 9.8 per cent. the pyorrhea immediately followed the incipiency of the diabetes. In 25.3 per cent. the pyorrhea alveolaris appeared simultaneously with the diabetes.

The fact that in 28 per cent. of cases the appearance of diabetes and pyorrhea was associated with circular caries [erosions?] at the cervical margins of the anterior teeth and bicuspids as well as at the buccal surface of the molars, corroborates Scheff's view that caries appears relatively soon after diabetic affection, and in some cases may be utilized

as a diagnostic symptom. It is not surprising to find dental caries in diabetics, since in diabetes there are disturbances of the pancreatic secretions, diabetes being artificially produced in animals by extirpation of the pancreas. This pancreatitis arises in diabetics no matter whether it be due to syphilis, arterio-sclerosis, former infectious disease, trauma, over-exertion, etc. According to Kranz, pyorrhea alveolaris is a very good aid in the early diagnosis of disturbed carbohydrate metabolism, which is regulated by the pancreas, the suprarenal capsule, and the hypophysis cerebri.

Of twenty-nine diabetics examined who exhibited no pyorrhea, sixteen had suffered with diabetes only a few weeks; yet even in these, subjective discomfort as well as slight redness of the gingival papillæ and viscous deposits upon the cervical margins labially and lingually of the incisors and molars were noted. In three edentulous patients who wore full dentures, soreness of the gums and ulcerations had occurred simultaneously with the beginning of the diabetes, and the wearing of the dentures had become impossible. In five patients of sixteen years and less, no pyorrhea could be observed.

In two other carefully compiled tables, Zilz gives the appalling number of 522 teeth which had fallen out in his one hundred patients, and the ratio of frequency of loss for each class of teeth, as follows: Lower centrals and laterals, upper centrals, laterals and second bicuspids, lower canines and second bicuspids, upper canines, lower first molars, upper first molars, lower first bicuspids, lower second and third molars, upper first bicuspids, second and third molars. The ages of the patients in whom this ratio was obtained ranged between thirty-five and seventy years of age, and the ratio of loss between lower centrals and upper third molars ranged between 84 and 4 per cent. The saliva in all these patients showed acid reaction, and there was increased sensitivity of the teeth to thermal changes and fruit acids. In almost all cases, subgingival calculus, gingival inflammations and pockets, necrosis and resorption of the alveolar process and pus on the labial cervices of lower incisors and upper molars were observed. Microscopic examination of pus smears always showed a mixed infection. In several cases the loose teeth became firm again upon the institution of therapeutic treatment of the diabetes.

[*Oesterreich.-ungarische Vierteljahrsschrift für Zahnheilkunde*, Vienna, April 1914.]

IMPLANTATION OF ARTIFICIAL ROOTS BY THE GREENFIELD METHOD. By Dr. J. Peter.

Peter gives a very interesting history of the efforts at replacing lost teeth by replantation, transplantation, and implantation, the first authentic case of which is reported by Ambroise Paré in 1594. He criticizes the incomplete description of technique and the fragmentary case histories which Greenfield gives in his article published in the April 1913 issue of the Dental Cosmos, and also the lack of explanation of the healing process which follows the implantation of artificial roots. Peter's technique differs from that of Greenfield in that he does not always leave a central core of bone, the nutrition of which he considers so seriously impaired, for some time at least, that the danger of its becoming infected is very great. Instead of cylindrical trephines like Greenfield's he uses conical ones with larger diameter at the cutting edge. Instead of filling the root-socket with bismuth paste—which he considers impossible—he dips his cribs into liquefied bismuth paste. These cribs, which are also slightly conical, corresponding to the shape of the trephine, are made of 20 per cent. iridioplatinum with a 20-karat gold base, and have a diameter of 5, 7, and 9 mm., the 11-mm. size being too large for European jaws. Owing to the conical shape of the crib, no fixation or other protection is necessary. Peter, following Schroeder's opinion, believes that the crib is surrounded by a more or less thick layer of connective tissue, resembling periosteum, and that new bone will form only in very favorable cases. The chances of an artificial root healing-in are the better the sooner after the loss of a tooth the operation is made. The character of the alveolar process must be closely examined. In arteriosclerosis, implantation is contra-indicated. Great caution is necessary in manipulating the trephine, as the jaw-bone varies in thickness, hence also in resistance. Peter's arguments are supported by several text figures, illustrating the technique, and thirty beautiful radiographs showing various stages of the

healing process in the five cases of implantation reported, one of which proved a failure owing to infection supervening.

ON THE PROCESS OF CALCIFICATION IN ENAMEL AND DENTIN. By J. Howard Mummery, L.D.S., M.R.C.S.

Mummery's name is so intimately connected with research in dental histology that we have come to regard any of his writings on this subject as of highest authority. In the present essay he endeavors to show that calcification in dentin and enamel is in great part a physical phenomenon, and that the actual deposit occurs in the form of calcospherites. While it is true that no artificial experiment can accurately represent what occurs in the living body, the resemblances are very strong, and the objections have been chiefly based on the chemical difficulty of the composition of the dentin and enamel. He has, however, endeavored to show that the spherical form is not retained in completed, well-formed dentin or enamel, and it is highly probable that when the lime salts are deposited in the colloid matrix substance, they are true calcospherites as produced artificially, the carbonate of calcium being combined with a small proportion only of phosphate. As phosphates are added from the blood, the large calcospherites break down, and the disintegrated particles form the finally consolidated enamel.

In dentin, also, except where the process has been arrested at the interglobular spaces, a similar breaking down takes place, the only evidence of their former presence being the lamination of the dentin, finally obscured by full calcification.

The protoplasmic prolongation of the cell in the form of the dentinal fibril would be considered to share in the functions of the cell of which it forms a part, and there are strong evidences that calcific matter is transmitted by the fibril. The translucent zone in caries, which a great weight of evidence suggests is due to calcification in the tubes, and the peripheral occlusion of the tubes on exposed surfaces, point to this extension of the cell protoplasm being the channel by which lime salts are conveyed to the dentin.

If, as is claimed, the sheath of Neumann serves as a dialyzing membrane, the comprehension of calcification in the dentin is simplified. The odontoblast cell, either alone or in common with other cells in the pulp, would deposit the gelatinous basis substance of the odontogenetic zone, the lime salts from the circulating blood would be transmitted by the fibril, and, by dialysis into the matrix, lay down the calcifying material in globular form, slow diffusion of the component salts being an important factor. Globular calcospherites in the enamel also suggest this slow diffusion, by dialysis through the inner ameloblastic membrane, or its equivalent—the outer surface of the albuminoid material in which the deposit takes place—and, as the matrix substance becomes richer in phosphates, the breaking-up of these bodies into smaller elements.

[*Universal Medical Record*, London, May 1914.]

DENTAL CARIES IN CHILDHOOD. CRITICAL ANNOTATIONS.

The *Record's* critical review of several important papers on dental caries in childhood is not only a welcome symptom of the recognition of the importance of this problem in medical circles, but it contains so many points valuable to the dentist who, with the increasing enlightenment of the public in dental matters, is so often called upon for advice in regard to dietetics, that it deserves special consideration in these columns.

If we indeed dig our graves with our teeth it would appear that there are those who hasten the work not by energy but by neglect of the instruments. Dental caries is favored by too easy a treatment of the teeth, and the fault takes divers forms, some of which are discussed by Fordyce and Gibbs (*Edin. Med. Journ.*, March 1914). These observers believe that the common causes of dental caries and dyspepsia in childhood are: (1) lack of breast-nursing, improper hand-feeding; (2) pap-feeding on weaning; (3) misuse of raw fruit, habitual sweet-eating; (4) excess of carbohydrate food; (5) lack of animal food.

Three months of breast-feeding is generally held to be very advisable, but the welfare of the teeth requires a longer period. The child fed naturally for a longer time has larger arches than the hand-fed one, because of the effort of suckling and the spreading effect of the nipple which is pressed on the palate by the tongue. Hand-feeding favors maldevelopment of the teeth, which are subsequently

removed because of their unsightly appearance.

Toward the end of the first year too great distrust of the baby's digestive power is very common, and concentrated soft pap, generally over-rich in carbohydrate, is freely administered. Now, the teeth suitable for chewing appear in the second year; the incisors, which are meant for tearing and gnawing, are the first to show. The gnawing of bones under supervision is beneficial, and the child should also have fresh fruit juice by being allowed to suck the juice from an orange. Raw fruit may be given to chew and suck only if great care is exercised.

In the second year, milk is still the chief part of the diet, but animal food is required —eggs, soup, fish, and light meat—and a variety of vegetable food is advisable. The desire to use the teeth is destroyed by giving food which does not require mastication. Therefore starchy food should be given in as dry, coarse, and hard a form as possible. Abstinence from meat in the second year favors flabbiness and a tendency to adenoids and tonsillar, pharyngeal, and glandular tuberculosis. The potato, of which we hear so much in these days, is often less valuable than well-boiled vegetables, and stewed fruit is generally safe.

No meal should end with biscuit, jam, or cake. The fragments lodge and ferment. They ought to be scrubbed off with hard toast and butter, or rusk, and if possible followed by fresh fruit. Apple juice is acid, and has a good scouring effect. A good substitute is a saturated solution of acid potassium tartrate, with which the mouth may be rinsed.

It is interesting to note that, however useful acid be in the mouth when the teeth are sound, in the presence of caries it causes pain. Hence a useful symptomatic treatment of toothache is to use a solution of bicarbonate of soda or sal volatile, which neutralizes the acidity and checks the pain. We must note, however, that many dentists hold that acid products from carbohydrates favor caries by attacking the enamel.

The indiscriminate eating of sweets is a great evil. The value of a tooth-brush used at bedtime is very small. After each meal the mouth ought to be left in a naturally hygienic state. The dyspepsia in childhood is usually of carbohydrate origin, and bread, biscuits, porridge, potatoes, and puddings have their dangers from excess. The gastroenterology of childhood should concern itself with prescribing *apéritifs* less than with a sufficiency of proteins.

The quinquennium starting with the age of eight is a unique period of health, activity, endurance, and extension of interests outside of adult influence. Breakfast should be the first meal, and there should be three others between it and supper at 6.30 P.M. Dental caries is very common, and an affected tooth should be filled without delay so that it may be used. A tooth which cannot bite because it is tender favors irregularity of the permanent teeth.

At this age, too, the child has orgies of "tuck" at any odd time. Sweets ought to be eaten in small quantities at dinner and tea and followed by raw fruit. Sugar always occurs in nature (except with honey) mixed with a large proportion of detergent fibrous tissue and acid salts; thus mixed it is harmless.

Another investigation into the causation of dental caries in childhood has lately been reported by Cook (*Lancet*, March 28, 1914). His study deals with the effects of drinking-water in eighty districts on the teeth of children over twelve years old. His article represents a vast amount of labor of a severely statistical kind, but it may be said that he aimed at correlating the total, the temporary and the permanent hardness of the drinking-water with the percentage of children having four or more carious teeth—this standard coinciding with the returns required by the medical officer to the Board of Education. He finds a definite association between the quality of the drinking-water and the amount of dental caries amongst the school children: the harder the water the better the teeth, and obversely. The correlation is highest (0.491) in the case of the temporary hardness, and this is of interest in view of the recently advanced conjecture concerning calcium metabolism and dental caries.

Cook has also found that districts with harder water have a lower infantile mortality, also that where the infantile mortality is low the children are found to have better teeth. There is no evidence to show that unfavorable surroundings, such as are found in the industrial districts of Yorkshire and Lancashire, have any influence upon the relationship between the hardness of water and the amount of caries amongst school children.

There is thus an association between excessive softness of water and an increased amount of dental caries amongst the school children (so far as urban districts are concerned) and obversely. Environmental conditions do not seem to be a source of the relation, which Cook points out specifically as merely an association and must not be regarded as necessarily cause and effect.

One may adduce, in support of Cook's study, the appalling prevalence of vile teeth among the natives in Wales, and the possibility of an increase in the amount of dental caries in Birmingham, which has a soft water, drawn from the Welsh mountains.

It was stated above that lack of breast-feeding was a fruitful cause of dental caries in childhood. It may be necessary, however, to wean a child in conditions such as those suggested a year ago (*Univ. Med. Record*, 1913, i, p. 212). Similar and other considerations on weaning are discussed by Leuret (*Journ. de Méd. de Bordeaux*, April 5, 1914). He is in favor of partly weaning an infant after the fourth month, even though it is progressing well on breast milk and the mother's health is good; giving just one bottleful of cow's milk a day. thus providing for the case of a severe illness or death suddenly interrupting lactation. He advises 100 c.cm. of pure milk, three hours before the next breast feed is given, and this should gradually lead toward four-bottle feeds in the eighth month.

He also points out that approximately 11 per cent. only of women desire to suckle their babies, quoting Buller of Madrid, though Marfan and Aschoff (in 1911) found about 9.3 per cent. of women were incapable of doing so. Much the same figure has recently been given in this country for women of the higher classes, who have a sincere wish to complete their natural function.

We shall not follow Leuret in his enumeration of the well-known local and constitutional states which necessitate weaning. His remarks on the better-known of these contain nothing novel, while the others he cites require much further evidence before their relationship with weaning can be accepted. His remarks on alcoholism in the mother would be well ignored in favor of those by Ortali (*Gazz. degli Osped.*, November 30, 1913), who dwelt at length on the results, in children, of drunkenness in parents, though his conclusions also erred on the sweeping side.

Leuret points out that the quantity of iron in the infant is important with regard to weaning. The iron in the suckling is more than that in the ash of the milk. Increase in weight depends on the amount of iron fixed in liver and spleen, and therefore when an infant has to be weaned early, iron should be given. According to Barber, spinach soup (containing 36 mgm. to 100 gm.) has no result. Meat-juice, containing 20 to 37 mgm., may be given up to six drams a day; egg yolk, which contains 15 to 24 mgm., also contains fats which disturb digestion; barley contains 21 mgm.

Leuret concludes that the normal child should be weaned gradually from the ninth month; the syphilitic or tuberculous, or born of debilitated parents, about the fifth month.

RÉSUMÉS OF PAPERS PRESENTED AT THE SIXTH INTERNATIONAL DENTAL CONGRESS,

London, Eng., August 3, 1914.

SECTION V.—*Dental Prosthesis.*

PORCELAIN WORK. By DOUGLAS GABELL, M.R.C.S., L.R.C.P., L.D.S.ENG.

Porcelain powder cannot be packed to more than two-thirds fill any space. This is the only cause of shrinkage. There are other causes for distortion and fracture during fusing.

Maximum consolidation takes place at a temperature far below the advertised fusing-points, and before glazing of the surface.

Time is as important as temperature in fusing.

The amount of shrinkage cannot be reduced, but the effects can be controlled.

Porcelains vary very little in strength and shrinkage, but very much in fusing-points, working qualities, appearance, weight, and solubility.

Platinum gauze and wire, correctly placed, can greatly strengthen and assist in the manipulation of porcelain.

Price's "artificial stone" is of great value in manipulating porcelain.

Porcelain body should be fused inclosed in an investment and not openly exposed in the furnace.

Section VI.—*Orthodontics.*

A MODIFIED JACKSON CRIB. By Hubert C. Visick.

The Jackson crib is an excellent means for retaining removable orthodontic appliances, but where one has to crib a permanent tooth which is only partly erupted, it is sometimes impossible to get a secure hold.

In these cases one can obtain all the necessary hold by soldering a piece of metal plate to the gingival aspect of the crib, and shaping the plate to grip the neck of the tooth, particularly at the medial and distal angles.

Another piece of plate fitted to the neck, on the lingual side, still further increases the grip.

A NEW SYSTEM FOR THE CORRECTION OF PROGNATHISM AND ANTEVERSION OF THE TEETH WITHOUT HEAD-GEAR OR ANY OTHER EXTERIOR APPARATUS. By Dr. Vincenzo Guebini, Naples.

The difficulty of persuading patients, especially young ladies, to carry external orthodontic apparatus, and the accidental displacement of the same during the night, have brought me to invent a more rational, easy, and sure method for the correction of prognathism and anteversion. This method has also the advantage of avoiding the unpleasant and often injurious application of gold bands to the molars.

The apparatus consists of three pieces, two lateral and one anterior. Each lateral piece is formed by a long cap of fused gold applied to the molar and premolar teeth, and upon which a retention point is to be found near the first premolar. The front piece consists of a gold plate covering the incisors and canines and to which two buttons are soldered, one at each lateral end. On each side a ring of elastic rubber clasps the button and the above-mentioned retention point, so that, by means of the traction of these two elastic rings, the plate is continually pressed on the anterior surface of the front teeth.

Section VII.—*Oral Surgery and Surgical Prosthesis.*

THE VELUM OBTURATOR FOR THE MECHANICAL CORRECTION OF CLEFT PALATE. By Calvin S. Case, D.D.S., M.D., Chicago.

The principal claims of this paper which are new and as yet unpublished relate to the possibility and importance of retaining the velum obturator in its position in the mouth principally through the involuntary activities of the palatal and pharyngeal muscles, without the employment of any dental plate or other contrivance to which artificial palates are usually attached. And while it rests lightly and comparatively loosely in its place, giving free access of air through the nasal passage for healthful breathing, but with power on the part of the muscles to effectively close this opening in the utterance of nearly all the sounds of speech, and while patients are enabled to easily remove it at will for cleansing purposes, it is secured from the dangers of accidental dislodgment in any position of the head during either waking or sleeping hours, and consequently is worn with perfect unconsciousness of its presence in the mouth. It is shown, moreover, that the importance of this qualification lies not so much in the matter of convenience to patients, as in that it enables them to attain to those higher qualities of speech—especially resonance—which are found to be so invariably absent with all who wear artificial palates.

A NEW TREATMENT OF MAXILLARY SINUSITIS. By Dr. B. Landete, Madrid.

The well-known inflammation of the maxillary sinus has been treated by several processes, according to its character—empyema, pyo-sinus, simple sinusitis (pyo-sinusitis), or fungous sinusitis, caused by hypertrophy of the mucous membrane which covers the sinus.

More than a year ago (May 1913) we first operated on a patient by our new extra-simplified proceeding. The case was that of a physician, who had suffered for fourteen months from nasal suppuration consequent to periodontitis of the upper right first molar, the alveolus of which exhibited a fistula. We employed the first time the Caldwell-Luc radical operation, through the canine fossa, under local anesthesia; careful scraping of

the sinus was performed; we then proceeded to fill it with iodoform paste, and immediately sutured the mucous membrane.

The patient became completely cured, so that it was not necessary to operate further; the cure was therefore by first intention. We, so far, have treated about one dozen cases and employed different iodic mixtures or pastes —iodol, iodo-anisol, iodocresol, azodolene, pellidol, etc., all of them having been followed by marked success.

In presence of such results, we venture to recommend this procedure.

SECTION VIII.—*Anesthesia (General and Local).*

ANESTHETICS AND DENTISTS, AND THE VERY EARLIEST CASES OF ETHER ADMINISTRATION IN ENGLAND. By Dr. W. A. Hunt, Yeovil.

1. The important part the dentist has played in the discovery and development of anesthesia, whether general or local.

2. This is exemplified in the history of nitrous oxid for general anesthesia, and in the installation and also the hypodermic injection of cocain and its congeners for local anesthesia;

3. But more particularly in the dawn of the use of ether in America by Dentist Morton, and its first use in England by Dentist Robinson, as given in his personal notes, and his descriptions of his apparatus and methods of administration, and of its use in ten large London hospitals, and in numberless private cases by him for the most severe operations; and references to twenty-five large provincial hospitals, as well as at St. Louis Hospital, Paris, by Malgagne and Velpeau, etc.; and all this before the year 1847 had passed.

The notes came to the writer from his father, who was a personal and intimate friend of Robinson.

4. The strange opinion of some in this country, who *now* think the dentist should not be allowed to administer any anesthetic, even though he hold a legal dental diploma!

5. Reference to the excellent Wellcombe Historical Medical Museum, where are oil-paintings and drawings, etc., of the very first cases of anesthesia—an admirable collection of very varied apparatus for and connected with anesthesia by inhalation, with an exact model of the very thing used for Liston during the first amputation of a thigh under ether, 1846, anesthetics of the ancients, etc., altogether an admirable collection—curator, Mr. Thomson.

SECTION IX.—*Oral Hygiene, Public Instruction, and Public Dental Services.*

PRACTICAL RESULTS OF SCHOOL DENTAL TREATMENT IN THE PROMOTION OF NATIONAL HEALTH. By Professor Dr. E. Jessen, Strassburg.

Public mouth hygiene is of international concern. Nevertheless its importance has only been recognized within recent decades, but it has now been introduced into all civilized countries. The basis upon which mouth hygiene must be built is dental treatment in schools, and consequently this is the object in view at present in all countries.

From 1892 the town of Strassburg contributed an annual grant of about Mk. 1200 for the dental inspection of school children, and thus recognized the necessity of their dental treatment, and thereupon opened the first municipal school dental clinic on October 15, 1902. The work was begun with limited accommodation, a modest equipment, and only one assistant. Their yearly accounts amounted to Mk. 2400, and increased steadily to Mk. 11,400 in 1910. In the year 1911, when established in the splendid hygienic institution fitted out with model equipments, and specially built for the school dental clinic, the staff consisted of nine persons, and the annual cost amounted to Mk. 26,500.

From the time of the opening of the school dental clinic 30,000 children were inspected, 70,000 treated, and in round numbers there were 75,000 fillings and 75,000 extractions in eleven years. Altogether the town of Strassburg had spent Mk. 152,000 on school dental treatment since 1892.

Soon other German towns followed the example set by Strassburg. In less than ten years 213 school dental clinics had been established, having an aggregate yearly expenditure of Mk. 560,000. Nearly two million national school children were entitled to be treated in these clinics, and altogether about 227,000 children received treatment in 1913.

It must be the task of school dental treatment to reduce the percentage of decayed teeth in the shortest possible time, and to

increase that of the sound teeth in order to bring nearer the realization of our ideal of a completely healthy mouth in every child attending school.

SECTION X.—*Dental Education.*

DENTAL POSTGRADUATE EDUCATION IN GERMANY. By PROF. DR. W. DIECK, BERLIN.

Dental surgery has developed so rapidly that the need for further education in new methods of practice was felt in Germany so strongly that a Committee for Postgraduate Dental Education was formed as far back as 1902.

The means employed for this purpose are—

1. Separate courses with demonstrations, in which the participants do practical work as far as possible.

2. Courses of one week's duration held in large towns, preferably a university town.

3. Single lectures on important subjects in scientific and practical dentistry or in other medical subjects related to dentistry.

Postgraduate education in Germany is decentralized; there have been formed in most of the provinces local committees which arrange courses and demonstrating lectures independently, the central committee lending support by supplying expert teachers or in other ways.

The "collection of objects for dental instruction" now kept in the dental college of Berlin University, is an additional means of instruction. The objects of this collection are sent free of cost anywhere when required for lectures or demonstrations.

The most recent effort to extend dental postgraduate education is the attempt to organize an international exchange of prominent men in the profession. Preliminary negotiations toward this end are being conducted between Germany and the United States of America.

PERISCOPE.

Calcium Chlorid in Hemophilia.—Patients suffering from hemophilia should be given calcium chlorid mixed with a little chloroform water, in 5-grain doses three times a day for a few days before extraction. —C. CHARLTON, *Commonwealth Dental Review.*

Keeping Gutta-percha Points Sterile.—Three clear glass dental medicine bottles are filled with alcohol, and the different sized points are placed in them. In this way, sterile points of the various sizes may always be had ready for immediate use.—F. E. CLINITE, *Dental Digest.*

Effect of Drinking-water Upon the Prevalence of Caries in School Children.—The harder the drinking-water, the better the teeth and the lesser the infant mortality; again, the lesser the infant mortality the better the teeth. Districts with soft water are preferred by industrial concerns; the poor hygienic conditions prevalent in manufacturing districts enhance the detrimental effect of the soft water.—COOK, *Lancet.*

Foot or Elbow Taps for the Wash-basin in the Dental Office Essential to Aseptic Practice.—When practicable, it is very desirable for the water supply to the wash-basin in a dental office to be fitted with the hospital foot or elbow tap. This obviates the necessity of touching the tap with soiled fingers, and prevents the possibility of passing infection or dirt from one patient to another.—B. CORBETT, *Commonwealth Dental Review.*

Nitrous Oxid Analgesia in "Insusceptibles."—Some persons can take almost pure nitrous oxid without losing consciousness, but it is not always necessary with these insusceptibles to give a particularly strong mixture for anesthetic purposes. We may find a very few patients who, do what we will short of rendering them unconscious, still say that they feel pain; but they will usually admit that it is but slight, and they are too contented to mind it, in which case it will be better not to push the anesthetic farther, as the after-effects, usually insignificant, will be more pronounced.—*British Dental Journal.*

Sterilization of Anesthetic Inhalers.—Particular caution should be exercised in the care of inhalers and breathing tube, that they are not a means of communicating infection from one patient to another. A few minutes' bath of the inhalers and tubing in a 1:5000 or 1:10,000 cyanid of mercury solution, followed by rinsing in water, and the use of the tubing with the inside wet, will prevent this contamination, and will insure a dust- and germ-free gas for the patient.—E. I. McKesson, *Ash's Monthly.*

Calcium Lactate as a Safeguard Against Hemorrhage.—It is not uncommon that cases present for extractions who give a previous history of severe and long-continued hemorrhage. One of the simplest and safest drugs for controlling this idiosyncrasy is calcium lactate. A dose of 5 grains three times a day, for several days before the operation, generally insures an absence of trouble in this direction. The drug can be obtained in tabloid form, and can be continued subsequent to the operation, if any doubt still exists as to the possibility of secondary hemorrhage.—E. S. Fischer, *Australian Journ. of Dentistry.*

Diagnosis of Necrosed Pulp.—Necrosis of the pulp is frequently met with. A pulp may be dead for months without causing any disturbance; it may be discovered on examining the teeth of a patient without the latter having any knowledge of its existence. The tooth under observation is often more or less discolored, heat or cold produces little or no reaction, and the translucence has usually become dulled. But the safest diagnostic aid is the electric current—a necrotic pulp does not respond to even the full current of the ordinary battery. The pathological types of pulp necrosis, viz, coagulation, colliquation, caseation, and mummification, play no part in the diagnosis proper.—H. Prinz, *Dental Summary.*

Effective Method of Removing a Broken Reamer or Bur from a Root.—The following is a simple method for removing a reamer or bur broken and lodged in the recesses of a root-canal: Two thin but stiff nerve broaches are set into a broach-holder, and passed into the root one on each side of the broken reamer. If the latter hugs the root walls too firmly, a small round bur is used until the broaches can be passed between the fractured bur and the root walls. The broaches are then twisted around the obstinate fragment. The operation may not be successful in the first few attempts, but anyone who tries this method will be agreeably surprised to find how firm a grip the broaches take on the broken bur.—M. H. Feldman, *Dental Outlook.*

Teeth, Health, and Social Competency.—Industrial inefficiency frequently results from physical incompetency. The ills traceable to diseased teeth represent many days away from work. These lapses in production are sometimes the determining factor in a man's becoming dependent. If all men had steady work at reasonable wages, free from the burdening cost of sickness, the producing power of the individual would be sufficiently high to maintain him without contribution from tax levies. As it is, many of the preventable diseases lie at the root of poverty. While oral health is not urged as a panacea, undoubtedly the care and preservation of the teeth will increase the working efficiency of the individual, reduce preventable illness, and in many ways go toward making the individual economically independent.—E. F. Brown, *Health News.*

Sterilization of Impression Compound.—Various experiments have been made with a view to rendering used impression compound sterile. Microscopic examinations of quantities treated under various conditions and by the usually recognized methods showed that, unless the impression compound was thoroughly boiled, it could not be made sterile. The process of boiling, however, causes serious deterioration of the quality, making it almost useless for taking an accurate impression. The difficulty may be circumvented in the following way:

The modeling compound is placed in a receptacle in a dry vulcanizer, and the temperature is run up until the gage registers 230° F. The liquid mass is then poured into suitable molds, and upon examination it will be found that the mass is quite sterile and as serviceable as ever for taking impressions, etc.—*Elliot's Quarterly.*

"Daylight" Spectacles for Artificial Light, for Selecting Tooth Shades.—H. E. Ives, a Philadelphia physicist, who has been for some time investigating the production of light giving a daylight spectrum, has recently suggested the use of colored glass spectacles for viewing objects illuminated by artificial light when it is desired to see such objects exactly as they would appear in daylight. The glass is covered with a collodion or gelatin surface, stained with anilin dyes carefully selected to filter out the light-rays peculiar to artificial light. For each kind of

the latter a special formula is to be followed in preparing the spectacles. These spectacles are useful in many industries, as, for example, the making of artificial teeth, where color has to be most accurately matched. Many other dental uses, such as the selecting of shades in crown and bridge and plate work suggest themselves.—*Scientific American.*

Alveolotomy and Its Indications.—Alveolotomy is a much less formidable operation than its name implies: With a large, round bur the gums and alveolar process are drilled through to the apex of the tooth in question. The conditions where this treatment is indicated are as follows: The incipient stages of abscess formation with symptoms of pericementitis, when the tooth is so tender to touch that we are unable to operate on it; or when we are unable for some other reason, such as an obstruction in the root-canal, to reach the apex and permit the escape of the mephitic gases there confined. When pus has already formed, but as yet has not penetrated through the alveolar process, we secure a chance for its escape in this way and afford a great deal of relief. Before drilling through the alveolus, we may anesthetize the area with a local anesthetic, or we may dip the bur into phenol and depend upon the escharotic action of this drug to desensitize the tissues before it.—A. Berger, *Items of Interest.*

Easy Method of Withdrawing Wax Models for Cast Gold Inlays.—Great difficulty is sometimes experienced in removing the wax form from a cavity without distortion. The following simple method will be found to overcome all difficulties in this respect: A small 22-karat gold disk is made, about 1/8 inch in circumference, with a tiny hole in the center large enough to admit a cotton thread. A knot is made at one end of the cotton, and the free end is threaded through the hole in the disk. The disk is then dipped into molten wax several times, until it is about the size of a pea, whereupon it is pressed into the cavity and contoured. Over the free end of the cotton, a piece of metal tubing—a broken hypodermic needle serves very well—is slid down until it rests upon the wax inlay, to which it is tacked with a little sticky-wax. After being chilled, the wax inlay can easily be withdrawn from the cavity without injury.

In the heating-up process, the wax of course disappears as usual, but the disk is retained in the mold in the investment and forms part of the gold inlay, when the gold is cast.—S. A. Coxan, *Ash's Canadian Monthly Circular.*

Suggestions Regarding Nitrous Oxid and Oxygen Anesthesia and Analgesia.—Nitrous oxid analgesia and anesthesia differ from each other in degree only, the one being a continuation of the other, and as such we may obtain any necessary degree of anesthesia to meet a corresponding degree of pain. The sensations incident to analgesia should be utilized in strengthening mental suggestion in patients who are not easily controlled.

Asphyxia, the only danger in nitrous oxid anesthesia or analgesia, may be eliminated absolutely in the latter by administering at least eighteen to twenty per cent. of oxygen with the gas. A portion of this oxygen must come from a pure supply.

Air as a source of oxygen supply is insufficient to eliminate asphyxia in all cases; oxygen used alone is expensive; but a combination of air and oxygen makes the ideal diluting mixture for nitrous oxid analgesia.

Accurate rebreathing is a means of regulating the ventilation, stimulating it when insufficient for adequate absorption of gases in the lungs, and reducing the fresh gas consumption when the patient would over-ventilate if left alone. Incidentally, it saves gas and reduces the cost.—E. I. McKesson, *Ash's Monthly.*

Method of Firm Attachment of Vulcanite to Aluminum Dentures.—An aluminum plate with teeth attached by vulcanite forms a very light denture, comfortable to wear and of little bulk. It is well known, however, that after being for some time in use, the vulcanite is liable to separate from the aluminum, as the result of some chemical or electro-chemical action. A method of obviating a breakdown from this particular cause would probably lead many practitioners who have abandoned the combination to try it afresh. When the case is ready for rubber packing, the cleaned aluminum surface is coated with a thin solution of rubber in chloroform, and over this, when dry, is carefully packed a layer of weighted rubber. and the further filling of the mold space is completed with ordinary rubber. Those who have tried this method claim that the attachment between vulcanite and aluminum remains sound, and a stable union between the two is secured. A similar use of weighted rubber—of the metallic filling kind—was some years ago found very serviceable with the other metals in attaching teeth by vulcanite to "wire bar" lower cases; the resulting union was so very close and intimate that hardly anything short of filing or chiseling would effect their separation.—*Dental Record.*

Indications for Pulp Capping.—Pulp capping has quite generally been tabooed of late years by the profession, and yet in certain well-defined cases it is the best possible practice. Pulp capping is indicated in the following cases: When the tooth has given little history of pain and when the pulp has been only slightly exposed by instrumentation without being infected or subjected to infection by being bathed in the fluids of the mouth; in cases of young patients where we are not certain that the apical ends of the roots are completely formed; and in those cases of adults where there is any promise of saving the pulp in teeth the cavities of which are so located that it is difficult to reach the canals and properly treat and fill them without grinding or drilling away most of the crown. We may not always succeed in saving the pulp by capping, but we should at least try in the cases indicated, and we should have a frank understanding with the patient as to the possibility that we may fail.—C. N. Johnson, *Dental Review.*

Pulp Preservation in First Permanent Molars in Children.—We occasionally are called upon to devitalize the pulp in a first permanent molar before the root has been completed. When a patient presents with an exposed or hyperemic pulp in such a tooth, every effort should be made to treat so as to keep it comfortable for a time without destroying the pulp, in the hope that the apical foramen might still be narrowed down. Every effort should be made to reduce the hyperemia by the use of sedatives. The rubber dam is placed over the tooth, the cavity and tooth are washed with an antiseptic solution, overhanging walls of enamel are broken down, and all food and carious portions are carefully removed from the cavity. After the dentin has been sterilized by contact for several days with a dressing of eugenol or beechwood creasote and oxid of zinc paste, which has been carefully sealed in the cavity, the dam is adjusted, the dressing removed, and the pulpal wall covered with varnish—amber or Zanzibar gum cut in ether—over which a paste of oxid of zinc and eugenol is gently flowed.

All excess eugenol is absorbed away, and the whole is covered with oxyphosphate of zinc cement—a permanent filling to replace a portion of this later. Should the pulp be accidentally exposed while excavating, the varnish may be made to bridge the exposure and the capping made as above. Such a tooth will very often continue its development and perform its full duty as an organ of mastication. If pulp removal is found unavoidable, a radiograph should invariably be taken to determine the degree of development of the root. With this information at hand, it may be determined whether or not an attempt shall be made to save the tooth. —J. F. Stephan, *Dental Review.*

Removal of Upper Left Third Molar by Means of the Elevator.—Assuming that there are no teeth missing on the left side, and the third molar has to be removed, this is invariably difficult to see, because in persons who possess the complete number of teeth the masseter muscles are often constricted and the mouth cannot be opened wide, added to which there is perhaps elongation of the second molar. The region should be carefully examined with mirror and probe to make quite certain of position and solidity. If location of the root and flexibility of the lips and cheek allow, a straight elevator should be used; if they do not allow, the obtuse-angle elevator should be employed. The operator—standing, of course, on the right side of the chair—should rest the patient's head in a position comfortable for operating, but not reclining too much. The operator's left arm should be fixed firmly round the patient's head, and the left forefinger should rest on or near the second molar—a position suitable for lifting the lips and cheek and giving a clear view. Further, the operator's head should be bent forward over the patient, and the elevator should be grasped firmly in the hand, the thumb extending along the blade to within three-quarters of an inch of the point, or as near this as possible, to insure full control of the blade and to avoid the possibility of accident from slipping, etc. The elevator should be fixed at almost a right angle to the root, and nearly horizontal, pressed well home so as to depress, and even cut through, when necessary, the outer wall of bone. Leverage alone should not be depended upon, but the point of the elevator should be depressed and both the neck of the second molar and the bony process by the gum margin should equally share in distributing the force or fulcrage necessary. The root should be pressed downward and slightly outward, never directed backward. By such action the tooth will be forced out toward the cheek and easily removed with the finger.—T. Quinlan, *Ash's Monthly.*

HINTS, QUERIES, AND COMMENTS.

SHEETING WAX.

SHEET wax is often prepared by dipping strips of glass into the melted wax. But to prevent the wax from sticking to the glass, the latter must be in such condition that a pellicle of water will adhere to its surface. It is not so easy to maintain this condition, especially if any resinous matter is incorporated with the wax. Moreover, vertical dipping produces sheets of varying thickness, thin above and thicker below. Soft, non-resinous woods, such as basswood, white-wood, or white pine, retain a water-coated surface better than glass, and by following the process detailed below, sheets may be obtained of a fairly even thickness throughout. Three pieces are cut out from a thick board, one inch or one inch and a quarter thick, of the size of the wax sheets desired, and smoothed up nicely all around. A handle is attached to one of the flat surfaces of each piece; an ordinary drawer-knob, or a wire handle such as is used on screen doors, will answer. These pieces are soaked in water and used alternately.

The wax is melted in a pan, larger than the dimensions of the dipping boards. A wet board is held over the wax, inclined so that one edge will enter the wax first. A rocking motion is produced, so that the edge which enters the wax first will be the first to leave it, and this edge is held above the wax for the melted wax to drain off. Then the board is dipped again, letting the edge which last left the wax be the first to enter it. To increase the thickness of the sheet, this process is repeated. The board and wax are put into cold water, using the other boards while the first one cools.

If the boards are well wetted before using them, the wax will never stick to them, and sheets of uniform thickness will be found preferable for laboratory use.

A good quality of beeswax to which a third of its weight of paraffin and about one ounce of Burgundy pitch to the pound of the mixture has been incorporated, will be found preferable to pure wax for laboratory use. A part of the wax is melted without water, heating it somewhat hotter than boiling water, and the Burgundy pitch is added, as the melting-point of the latter is rather high. When the pitch is incorporated, the mixture may be poured into the remainder of the wax and paraffin, and all of it can be melted over water, as usual.

S.

A PALATAL SUTURE-OPENER FOR UPPER EXPANSION.

THE appliance for the expansion of the dental arch which, in my opinion, meets almost every requirement of the specialist is the Angle "new appliance," but as it requires special training in technique and a great deal of experience to properly use it, I am offering an appliance which may be valuable to the general practitioner, if not to the specialist.

There are many very deep palatal vaults where it is impossible, by simply expanding the teeth alone, to obtain sufficient development of the palate to accommodate the tongue, and I have found that in these cases a split-plate is advantageous.

The appliance shown in Fig. 1 was used by me in the treatment of a girl who had lost the first molars; the palatal vault was deep, with a very narrow arch, the left nostril almost closed, and the nose disfigured. As the patient had great difficulty in breathing, and her health was impaired, I deemed it imperative to give her relief at once, and not wait for the eruption of the second molars.

The bicuspids alone being in position, I did not believe that sufficient development or broadening of the arch could be accomplished by simply expanding them. An appliance (as shown in Fig. 1) was constructed, and the patient wore it with great comfort. All that was necessary at each sitting was to spring the lateral halves apart, and snap the appliance into position.

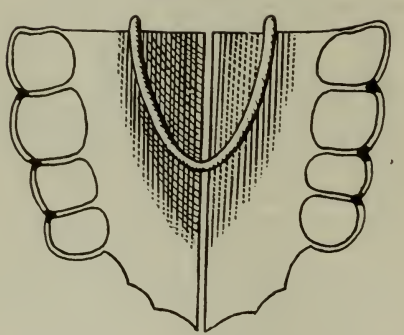
The result of the treatment was an arch sufficiently wide to accommodate the tongue, an opened nostril, no difficulty in breathing,

and great improvement in the health of the child.

The appliance is constructed in very much the same manner as a Jackson appliance,

Fig. 1.

Fig. 2.



with the exception that the lingual plates are not used, allowing the vulcanite to take their place. The wires forming the spring clasps and base wire are so arranged that the vulcanite will engage them securely.

In Fig. 1 the base wire is placed beyond the posterior border of the plate, as the molars were not in position. By making a base wire such as is used in a lower Jackson appliance, and placing it as shown in Fig. 2, the anterior and posterior expansion can be controlled at will.

This appliance is a modification of the Jackson or Ottolengui suture-opener and the Coffin split-plate, but it is more efficient, hygienic, and easier to manipulate than the last two mentioned.

W. A. White, D.D.S.

Atlanta, Ga.

RECEPTACLE FOR STERILIZING PULP BROACHES, BURS, ETC., BY FORMALDEHYD.

The difficulties encountered in the sterilization by any of the wet methods of pulp broaches, burs, and similarly delicate dental instruments are largely responsible for the omission of this essential precaution on the part of many practitioners. Sterility can be obtained if all débris is carefully brushed out from the bristles, grooves, or blades of such instruments, and these are preserved in a shallow tobacco jar with a hollow glass knob in the lid which, when filled with a small wet sponge, serves as a humidor. In this hollow glass knob a few tablets of formaldehyd are inserted and held in place by a wad of dry cotton, the evaporating formaldehyd sterilizing the instruments if they are kept long enough under the action of the gas. Enough instruments should be kept in the jar, of course, to allow of the employment of a freshly sterilized one for every case, as the gas must be allowed to act upon them for some time to produce the desired sterility. Even newly purchased broaches, burs, etc., should be subjected to such sterilization, as they are not sterile when removed from their packing. Vastly better results in root-canal treatments will amply repay the small trouble occasioned by this simple precaution.

Richard H. Riethmüller, Ph.D., D.D.S.

SAVING TIME IN MAKING PLASTER CASTS.

A strip of cardboard bent around the impression, with the two overlapping ends pinned together, produces a beautifully finished cast and saves a great deal of time otherwise consumed in trimming the cast. The cardboard can be cut to any width according to the desired thickness of the cast. After the plaster cast has been poured, the plaster is leveled off to the margins of the cardboard, which is removed when the plaster has sufficiently set, producing a very pleasing result in regard to smoothness of the cast.

Wright B. Lee, D.D.S.

Eugene, Oregon.

OBITUARY.

DR. JAMES TRUMAN.

[See Frontispiece.]

Died, from an attack of œdema of the lungs, at his home in Philadelphia, November 26, 1914, James Truman, D.D.S., LL.D., in his eighty-eighth year.

Dr. Truman had for some time been suffering from the infirmities of advancing age, but although physically enfeebled he retained the normal clearness and activity of his intellectual faculties until failure of respiration ushered in the unconsciousness which rapidly led to his death.

Following is his biography as prepared by himself some years ago, at the request of the Editor of the Dental Cosmos:

[*Autobiographical Sketch.*]

Dr. Truman was born at Abington (Jenkintown) a suburb of Philadelphia, November 22, 1826. When he was two years of age, his parents, George and Catharine L. Truman, returned to Philadelphia, where the family had resided for many generations, its original founder having emigrated from England with William Penn.

Upon the completion of his general education he commenced the study of dentistry with his father, a practitioner of both medicine and dentistry, and then went into practice. This was continued, with some interruptions, until his final graduation at the Philadelphia College of Dental Surgery in 1854. In 1855 he removed to Waterloo, in western New York, where he practiced for three years, returning to Philadelphia in 1858. In 1864 he accepted the position offered him of demonstrator-in-chief of operative dentistry in the Pennsylvania College of Dental Surgery.

The efforts of the earlier workers in this country had been devoted mainly to developing the mechanical side of dentistry, leaving scientific deductions to a future growth. This was at the time unavoidable, but unsatisfactory. Dr. Truman was fully impressed with the importance of extending the scope of inquiry into many unsolved problems. He spent much time in the study, through dissection and otherwise, of the teeth of inferior forms, and this led to a careful examination of the supplemental and supernumerary forms of the human series of teeth, and he subsequently presented a paper on this subject which received recognition both at home and abroad.

He spent much time in an effort to solve the problem of bleaching teeth. There had been some effort in this direction by others with no practical results, and discolored teeth were either permitted to remain a disfigurement or were extracted. The difficulties surrounding examinations in this direction can only be appreciated by practical investigations, but those made by the subject of this sketch finally resulted in a process more satisfactory than any previously applied. The general manipulation of such teeth, and the preparation of the canals, was carefully considered, and while changes in the process of bleaching have been made, the general plan of preliminary treatment remains as he gave it in 1868. It, however, continued for twenty-five years to be an operation subject to much criticism, and one rarely attempted. At present, through the use of other agencies than were originally adopted, the process has become an accepted part of operative dentistry.

The need of a system of preparing cavities in the teeth for filling with cohesive gold very early claimed Dr. Truman's attention, and efforts were made to meet this want. His ideas in this direction were formulated in an article in the *Dental Times*, in which he endeavored to reduce the operation to mechanical principles, systematizing the formation of anchorage and making the preparation of the cavity the important basis of successful work. The views of dentists upon this subject have undergone considerable changes since that period.

In 1865 Dr. Truman was elected to fill the chair of "dental physiology and operative dentistry" in the Pennsylvania College of

Dental Surgery, and held that position until his resignation in 1876.

It was during his connection with this college that the question of woman's place in dentistry caused much disturbance in the faculty. Prior to 1869 dentistry was regarded as wholly unfit for women to practice, indeed it was not regarded as one of the occupations which at any time would be attractive to her. The feeling against any change from what had been regarded as her proper sphere was still operating powerfully against her success in medicine.

The peculiar adaptability of women for dentistry as an occupation had long claimed Dr. Truman's earnest consideration, and being fully satisfied that it would furnish an agreeable and remunerative calling for many, he determined to openly advocate it. To this end he incorporated his views in a valedictory to the graduating class delivered to a large audience in Musical Fund Hall, Philadelphia, in 1866. This created some sensation and placed him at once in antagonism with the faculty and generally with the dental profession.

It was not until 1869 that an opportunity occurred to put in practical operation the theories then enunciated. Application was made that year by Mrs. Henriette Hirschfeld-Tiburtius of Berlin, Germany, to be permitted to matriculate as a student. She had come to America highly recommended. The struggle for admission was a memorable one, but was successful, and she finally graduated and returned to her native country to enter upon a remunerative practice. In 1866 a woman, Mrs. Lucy Hobbs-Taylor, had graduated from the Ohio College of Dental Surgery. These two constituted the only two women in the world possessing the diploma of a dental college.

The importance of this matter, as Dr. Truman regarded it, led him to introduce a resolution in the American Dental Association convened at Saratoga, August 1869, asking for "recommendation to subordinate associations to admit to full membership any women duly qualified." This was laid on the table—a result anticipated by the mover, and while its introduction led to no immediate change in the feeling of antagonism to women in dentistry, it did make eventually a marked impression upon the thought of the profession, and led up to the opening of nearly all dental college doors to women. The immediate result, however, was much bitter feeling in professional circles, which reacted upon the originator of this movement. Time has changed all this, and women are now practicing dentistry in all parts of the civilized world; the United States has a dental organization composed wholly of women, and several women have become leading scientific workers, devoting their time to the elucidation of many unsolved problems.

While connected with the Pennsylvania College of Dental Surgery Dr. Truman became editor of the *Dental Times*, a position he continued to fill for four years. Nearly all the productions of his pen during this period were published in that journal.

The use of the mallet in dental filling operations had, up to that time, given such peculiar and varying results that he determined to commence investigations in that direction. This involved the preparation of instruments, and months of careful work. The results were given to the dental profession, establishing very conclusively that the then much-lauded lead mallet was not equal to the light steel mallet, and that the electro-magnetic mallet of Bonwill, then in its infancy, was far superior to all other mallets, as it entirely overcame mobility. These conclusions have never been contradicted, time simply enforcing the principles then demonstrated.

The use of tin as a filling material had for an indefinite period been part of the armamentarium of the dental profession, but Dr. Truman regarded the methods adopted as defective and the material as not properly prepared. He made extended experiments with tin in various forms—rolled tin, chipped tin from block, etc.—to secure the greatest amount of cohesion. It was proved that the old method of using tin upon the non-cohesive principle was defective, and that the best results could be obtained by depending upon the slight but effectual cohesive property of the metal.

In 1876 his health was so much broken by persistent efforts in various kinds of work that he concluded to make an entire change, and accepted what seemed a favorable offer at Frankfurt a/M., Germany, and removed his family to that city in the same year, resigning his position in the Pennsylvania College of Dental Surgery. The condition of things at Frankfurt not meeting his expectations, he left that city in the winter of 1877 and established himself in the city of Hanover.

He was there received with confidence by the better class of citizens, but was subject to much annoyance by the jealousy of members of the dental profession. His practice,

notwithstanding, grew rapidly among the nobility and wealthy residents of the province. In 1880 the death of his wife made life in Germany unbearable, and he returned to America and commenced practice in Philadelphia.

On February 28, 1877, the honorary degree of D.D.S. was conferred upon him by the Pennsylvania College of Dental Surgery.

His pen was active from this period as a contributor to dental periodicals in original articles, reviews, and translations. He was one of the associate revisers of the American edition of Tomes' Surgery, and also at a later period became a contributor to the "American System of Dentistry."

In 1882 he was elected professor of dental pathology, therapeutics, and materia medica in the Department of Dentistry of the University of Pennsylvania. In 1883 he was made secretary, and subsequently dean, which position he held until he retired in 1896.

In 1890 he was chosen to conduct the editorial work of the *International Dental Journal*, published solely by dentists to advance the interests of the dental profession. He continued to be editor of that journal until it ceased publication in 1905. His contributions to the literature of the profession have been mainly confined to work upon dental periodicals, with the exception named and as a contributor to the "American Text-book of Operative Dentistry."

He was a member of various dental associations of America and Europe, and was one of the four who issued the original call for the formation of the National Association of Dental Faculties, which was subsequently organized in 1884 at New York and by adjournment to Saratoga. He has filled various offices of responsibility in this body, having been its president one year. He was the last president of the American Dental Association, and assisted in its transfer to the National Dental Association. This was perfected by the union of the Southern Dental Association and the American Dental Association.

He received the honorary degree of LL.D. from the University of Pennsylvania in 1904.

In 1909 he retired from active teaching and was made professor emeritus of dental pathology, therapeutics, and materia medica in the University of Pennsylvania, the title of the chair he had actively and efficiently filled for a period of twenty-seven years.

The passing of Dr. Truman removes one of the commanding figures from the rapidly diminishing group of men who are fairly entitled to be designated as the pioneers of organized professional dentistry. Dr. Truman entered upon the active practice of his profession fourteen years after the establishment of the first institution in the world for the systematic training of dental students. Previous to that time the only means for obtaining an education in dentistry was through the system of apprenticeship then in vogue, at which time, and for many years thereafter in its professional infancy, the practice of dentistry was little more than a trained handicraft. Moreover, its practice was distinctly handicapped by the ideal of commercialism. The possibilities of its scientific development were unrecognized, excepting by a small minority of its more prominent exponents. It was those conditions and that professional atmosphere that confronted Dr. Truman as a novitiate in the ranks of dental practitioners when he received his qualification to practice his profession in 1854. His reaction to the surrounding professional conditions of his time was characteristic. His larger vision recognized the intrinsic possibilities of his professional calling, and it became his life-problem to demonstrate by his work, by his educational efforts, by his contributions to the literature of his profession, and by his active participation in the deliberations of dental professional associations, his convictions as to the larger possibilities of usefulness which dentistry had to offer to mankind. He brought to the solution of his problem a commanding personality, a vigorous, even at times aggressive intellectuality, a masterly command of the English language, and a dignity and forcefulness of mind which inevitably carried conviction with his utterances.

Dental literature contains no more striking example of impressive oratory than the apotheosis of anesthesia pronounced by Dr. Truman at the banquet given in Philadelphia upon the occasion of the celebration of the fiftieth anniversary of the discovery of nitrous oxid anesthesia by Horace Wells. It is not only a literary classic, but an utterance characteristic of the spirit and ideals of its author.

His unfailing energy, and above all his honesty of purpose, crowned his life's work with success, and he lived to see his chosen calling elevated from the status of a mechanic art to the dignity of a recognized profession. The larger service of his life has been that rendered to dental education, the major portion of which has been given through his service to the Dental School of the University of Pennsylvania. Quite apart from the value of his teachings from the technical standpoint, the influence which as a teacher he exerted over the moral life and the ethical professional standards of his students was invaluable. It was the deep and genuine interest that he felt in the moral development and spiritual growth of his students that served to establish such close and intimate relations between him and those whom he taught. No student who had benefited by his instruction failed to reverence him as a father and friend; even the wrongdoer whom, as dean of the dental school, he was obliged to reprimand, received his admonitions without resentment, for there was always that in his manner which gave assurance that he corrected without malice and with a single eye to helpfulness. If he ever had enemies they were such as were an honor to him, for none who came into contact with him sufficiently to realize the character of the man ever failed to love him.

The loss of Dr. Truman will be mourned wherever dentistry is known and practiced throughout the civilized world, for he was one of the makers of dentistry and one of the best exponents of its larger possibilities.

It was his specific request personally made to the writer that no reference to his religious views should be published; but without breach of trust, one may be permitted to quote here a statement made by his colleague and almost lifelong friend, Dr. Darby, in connection with his funeral services. Dr. Darby said, "I have never crossed the river of death; I know not (except by the eye of faith) what is beyond the farther shore; but if nobility of character, righteous living, love of mankind and love of justice, charity for all mankind without envy or malice, count for anything as prerequisites for citizenship in that country, then my dead friend will be there."

DR. THOMAS EDWARD TURNER.

Died, November 14, 1914, at St. Louis, Mo., from an accident, in his forty-seventh year, Thomas Edward Turner, D.D.S.

Thomas Edward Turner was born in Carrollton, Mo., June 22, 1868. He was educated in the public school and high school of that city, and was a clerk in the Missouri legislature at Jefferson City for several years.

He began the study of dentistry in the office of Dr. J. S. Hassell of Carrollton, and entered the Missouri Dental College, now Washington University Dental School, in September 1888, graduating in the class of 1890. Immediately after graduating he located in Neosha, Mo., for several years, and in that city married, September 21, 1892, Miss Mary Lee Moss, who survives him. He came to St. Louis about 1896, and entered into partnership with Dr. Holmes; the partnership continued until 1900, when it was dissolved, Dr. Turner continuing in practice alone until November 14, 1914, when he was accidentally killed while cranking his automobile.

Soon after graduation he became a member of the Missouri State Dental Association, and he was elected vice-president in 1914. After moving to St. Louis he connected himself with the St. Louis Dental Society, and was its president in 1903. In 1904 Dr. Turner was appointed a member of the Missouri State Board of Dental Examiners, which position he retained to the time of his death. He enjoyed the distinction of being the only democrat reappointed on the board by a republican governor. His work on the board was such that through his efforts St. Louis, the fourth largest city in the United States, enjoys the distinction of being freer from dental quackery than any other city of similar size in the country. He was especially active in all the meetings of the National Association of Dental Examiners and the National Dental Association during the last ten years. He was president of the National Association of Dental Examiners in 1912, and third vice-president of the National Dental Association at the time of his death. He was a member of the Masonic Fraternity, being a past-master of Rose Hill Lodge, No. 550.

The work of Dr. Turner, since he located in St. Louis, has been of such a character as to attract the attention of the profession, not

only in his own state but throughout the country. In the death of Dr. Turner the dental profession has sustained a loss that will be hard to fill—just how hard, only those who knew him best and loved him most can tell. His professional ability and his modest Christian character endeared him to a host of friends, who mourn most sincerely with his bereaved widow and family.

J. H. Kennerly.

Death of Dr. Louis Jack.

We have received notice of the death, on December 9th, in his eighty-second year, of Dr. Louis Jack. He was the last survivor of the class of 1854 of the old Philadelphia College of Dental Surgery, of which Dr. James Truman—of whom an extended notice is given in the preceding columns—was also a member.

Society Notes and Announcements.

PANAMA-PACIFIC DENTAL CONGRESS.

The Committee of Organization of the Panama-Pacific Dental Congress wishes it distinctly understood that the Panama-Pacific International Exposition will not be postponed, but will open on time, as will also the Panama-Pacific Dental Congress. The authority for this statement is impressed in the following letter from President Moore of the Exposition Company:

To the Commissioners from Foreign Nations and from the States and Territories of the United States to the Panama-Pacific International Exposition.

Gentlemen,—There have been reports that the Exposition, because of the war in Europe, would be postponed. It will not be postponed. There have been published statements that the war in Europe would seriously affect the commercial or educational importance or the financial success of the Exposition. They will not be so affected.

The Exposition will open on its scheduled date—February 20, 1915. It will be completely ready when opened. It is more than ninety per cent. completed today. Nothing will be permitted to interfere with the consummation of the plans originally laid down.

Many friends and parties in interest have presented arguments in support of postponement for a year. These have been given anxious study and careful analysis. Most of them are merely counsels of timidity, based on nothing save a general feeling of doubt and uncertainty. These are sufficiently answered by saying that there is no longer any doubt or uncertainty as to the success of the Exposition, whatever the situation in Europe may be. Other arguments for postponement have some practical foundation, but for every one of these there is a stronger and better argument for proceeding with our plans. Not one of the nations at war has notified us of an intention to withdraw her participation; in fact, France and Italy notify us that their plans remain unchanged; even if we should lose the others, the interest and importance of the Exposition would still, as a whole, surpass all precedent.

As to the domestic participation, the effect of the European war seems likely to be rather advantageous than otherwise. The stimulus on exhibits is already felt, as American manufacturers become impressed with the opportunity given by the Exposition for bringing their goods to the attention of the large distributers of Central and South America, the Orient, and Canada.

Expert opinion agrees that there is nothing in the situation to affect seriously the willingness or ability of the people of the western hemisphere and of the far East to visit the Exposition. The decision of the Exposition

management has, however, been reached without regard to that consideration. We consider it our duty alike to our nation, to the participating nations, to our exhibitors, and to ourselves, to carry out the plans as originally laid down—which, now nearly at fruition, promise the most important, the most beautiful, and the most successful Exposition in history.

CHAS. C. MOORE, *President.*

At the present time matters relating to the PANAMA-PACIFIC DENTAL CONGRESS are most encouraging. The attendance so far as can be judged by the expressions of those who attended the meeting of the National Dental Association in Rochester, and the meeting of the New Jersey State Dental Society, will break all previous records. Everyone said he was coming. The Committee of Organization wishes to assure all prospective members that they will be well cared for in every way.

COMMITTEE OF ORGANIZATION.

AMERICAN MILLER MEMORIAL.

TO THE DENTAL PROFESSION OF AMERICA:

The committee appointed by the Ohio State Dental Society at the 1909 meeting for the purpose of raising funds for an American Memorial to the late Dr. W. D. Miller desire to make the following report:

Funds have been received from the following states: Alabama $25.00, Arizona $25.00, Arkansas $50.00, California $60.00, Colorado $82.00, Connecticut $50.00, Georgia $60.00, Illinois $531.00, Iowa $200.00, Indiana $75.00, Kansas $134.50, Kentucky $105.00, Maine $25.00, Massachusetts $100.00, Michigan $300.00, Minnesota $100.00, Missouri $100.00, Montana $15.00, Nebraska $100.00, New Hampshire $25.00, New Mexico $25.00, New York $125.00, Ohio $1303.00, South Carolina $25.00, North Dakota $50.00, South Dakota $15.00, Oklahoma $31.00, Oregon $50.00, Pennsylvania $20.00, Tennessee $50.00, West Virginia $25.00, Washington $50.00, Wisconsin $25.00, Wyoming $10.00, Texas $50.00, Utah $14.00, Vermont $20.00, Virginia $50.00. Total $4300.50; interest on this fund to December 1, 1913, amounts to $382.94, making a total in the hands of the treasurer, Dr. Weston A. Price, of $4683.44. Florida and Mississippi have each voted $50.00, but the amounts are not in the treasurer's hands at this date.

The memorial will consist of an 8-foot bronze statue of Dr. Miller mounted on a 7-foot granite pedestal, to be placed on the lawn of the public library, the most appropriate site in the city of Columbus, the capital of Dr. Miller's native state. Suitable tablets will be prepared, and it is the desire of the committee to state on one of them that the monument is erected by funds from every state in the Union. If your state is not represented in the above list, we want your co-operation in placing it there.

It is hoped that sufficient funds—$5500.00—will be in the treasury that steps can be taken at once toward the construction of this memorial, so that it may be finished and ready for unveiling at the 1915 meeting, which will be the fiftieth anniversary of the Ohio State Society. The valuable co-operation of the honorary committees in the several states is hereby acknowledged; they have made this memorial a reality.

Other professions have done honor to their distinguished dead; let us do the same for Dr. Miller, whose life was one of unselfish devotion to the scientific advancement of dentistry.

Yours very truly,

EDWARD C. MILLS, *Chairman,*
J. R. CALLAHAN,
S. D. RUGGLES,
Committee.

COLUMBUS, OHIO, April 7, 1914.

NATIONAL MOUTH HYGIENE ASSOCIATION.

A SERIES of illustrated lectures on Mouth Hygiene is being prepared by this association for rental service. The first lecture of the series, a talk suitable for a mixed adult audience or school pupils above the age of twelve years (designated as lecture "A") is now ready. The lecture set (manuscript and 36 slides) will be furnished to members of state dental societies and others who may be considered as competent to present the matter to the public, at a fee of One Dollar per use.

For further particulars and application blanks, address the Director of Extension Lectures,

EDWIN M. KENT, D.M.D.,
222 Washington st., Brookline, Mass.

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

THE Dental Faculties Association of American Universities will meet on February 24 and 25, 1915, in the Thomas W. Evans Museum and Dental Institute, at Fortieth and Spruce sts., Philadelphia, Pa.

EDWARD C. KIRK, *Sec'y.*

AMERICAN INSTITUTE OF DENTAL TEACHERS.

THE annual meeting of the American Institute of Dental Teachers will be held at Ann Arbor, Mich., January 26, 27, and 28, 1915.

There will be a number of interesting papers, reports, and discussions by prominent dental educators. All dental teachers are cordially invited to be present.

J. F. BIDDLE, *Sec'y,*
517 Arch st., N. S. Pittsburgh, Pa.

NATIONAL ASSOCIATION OF DENTAL FACULTIES.

THE National Association of Dental Faculties will hold its meeting on January 25 and 26, 1915, at Ann Arbor, Mich. Headquarters, Allen Hotel.

This meeting will precede the Teachers' Association meeting, which will be held January 26th, 27th, and 28th.

Besides the regular business there will be several papers of interest to educators read before the association.

The Executive Committee meets at nine o'clock, on Monday, January 25th. Regular session will open at ten.

B. HOLLY SMITH,
Ch'mn Executive Committee,
CHAS. C. ALLEN, *Sec'y.*

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

A REGULAR meeting of the Academy of Stomatology will be held at the College of Physicians, Twenty-second st. below Market, on Tuesday, January 26, 1915, at 8 P.M.

Arthur Hopewell-Smith, L.D.S., M.R.C.S., L.R.C.P., will present a paper entitled "Pain and Other Oral Sensations."

DUDLEY GUILFORD, *Sec'y.*

CHICAGO DENTAL SOCIETY.

ANNUAL MIDWINTER MEETING.

THE annual midwinter meeting of the Chicago Dental Society will be held in the Hotel La Salle, January 29 and 30, 1915.

Friday, 29th.

Friday, January 29th, Dr. Robert B. Preble will read a paper entitled "Diagnosis of Systemic Disturbances Due to Oral Infection." Dr. Preble is a physician, and one of the leading diagnosticians in America. The paper will be of practical interest to members of both the medical and dental professions. On the same date, Dr. Elmer E. Best will present a paper entitled "The Surgical Treatment of Pulp-canals as a Preventive of Systemic Disturbances." Dr. Best has made a special study of this phase of the subject, and will give us something revolutionary in character.

Saturday, 30th.

Saturday, January 30th, will be devoted to clinics. The clinicians will be so arranged that one can see to the best advantage the clinic in which he is especially interested.

BANQUET.

The meeting closes with a banquet Saturday evening, at which there will be speakers of national reputation and other attractions of equal interest to the audience.

The exhibitors' display room will be open during the entire meeting.

T. L. GRISAMORE, *President.*
P. B. D. IDLER, *Sec'y.*

HARVARD DENTAL ALUMNI ASSOCIATION.

A SPECIAL meeting of the Harvard Dental Alumni Association will be held at the Harvard Union, corner of Harvard and Quincy sts., Cambridge, Mass., on Thursday, January 14, 1915, at 6 o'clock. Dinner will be served at 7 o'clock; tickets $1.50 each.

Each of the graduates of the school is cordially invited to attend, whether or not he is a member of the association. After dinner we will hear something about Harvard athletics, and we have the promise of the use of the reel of moving pictures of the last Yale game.

HAROLD DEW. CROSS, *President,*
FRANK T. TAYLOR, *Sec'y.*

WASHINGTON UNIVERSITY DENTAL SCHOOL.

ALUMNI ASSOCIATION.

THE forty-ninth annual clinic of the Alumni Association of the Washington University Dental School will be held on Monday and Tuesday, February 8 and 9, 1915, in St. Louis, Mo. Papers of interest to the progressive dentist will be read. The Executive Committee is making every effort to have this meeting one where the practical as well as scientific side of modern dentistry shall be shown. Mark off the dates—come—get new inspiration. All ethical dentists cordially invited.

H. M. FISCHER, *Sec'y*,
St. Louis, Mo.

MINNEAPOLIS DISTRICT DENTAL SOCIETY.

THE Minneapolis District Dental Society will hold its annual meeting on February 11, 12, and 13, 1915, in the City Hall, Minneapolis, Minn.

The first two days will be devoted to progressive clinics, papers, and exhibits, and the third day to an office-to-office clinic.

Everything points to a most successful meeting, so reserve the time now.

HARRY W. NELSON, *Sec'y*,
Minneapolis, Minn.

CONNECTICUT STATE DENTAL ASSOCIATION.

THE fifty-first annual meeting of the Connecticut State Dental Association will be held at Hartford, Conn., April 20, 21, and 22, 1915.

CHARLES H. RIGGS, *President*,
Hartford, Conn.
ELWYN R. BRYANT, *Sec'y*,
New Haven, Conn.

MASSACHUSETTS DENTAL SOCIETY.

THE fifty-first annual meeting of the Massachusetts Dental Society will be held May 5, 6, and 7, 1915, in the Hotel Somerset, Boston, Mass.

A. H. ST.C. CHASE, *Sec'y*.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

THE forty-seventh annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May 13, 14, and 15, 1915.

The Executive Council will meet at the Hotel Ten Eyck, Wednesday afternoon, May 12th, at 3 P.M., for the transaction of business in the interests of the society.

The first regular session of the society will open on Thursday at 10.30 A. M. The literary program will be rendered in the auditorium of the Educational Building. Headquarters for Officers and Executive Council will be at the Hotel Ten Eyck.

The clinics and exhibits will be at the Hotel Ten Eyck. Exhibitors are cordially invited to visit this meeting, and requested to make early reservations for space. Address Dr. O. J. Gross, Schenectady, N. Y., for space.

A cordial invitation is extended to all ethical dentists in New York and sister states.

A. P. BURKHART, *Sec'y*,
52 Genesee st., Auburn, N. Y.

INDIANA STATE DENTAL ASSOCIATION.

THE next annual meeting of the Indiana State Dental Association will be held on May 18, 19, and 20, 1915. A distinctive feature of this meeting will be that the program will be made up exclusively of Indiana dentists. A cordial invitation is extended to members of other dental societies to attend the meeting.

A. R. ROSS, *Sec'y*,
Lafayette, Ind.

ARIZONA STATE DENTAL SOCIETY.

THE sixth annual meeting of the Arizona State Dental Society was held at Phœnix, Ariz., November 11, 12, and 13, 1914.

The following officers were elected for the ensuing year: H. H. Wilson, Phœnix, president; L. A. Hawkins, Jerome, vice-president; J. L. O'Connell, Phœnix, secretary-treasurer.

J. L. O'CONNELL, *Sec'y*.

FLORIDA STATE DENTAL SOCIETY.

At the annual meeting of the Florida State Dental Society, held at Atlantic Beach Hotel, Atlantic Beach, Fla., July 1, 2, and 3, 1914, the following officers were elected for the ensuing year: W. E. VanBrunt, Tallahassee, president; R. C. McClellan, Fort Meade, first vice-president; O. R. Cheatham, Jacksonville, second vice-president; A. M. Jackson, Lakeland, recording secretary; Alice P. Butler, Gainesville, corresponding secretary; F. S. Robinson, Jacksonville, treasurer. Executive Committee—Jesse L. Williams, Jacksonville, W. K. Bradfield, St. Petersburg, A. M. Jackson, Miami, D. B. Morris, Gainesville, and M. C. Izler, Ocala.

The place and date of the next annual meeting will be announced later.

Alice P. Butler, *Cor. Sec'y*,
Gainesville, Fla.

CHATTANOOGA (TENN.) DENTAL SOCIETY.

The annual business meeting of the Chattanooga (Tenn.) Dental Society was held recently, during which the following officers were elected: William F. Stone, president; N. C. Hunt, vice-president; I. R. Stone, secretary; George W. Wagner, treasurer.

A paper read by Dr. R. S. Henry on "Vaccine Therapy in Oral Infections" provoked much interesting discussion.

The society is planning to give semi-annual banquets, to which dentists of national reputation will be invited, to deliver scientific addresses. This organization is characterized by qualities of life and progressiveness, the latter being demonstrated by the members' desire to keep in touch with the latest thought and discoveries in connection with their profession, by hearing the principal exponents thereof in their own midst. Incidentally, they anticipate little trouble in getting the men they desire to hear to visit Chattanooga, a very attractive place on account of its historic and scenic wonders, such as Lookout Mountain, Chickamauga Park, Missionary Ridge, Signal Mountain, the beautifully winding and picturesque Tennessee river—every one of them in some way identified with stirring events of the civil war.

Hal F. Wiltse, *Ass't Sec'y*.

BOARD OF EXAMINERS FOR PHILIPPINE ISLANDS.

The next regular meeting of the Board of Dental Examiners for the Philippine Islands to examine applicants for license to practice dentistry in the Philippines will be held in Manila, January 5, 1915. Only those who have diplomas from reputable and legally incorporated dental colleges are eligible to examination.

Louis Ottofy, *Sec'y*, Manila, P. I.

DISTRICT OF COLUMBIA BOARD OF EXAMINERS.

The next examination of applicants for license to practice dentistry in the District of Columbia will be held at the George Washington University, January 4, 5, 6, and 7, 1915. Applications should be in the hands of the secretary two weeks before the date of examination. Fee $10.

Starr Parsons, *Sec'y*,
1309 L st., N. W., Washington, D. C.

SOUTH DAKOTA BOARD OF EXAMINERS.

The South Dakota State Board of Dental Examiners will hold its next meeting at Sioux Falls, S. D., January 19, 1915, at 9 A.M. sharp, continuing three days. All applications for examination can be made with the secretary on January 18th, at the above address. Fee $25.00.

Aris L. Revell, *Sec'y*, Lead, S. Dak.

MONTANA BOARD OF EXAMINERS.

The Montana State Board will hold a session for the examination of candidates on the second Monday in January 1915.

G. A. Chevigny, *Sec'y*, Butte, Mont.

IDAHO BOARD OF EXAMINERS.

The next meeting of the Idaho State Board of Dental Examiners for the examination of candidates will be held at Boise, Idaho, commencing Monday morning, January 4, 1915, at 9 A.M. For application blanks and particulars write to

Albert A. Jessup, *Sec'y*,
Box 1414, Boise, Idaho.

NEW SOUTH WALES.

AMENDING THE DENTISTS' ACT OF 1912.

A BILL has been introduced in the Legislative Council of New South Wales to further regulate practice in dentistry, and to amend the Dentists' Act of 1912. The bill provides that—

Any registered dentist who makes use of any title or description which has not been conferred upon him by some duly qualified body shall be deemed guilty of infamous conduct in a professional respect.

Any person who for five years immediately preceding the act going into force has solely and continuously practiced dentistry in New South Wales, on his own account, may, for three years after such commencement of the act, continue so to practice; and if before the expiration of such three years he passes before the board an examination in surgical and mechanical dentistry, and materia medica (dental), he shall be entitled to registration under the act.

Operative assistants for five years, who also pass the examinations, shall be entitled to registration. Two years' practice preceding the act shall entitle a person to serve as an assistant to a registered dentist for a term which, with the period of his practice, would amount to five years.

Persons must within three months register their names with the board, and satisfy the board as to their practice and employment and good character. Persons wrongfully taking the name of dentist will be liable to a penalty not exceeding £20. The same maximum penalty has been fixed for persons other than legally qualified medical practitioners, or registered dentists, or practitioners under the authority of the act, who practice dentistry.

ORIGINAL COMMUNICATIONS.

THE TEETH OF "EOANTHROPUS": THE PILTDOWN SKULL.

By ARTHUR S. UNDERWOOD, L.D.S.Eng., M.B.,B.S.Lond., L.R.C.P.,M.R.C.S.Eng.

THE interest of the Piltdown discovery, *Eoanthropus Dawsonii,* is more or less bound up with the deductions to be drawn from the mandibular teeth, two molars and a canine of the same side, which are the only dental remains exhumed so far.

The anatomy of the canine proves that the individual was prognathous to a greater extent than is the case in any other human remains, whether of recent or prehistoric races.

EVOLUTIONARY CHANGES OF BRAIN CAPACITY AND FACIAL PECULIARITIES.

This remarkable prognathism had already been suggested by the line of the lower margin of the mandibular fragment; the shape, size, and wear of the canine tooth had been accurately predicted, before the tooth itself was discovered, and when discovered it was found to conform entirely with the prediction in every detail.

If we allow Eoanthropus the lowest brain capacity which has yet been suggested (about 1100 cc.), this pronounced prognathism is truly remarkable. If the evolution of facial peculiarities proceeded side by side with and at the same pace as the evolution of the brain, the conjunction of such a braincase with such a face would present a state of affairs very difficult indeed to explain; but they do not proceed either side by side or at the same pace.

The evolutionary changes which transform the earliest form of brain into the extremely complicated cerebral apparatus possessed by modern man are not only incalculably slow, but they are also constantly progressing. There are no setbacks, no momentary changes dependent upon momentary changes of environment. I use the word "momentary" as applying to any space of time, whether long or short.

The evolutionary changes which have from time to time resulted in the facial peculiarities attending puberty in various primates are relatively capricious; they are not a process of continuous advancement, but from time to time record the ever-changing circumstances of environment. Thus we may find an animal whose ancestors comparatively recently possessed at puberty canine

teeth employed as weapons of sexual combat, developing under changed circumstances canine teeth with no such attributes at all. In short, while the brain evolution is a slow, steady, and continuous progress, the facial evolution is simply the reflection of the varying and evanescent circumstances of environment.

VARIOUS CONJECTURES AS TO THE TEETH OF THE PILTDOWN SKULL.

Although the mandibular fragment of the Piltdown skull and the teeth which were found in it, and particularly the sockets of the third molar (which was not found), tell a very plain tale to the student of odontology, it is by no means every anatomist who can read it.

One authority has actually suggested that the canine which was found might have been an upper tooth, although we all know that wear between upper and lower canines affects the posterior surface of the lower tooth and that the root of an upper canine of this type is not straight.

Another authority has thought that the third molar was not fully erupted, in defiance of the fact that the sockets are fully formed, and the alveolus dividing the anterior from the posterior roots rises a little higher than that belonging to the second molar.

A third author suggests that the canine was that of another individual, probably an ape, though the obvious signs in the fragment of what its canine ought to be like were sufficiently emphatic to enable me to make a model of the tooth a month before it was found by Père Teilhard. The canine ought never to have been mistaken for that of an ape; it differs from adult simian canines in many respects.

COMPARISON BETWEEN EARLY PLEISTOCENE CREATURES AND EXISTING ANIMALS.

In studying the relationship between creatures belonging to the dawn of the Pleistocene and existing animals, it is useful to bear in mind that the resemblances will be more easily observed if the specimen of the existing animal selected be a young female.

The differences which tend to mask underlying relationships become emphasized in the male animal at puberty. All the special armature which is acquired at this period by the male animal, such as excessively developed canine teeth, etc., tends to conceal the great racial affinities.

Thus the infants of homo, gorilla, chimpanzee, orang, and gibbon present great similarities, whereas the adult males differ profoundly, because of the special armature of puberty which they have acquired.

In comparing the mandible of Eoanthropus with that of a modern chimpanzee, a young female ape has been chosen for the foregoing reasons, although Eoanthropus is undoubtedly adult.

That the individual in question had attained full adult development is shown by two facts: The fully erupted condition of the third molars, which had escaped from the sockets after death, shows that the creature was at least adult; and the extreme degree of attrition of the masticating surfaces of the two existing molars, which are worn nearly flat and polished, shows that the creature had advanced beyond puberty.

DESCRIPTION OF FIRST LOWER MOLAR OF EOANTHROPUS.

The three teeth of Eoanthropus, two lower right molars and a lower right canine, I will now describe in detail:

The lower first molar is a five-cusped tooth, the cusps being worn down so far that the surface is almost flat. The indentations which represent all that remains of the pits between the cusps are very shallow and deeply stained, the color varying from the sepia tint to that of yellow ocher. (See Fig. 1.) The enamel covering, which is quite thin, is pure white. The radiograms taken by Dr. Archibald Reid, of 30 Welbeck st., show a fairly large pulp-stone in the

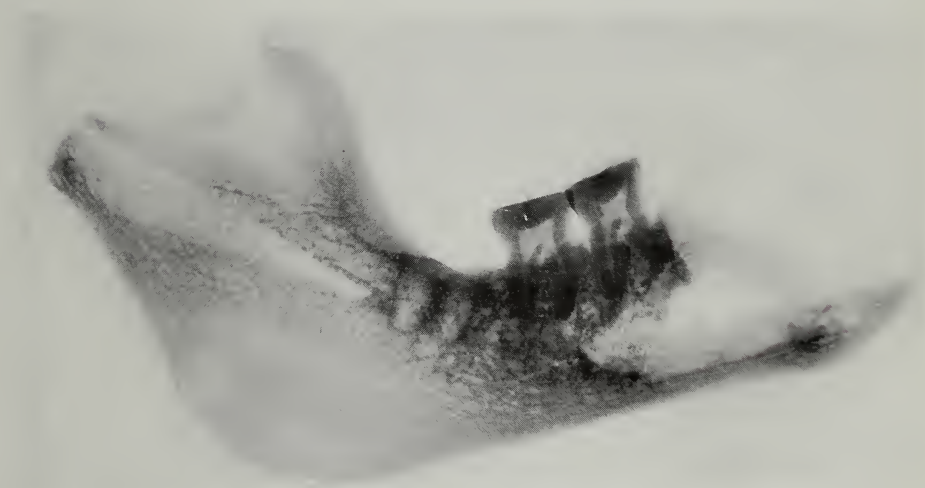
posterior cornu of the pulp chamber. (See Fig. 2.)

worn. The whole tooth is about 1/48 of an inch longer antero-posteriorly

Fig. 1.

Life-size reproduction of the upper surfaces of two lower molars of Eoanthropus.

Fig. 2.



Radiogram of mandible of Eoanthropus. (Taken by Dr. A. Reid.)

LOWER SECOND MOLAR.

The second molar has also five distinct cusps. Its surface is very similar to that of the first molar, but is less than the first molar, and about the same breadth, the pulp-chambers of both teeth are rather unusually large. There is nothing remarkable about the roots.

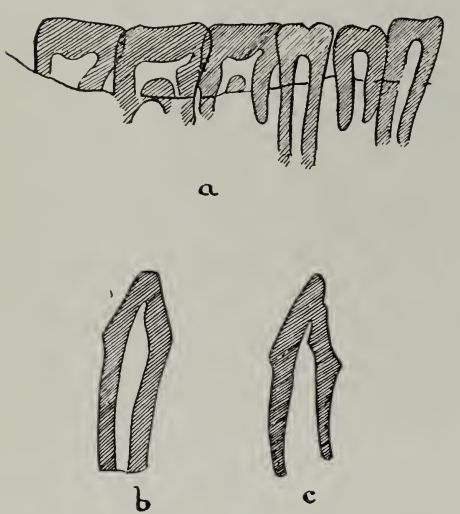
SOCKETS OF LOWER THIRD MOLAR.

The sockets of the third molar show that the tooth was fully erupted and had been in use for a long time. The backward direction of these roots is quite the common disposition of the roots of a modern lower third molar.

LOWER CANINE.

The canine tooth is 1 1/5 inches long. Its antero-posterior depth at the cingulum is 4/5 of an inch. There is a deep-worn facet on the posterior surface of the crown which is 4/5 of an inch in breadth as in length; this facet, caused by attrition against the upper canine during lateral movement of the mandible, is very deep. In the center of it there is an oval spot where the upper part of the pulp-chamber has been blocked up by secondary dentin.

FIG. 3.



Shaded reproductions of radiograms: *a*, Three lower molars, two bicuspids, and one canine of Homo Heidelbergensis. *b*, Canine of Eoanthropus. *c*, Incomplete canine of young female chimpanzee.

The apex of the root shows in the radiogram a very open apical foramen. It is possible, but by no means certain, that a tiny portion of the apex is missing. The apical foramina in the incisors of Homo Heidelbergensis are also very patent, as shown in Fig. 3.

The above description was written from the actual teeth, which Dr. Smith Woodward kindly allowed me to examine minutely with lenses and otherwise, while my wife was occupied in making the drawings.

PULP-STONE IN LOWER FIRST MOLAR.

The pulp-chamber is being filled up at the top with secondary dentin, while the beautiful radiograms (taken by Dr. Archibald Reid) show that this renewed activity of the odontoblasts, incidental to age and wear, has resulted in the formation of a large pulp-stone in the pulp-chamber of the first molar.

It may be as well to recall to readers the fact that the ondontoblast cells, having finished forming the dentin, rest inactive for a considerable period of years, but that when either attrition or caries in later life approaches the pulp, the old odontoblasts commence to be active a second time. They form dentin, called secondary dentin, in any situation where an exposure is threatened.

Their work at first is imperfect, just as the work of old soldiers called to the colors after a lapse of years is at first by no means perfection; afterward the cells seem to fall into their old habits and make pretty fair dentin. This imperfection is evidenced by the formation of islands or peninsulas of roughly made dentin; and from the presence of such an island in the pulp-chamber of Eoanthropus, it is fair to infer that the individual was advancing in middle age.

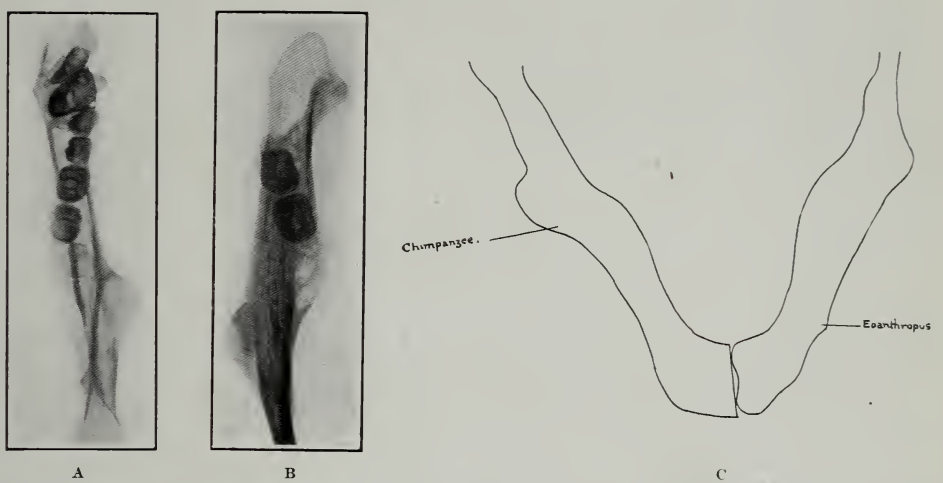
ATTRITION AS A FACTOR IN THE INTERPRETATION OF THE PILTDOWN FRAGMENT.

The fact that the molars have been worn fairly flat and very smooth has been used as an argument against the possibility of their coexisting with a raised canine. As a matter of fact, most animals with raised canines, or for the matter of that, raised incisors, do by

lateral or antero-posterior movement wear their cheek teeth approximately flat. Purely carnivorous animals do not do so, but wherever there is lateral movement of the mandible or the maxilla, however large canine teeth the animal may possess, the mutually opposing surfaces of the upper and lower canines—that is the anterior surface of the upper canine and the posterior surface of the lower canine—are worn into flat polished facets, and this is due to pattern on the worn surface. In all these cases the canines and incisors are also mutually attrided. Whether the resulting molar surface is *quite* smooth or not depends not on the amount of lateral movement, but on the arrangement and thickness of the plates of enamel.

An elephant or a horse has the worn surfaces kept rough, because of the thickness of the enamel ridges and the different power of resistance to attrition

FIG. 4.



A, Radiogram of half the mandible of young female chimpanzee, from above. (A. Reid.) B, Radiogram of fragment of the mandible of Eoanthropus, from above. (A. Reid.) C, Outline drawing from radiograms of half mandible of Eoanthropus and half mandible of young female chimpanzee placed as though articulated at the symphysis.

this very lateral movement, and to nothing else.

In felidæ, where there is practically no lateral movement and the temporo-maxillary joint is a simple hinge (the external pterygoid muscle not even being attached to the interarticular fibro-cartilage), though the canines are immense, they are not worn by mutual attrition, neither are the cheek teeth worn flat.

But in the ape, bear, hippopotamus, capybara (hydrochœrus) and histrix, etc., the cheek teeth are always worn down to a degree of flatness, sometimes with ridges of enamel making a raised of the more calcified and less calcified tissues. The amount of lateral movement is not the all-important factor.

I have spent some time on several occasions in a friendly meal with a young orang and two adult chimpanzees (male and female), and, although they all had well-developed canines, their principal movement in mastication was produced by alternate contraction of the external pterygoids. All these animals had relatively larger canines than Eoanthropus.

I have said more than once that I was so certain, from the consideration of the mandibular fragment of Eoanthropus, of what must necessarily have

been the shape of the missing canine, that I ventured to make a drawing and model of it a month before the actual tooth was found. I should like to state exactly the grounds for this certainty.

COMPARISON BETWEEN EOANTHROPUS AND SIMIANS.

Looking at the fragment from below as shown in the outline drawing, traced from a radiogram (see Fig. 4, A, B, C), it is plain that the under part of the mandible in the region of the six front teeth, and especially in the middle line, was as wide antero-posteriorly as that of a young chimpanzee. In the drawing I have shown the fragment and the half mandible of the chimpanzee placed as if articulated in the middle line.

It is plain that the degree of prognathism is not very different in the two animals; if a similar drawing of any other prehistoric mandible, such as that of Homo Heidelbergensis, be similarly placed beside the drawing of the fragment (see Fig. 5), it will be seen that the symphysis in Homo Heidelbergensis is not nearly so produced antero-posteriorly; this is still more obvious in the case of modern man. Looking at a tracing of a lateral view of a section at the symphysis of the fragment as compared with that of the chimpanzee (see Fig. 6), the similarity of curve is again apparent, and the absence of chin is much more pronounced and more simian in type than that of any other prehistoric human mandible.

Fig. 2 shows another point which has not up to the time of writing been alluded to, but which went far to assure me of the type of canine which would be found should the excavators be fortunate enough to find one.

The conformation of the bones supporting the teeth is profoundly modified by the form and uses of the teeth themselves, but especially is this the case when the canines are greatly developed. In adult apes the lower line of the mandible seen in profile descends to form a little lump or prominence just underneath the apex of the canine root.

There is no such lump in the lower outline of modern man nor in that of Neanderthal mandibles, but it is quite plain in the fragment of Eoanthropus. If the reader will take the trouble to observe carefully a large series of mandibles of various animals, he will readily be convinced that this buttress of bone always exists where a massive root approaches the lower surface. In modern man, the apex of the root of the lower canine does not approach very near the

Fig. 5.

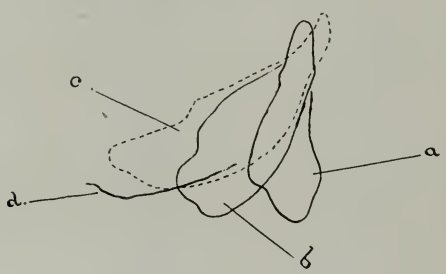
Fig. 6.



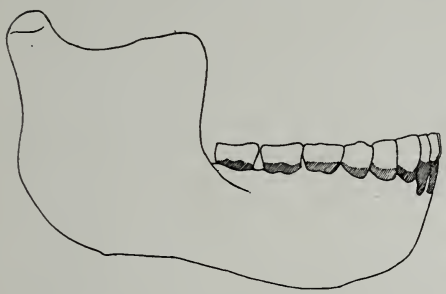
Sections in outline, at the symphysis, of mandibles of—*a*, Modern man. *b*, Homo Heidelbergensis. *c*, Gorilla. *d*, Eoanthropus.

lower margin of the mandible, and therefore such a buttressing of the bone would be quite uncalled-for. The same may be said of Homo Heidelbergensis or any other Neanderthal mandible. (See Fig. 7.)

There are various other simian characters in the mandibular fragment which may be noticed, if we look at Figs. 2 and 8. The shape of the coronoid process and the sigmoid notch are remarkably similar, if we make allowance for the fact that the ape is a young individual, not having erupted the third molar or worn down the other molars to any appreciable extent, while Eoanthropus was well on in middle age.

In this young ape, the backward development of the part of the mandible behind the teeth has not been completed, so that the coronoid process and the condyle are relatively farther forward than they would have been had the specimen been of adult age. The position of the mylo-hyoid groove behind and below the inferior dental foramen, instead of running right over it at the same level, is also a typically simian feature.

Fig. 7.



Side view of mandible of Homo Heidelbergensis.

CONCLUSIVE IDENTIFICATION OF LOWER CANINE.

It may be as well to notice the suggestion that the canine tooth which was found might have belonged to the upper jaw. It is difficult to understand why this suggestion was made; but having been made, it cannot be passed over.

Fig. 8.

Radiogram of half the mandible of young female chimpanzee. (A. Reid.)

The tooth found is extensively worn on the posterior surface only. This should dispose of the suggestion at once, but if that is not enough to decide the matter, the fact that the root is quite straight should do so. Had it been in the upper jaw of such a prognathous animal, the root would, of course, have been gradually curved backward, following the line of the maxillary surface; half an hour in any museum devoted to comparative anatomy ought to satisfy any careful observer of this fact.

TUBE TEETH AND PORCELAIN RODS: THEIR USES AND ADAPTATIONS IN PROSTHETIC DENTISTRY.

By JOHN GIRDWOOD, D.D.S.Univ.Pa., L.D.S.Edin., Edinburgh, Scotland.

(Continued from page 57.)

(X.)

CHAPTER XIII.—A Suggested Revival of Gum Tube Teeth and Sections, Especially in Connection with Modern Methods of Casting.

In bringing forward suggestions regarding a revival of the manufacture and use of gum teeth and sections, the statement was made that one of the objects in hastening the publication of these papers was to endeavor to stay the production of the ever-increasing number of new tooth forms. It was also intimated that such suggestions as would follow—with the exception of those dealing with porcelain tube rods—would have reference to the revival of tooth forms which, owing to a variety of causes, some of which have been already given, were never as fully presented as their outstanding merits demanded.

While the writer cannot hope to do full justice to the subject, he hopes that the claims which will presently be set forth may arouse a real and lasting interest on the part of the profession, when no doubt the makers of artificial teeth will show a practical interest and set about supplying the demand which he trusts will arise.

Various forms of gum tube teeth and sections were manufactured on a commercial basis at an early date—about 1846 by Messrs. Lemale and Messrs. Ash of London—and had their origin in the carved blocks of about eighty years ago. These gum tube teeth and sections were largely used prior to the introduction of vulcanite about 1858, and were then employed with decreasing frequency, while for many years their use had been entirely discontinued.

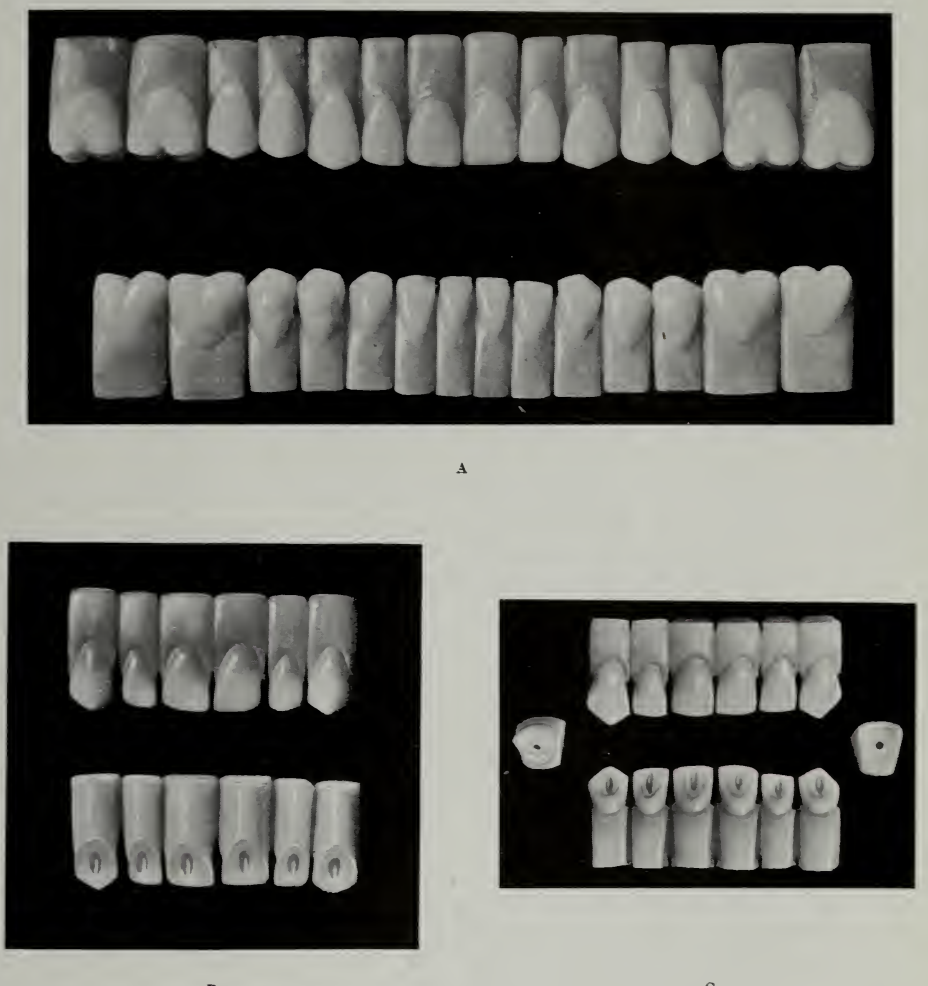
There is no evidence to show that gum tube teeth and sections were ever manufactured in America on a commercial basis, but about 1856 both gum teeth and sections—for use in connection with the Blandy Process—were manufactured by the S. S. White Co. (see S. S. White's Tooth Catalog pages 17 and 158), and were soon followed by gum teeth and sections with platinum pins for use in connection with a vulcanite base, and these latter have been largely used up to the present time. Those for use in plate work were doubtless introduced at an earlier date; at all events they were manufactured in England before 1850. It is surprising that the single gum pin teeth and sections for use in vulcanite work should have succeeded in displacing the pinless forms, as they are in no way superior, and it is not surprising that pinless forms of teeth should now be displacing those with platinum pins, although the latter are inferior in all respects to their prototype, the original pinless forms.

Had it been realized at the time when gum teeth and sections with platinum pins for use in vulcanite were introduced —about 1858—that platinum would ever reach its present price, and that pinless forms would prove as adaptable in every

way, it is safe to affirm that these gum teeth and sections with platinum pins would never have been introduced. An even greater mistake, however, was made in failing to recognize the superiority of contributed to prevent men from considering the possibilities in this connection.

Attention will now be directed to the advantages which would be derived by

FIG. 167.



A

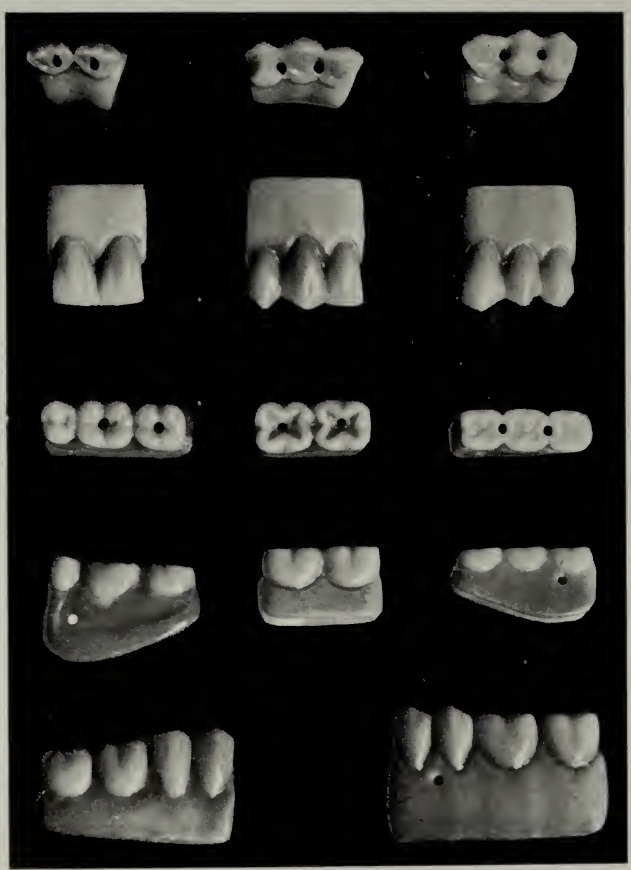
B C

Some old forms of single gum tube teeth.

gum tube teeth and sections for use in vulcanite, as well as plate work. Doubtless this arose from failure to recognize the possibility of employing them in this way, while the obstacles presented by the lack of suitable appliances for grinding the adoption of gum tube teeth and sections in place of the forms of platinum pin and pinless teeth at present in use. The outstanding point with regard to the superiority of the former is their suitability for use in connection with

Fig. 168.

A



B

Old forms of gum tube teeth and sections. Note the provision of swivel bolt for spiral springs in some of the bicuspid and molar sections.

the casting process. In this respect they hold a unique place, as none of the other forms are adapted for use in this way, but in addition to this, they are also

Fig. 169.

Showing the amount of overbite to be obtained even without grinding.

suitable for use in all cases where other forms of gum teeth are employed, yielding better results in most, while under no circumstances are they inferior. The claims advanced in favor of tube teeth are applicable also in connection with those sections, and at the risk of being accused of too frequent reiteration, a few of them may be repeated.

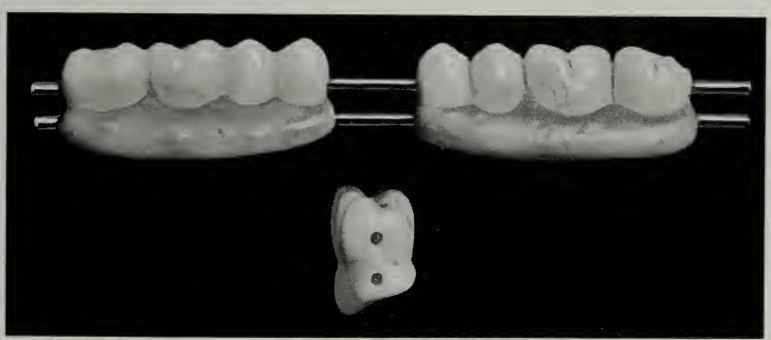
Their adaptability has already been spoken of in conjunction with the casting process, and will be described later on, as will also the use of tube teeth and single gum tube teeth in this way. Figs. 167 and 168 will show a few of these old forms of single gum tube teeth and sections. The advantages spoken of were strength, easiness of repair, security of anchorage, natural appearance, and comfort.

Strength. With regard to strength, this is apparent from the bulk of porcelain, which is disposed to greatest advantage for this purpose.

Easiness of repair. In the event of fracture, or from any other cause which may necessitate replacement, a new tooth or block can be substituted much more quickly than by either vulcanizing or soldering. In consequence, the risks associated with these methods are eliminated.

Anchorage. The subject of anchorage is one of great importance, and it will be observed that ample provision is made for this in connection with gum tube sections as well as single gum tube teeth when either the old method of grinding and fitting or the casting process is em

Fig. 170.



Gum section blocks shaped-up from rod No. 28. Time for shaping-up, about four and a half hours—not including time for fusing gum enamel.

ployed, while the same applies to their use in vulcanite work. But it may be worth while to point out once more that gum tube teeth and sections permit of greater adaptability in cases of abnormal overbite than do pin gum teeth and

sections, in dealing with which attempts to obtain additional overbite are made

The bridge worker will at once realize the possibility in connection with these

Fig. 171.

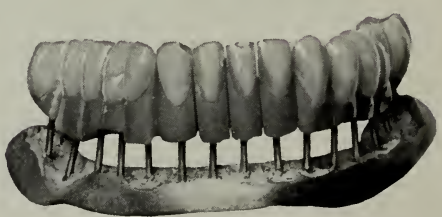
Fig. 173.

Fig. 174.



at the expense of the anchorage (Fig. 169.)

teeth and sections, the use of which would fill a gap at present imperfectly

occupied by fused gum body. The provision for anchorage, however, as will be seen from the illustrations, is confined to vertical tubes, and while these afford ample anchorage for fixed and removable saddle bridges, an additional horizontal tube or tubes would be advantageous (Fig. 170). This might be introduced without interfering with their employment in other ways.

Other advantages which would result from the use of these teeth are derived from the smooth wall of porcelain in the lingual surface, and the increased amount of room which is available for the tongue resulting from the disposition and nature of the anchorage.*

The application of these sections in plate work is similar to that described in connection with single tube teeth, or two or more teeth shaped-up from porcelain rods, and one of the objections which resulted in the displacement of tube teeth by the platinum pin variety was the time spent in grinding and fiting; but this objection no longer holds good, because of improved methods and appliances. If these teeth and sections were now available, they would doubtless be extensively used because of their suitability for use in the various classes of work spoken of.

It is, however, in connection with the casting process in plate work that the writer sees the greatest scope for their use, and the reasons for this, apart from those already given, may well be borrowed from the claims advanced in favor of continuous gum work. (See Figs. 171 and 172.) These are chiefly greater artistic freedom and hygiene. With reference to the former, it is true that greater scope is provided for obtaining any desired position for individual teeth than is possible with manufactured sections, but the bulk of porcelain and the ease with which it can be shaped up and afterward polished, render tube sections far superior to the ordinary kind, while admittedly inferior to continuous-gum work. On hygienic grounds the claims advanced are as sound for tube sections as for continuous-gum or any other forms of teeth.

It appears, then, that the possibility of adjusting individual teeth is the only point where continuous-gum work obtains an advantage over tube sections, while the corresponding advantage which they possess over all other forms will be apparent.

THE USE OF TUBE TEETH, GUM TUBE TEETH, AND SECTIONS IN CONNECTION WITH THE CASTING PROCESS.

After the model and bite have been obtained, the necessary steps with regard to the employment of gum tube teeth and sections in connection with cast plates are as follows: A wax base-plate is made in the ordinary way, and the base of the tube teeth or gum sections should be rough-fitted to the model, and their sharp edges neatly rounded off—they should also be fitted to suit the bite, and the joints accurately adapted in the ordinary way. (See Figs. 173 and 174.) The tubes are next to be hollowed out a little at their bases, in order to permit of an extra thickness of gold for the purpose of increasing the anchorage of the pins. The teeth should now be slightly oiled, in order to prevent them from sticking to the wax, when they should be gently pressed into it, and any deficiencies with regard to fit made good by careful waxing up. The pins may be of dental alloy or gold, the former for choice, as it gives a stronger union. The pins are next to be warmed, and all in turns placed in their respective tubes and pressed through the wax until they touch the model. Having chilled the sections and wax with water, they should be removed carefully, so as not to alter the position of the pins; any superfluous wax may now be removed, the teeth or sections once more tried, in order to make certain of their

* The writer is fortunate in possessing a large stock of the various forms of gum teeth and sections, most of which were made from thirty to seventy years ago, also some much older specimens. Most of these, some of which are illustrated in this paper, he owes to the kindness of Messrs. Lemale & Sons of London.

position, then removed, when the investment and casting should be carried out in the ordinary way. In order to add to the anchorage of the pins to the plate, a slight groove may be formed around the base of each, or a very slight amount of solder sweated on to the end.

After the plate has been cast, and before proceeding to finish it, the teeth or sections should be stuck on temporarily with hard wax, in order to obtain the best finish and prevent damage to the pins during the finishing process.

From the foregoing, then, it will be seen that a case in which gum tube teeth or sections are used may be as easily and quickly made as a vulcanite plate, and the description given is applicable to tube teeth as well as gum tube teeth and sections.

The question of weight is not one which is likely to cause difficulty, as cast plates with tube teeth or gum sections need be no heavier than ordinary plate work, and far lighter than continuous-gum work. There is also the choice of aluminum and certain alloys.

(To be continued.)

THE CEMENT LUTE IN INLAY WORK.

By J. B. PARFITT, L.R.C.P., M.R.C.S., L.D.S.Eng., Reading, Eng.

(Report presented to Section III, Sixth International Dental Congress, London, 1914.)

IT would be difficult to overrate the importance of the cement which fixes an inlay into its containing cavity, for if the cement gives way the most perfect inlay ever made will be a failure, whereas if the inlay should get broken, or even come out, the tooth will at least be preserved from decay as long as the cement lining remains intact.

With a considerable degree of truth an inlay may be defined as a cement filling of which the exposed part is to a great extent, although not entirely, protected by a layer of porcelain or metal, and a discussion of the cement lute practically resolves itself into an inquiry as to how far such a composite filling possesses the advantages and avoids the disadvantages of one composed of cement alone.

It may be stated at once that inlays have most of the advantages of cement, such as freedom from secular change, and from irritation or staining of the tooth substance.

This statement requires perhaps a little qualification or explanation. Laboratory experiments have very certainly shown that, after setting, cement undergoes changes, both in its internal structure and in bulk. Experience seems to show that, under ordinary conditions, change in bulk must be quite small, many old cement fillings on removal proving to have a join so close that there seems to be almost an actual adhesion to the dentin; moreover the particular disposition of the cement when it forms the lute of an inlay renders a slight change in bulk of comparatively little importance; even if there were a very large contraction, of the order of 1 per cent. linear, the effect on a cement margin 50 microns broad would be to open a chink only 0.5 micron broad, and in all probability the utmost we could expect would fall far short of this amount. With regard to absence of irritation, metal inlays will of course conduct heat to the pulp less or more in proportion to the thickness of the cement that lies between.

The important advantage of facility of manipulation cannot be claimed for inlays at all.

DISADVANTAGES OF CEMENT.

I will now pass on to the disadvantages of cement. Of these the only one that calls for discussion is its lack of permanence, cement fillings suffering both from mechanical wear and from chemical solution. Incidentally, this loss of substance frequently leads to the formation of a rough surface, and consequent mischief from lodgment of food.

Mechanical wear, that is the loss of substance by abrasion, is in inlay work prevented by the peculiar disposition of the materials which form the composite filling, as the hard layer of the inlay itself, whether it be metal or porcelain, protects the underlying and relatively softer cement from the stress of mechanical wear; the grave hygienic disadvantage of a rough surface is also avoided, one of the most valuable properties of inlays being that they can be made to take and permanently retain a high polish.

The question of chemical solution of the cement lute is one that will demand more detailed consideration than that of mechanical wear, as it is by no means so evident that the layer of inlay material will in this case afford adequate protection to the cement from the fluids in the mouth capable of dissolving it. If the fit of an inlay were perfect, as perfect for instance as the fit of a well-made glass bottle stopper, and if such an inlay could be accurately cemented into its place we should have perfect and permanent protection of the cement lute, in fact we should have a filling which would be everlasting, subject only to undermining by fresh caries, or the incidence of an overwhelming force. Unfortunately this ideal seems impossible of attainment; perhaps the nearest approach that can be made to it without much difficulty is by the use of the Dall method of grinding both cavity and inlay material to a form with a circular cross-section, the inlay itself being a truncated cone of small taper. In actual practice the protection of the cement is never absolute, there is always some area of it exposed, and unfortunately the dissolving fluids can penetrate into chinks and around corners and reach places that are quite immune from the attacks of mechanical agencies; in fact it may be that in some cases they act all the more quickly if they are not subjected to too much disturbance.

From the time when inlays were first introduced, the solution of the cement has always been the point as to which inlay workers have had doubts and fears, and, on the principle of a chain being no stronger than its weakest link, many have no doubt felt that an inlay would last no longer than a plain cement filling; experience, however, has shown that inlays have a very good record for lasting properties, and that in actual fact the cement is protected from solution to a very considerable degree.

In discussing the amount of protection from solution which its peculiar distribution gives to the cement, two questions call for consideration, namely, the factors that determine the thickness of the cement layer, and the influence which this particular manner of distribution had on the rate of solution.

THICKNESS OF THE "CEMENT LINE."

The factors which influence the thickness of the "cement line" are—

(1) The amount of discrepancy (if any) between the dimensions of the cavity and the inlay.

(2) The shape of the cavity in sections vertical to the floor.

(3) The size of the grains of cement.

(4) The consistence to which the cement is mixed and the amount of pressure used in forcing the inlay into its place.

(1) The discrepancy between the sizes of the cavity and the inlay will vary in different cases according to the material and method made use of.

Porcelain inlays made by the usual method of swaging a foil matrix into

the cavity or some reproduction of it must of necessity be smaller than the cavity to the extent of the thickness of the matrix. A useful and frequently employed thickness of foil is one-thousandth of an inch, or 25 microns, and this would be the width of the chink surrounding the inlay, and consequently the thickness of the "cement line."

In the method invented by and named after Dr. Peck, the thickness of the foil matrix does not come into the problem at all, as it is made on the counter, reverse, or, to use a photographic analogy, a negative of the cavity, and thus is itself an exact-size model thereof in its internal dimensions. In practice it is possible, with care, to make inlays that will go into the cavity with almost what engineers would call a "driving fit."

Of the methods in use for making gold inlays, that of the "Alexander plastic gold" probably yields an inlay the size of which is very near indeed to that of the cavity. Theoretically this should be the case, because the gold is actually molded into the cavity and is never melted in all the subsequent operations. This conclusion is borne out by experience, as it is quite possible to make inlays by the Alexander method with margins sufficiently good to bear inspection under a magnification of eight or ten diameters.

A somewhat similar result, both theoretically and practically, is arrived at by the "reinforced matrix" method, which consists in casting into a platinum matrix in two stages, the matrix, with its cast "core," being reburnished to the cavity margins before the second casting which completes the contour.

The ordinary or "lost wax" process generally yields an inlay which is too small for the containing cavity. It is not an easy matter to give a definite estimate of this contraction, because it is a sum of several different amounts, due to different causes which fortunately to some extent neutralize each other.

The causes of the discrepancy between the size of a cast inlay and its cavity are—

(*a*) The contraction of the wax pattern in cooling from mouth temperature to that of the investment. Some figures given by Van Horn* show that this is about of the order of 0.0002 for each degree C.

(*b*) Expansion of the investment on setting. This may be taken to be much the same as that of plaster, and in the case we are considering would probably be negligible; any influence it would have would be in the direction of lessening the total contraction of the inlay.

(*c*) Expansion of the investment in heating from room temperature to that of casting. This seems to be quite large in amount, Van Horn finding that there was a difference of about 1 per cent. linear between a block cast in a red-hot mold and one cast in a cold one.

(*d*) Contraction of the gold in cooling from its molten state to body temperature. The coefficient of expansion of gold is given as 0.000015 per degree C. between 0° and 100°, so that the total contraction would probably be 2 per cent. or more.

The sum of all these separate discrepancies almost always results in a certain amount of contraction, varying according to the manipulation employed; in some cases it may be as much as 1 per cent. linear, or even more.

(2) The shape of the cavity is of considerable importance in this connection, because in some cases a discrepancy at the margin can be lessened or removed altogether by the inlay sinking slightly into the cavity. The extent to which this diminution of the marginal chink can be carried depends on the amount of the departure of the cavity walls from the perpendicular. If the containing walls are perpendicular to the cavity floor; that is, if they are parallel to one another, it is obvious that no amount of sinking-in of the inlay toward the floor will diminish the marginal chink at all. In any actual case the distance the inlay will have to sink into the cavity in order to bring its edge

* "The Wax Pattern: A Technique," etc., by C. S. Van Horn, D.D.S., DENTAL COSMOS, 1912, vol. liv, p. 973.

into apposition with the enamel margin will be the width of the marginal chink multiplied by the cosecant of half the angle at which the opposite sides of the cavity are inclined to one another; thus, if the marginal chink is 20 microns broad and the opposite sides of the cavity are inclined at a right angle to one another, that is if they are each inclined 45° away from the vertical, a sinking of the inlay 28 microns into the cavity will bring it into complete apposition with the cavity wall. In the case of parallel walls cosec. 0° is infinity, which corresponds with the statement made above, namely, that in this case *no amount* of sinking-in of the inlay will make any difference to the marginal chink. The other extreme case would be the apposition of two flat surfaces, such as might occur in the fitting of a tip to a front tooth; here the opposite walls of the cavity may be considered to be in the same straight line, or to have an inclination of 180° to one another; half 180° is 90°, and cosec. 90° is 1, which corresponds to the fact that here a theoretically perfect joint is obtained by the inlay settling nearer to the tooth by an amount equal to the thickness of the foil matrix used.

These considerations justify us in concluding that with correct cavity preparation and choice of a suitable method we should theoretically be able to make an inlay whose margins are in perfect apposition. We have, however, still to reckon with the cement itself.

(3) The actual size of the grains of the cement is a matter of the greatest importance, as it is certain that many of them retain their individuality after mixing.

Valuable papers have been published, notably by Head* and Poundstone,† on the problems of the inlay cement line.

It appears that in the ordinary cements we must expect grains 25 microns thick or even larger, so that it is better to use a cement ground specially fine. We shall probably not be very far wrong if we assume that the size of the cement grains will prevent the reduction of the joint much below 25 microns.

(4) The amount of pressure used in setting the inlay will naturally influence the thickness of the cement margin to some extent. Some experiments made by Head showed that with a block ¼ in. square, eight pounds pressure with a certain cement gave a film $\frac{15}{10{,}000}$ in. or about 37 microns; an increase of the pressure to one hundred pounds caused a reduction of the thickness of the film to about 22 microns; with another cement a similar increase of the pressure caused a reduction of the thickness from 25 to 15 microns.

A hundred pounds might seem a very great pressure, but we must remember that it was distributed over the area of a ¼ in. square, and that what counts in these matters is not the total pressure but the amount of pressure per unit area. If the floor of the cavity were deepened so that the pressure fell on the margin alone, its intensity in the narrow band around the edge of the inlay might well equal or even exceed that used in Head's investigations. It should be mentioned that Head obtained films as thin as 7 microns, using specially ground cement powder and a pressure of only eight pounds to the ¼ in. square.

It is this peculiar disposition in a thin layer presenting only its edge to the solvent action of the saliva that explains the relative permanence of the cement forming the lute of an inlay.

INFLUENCE OF DISTRIBUTION OF CEMENT UPON ITS RATE OF SOLUTION.

Other things being equal, the rate of solution of a substance will depend on the area of it exposed to the action of the solvent and the rapidity with which the saturated solution can be removed so that a fresh portion of solvent can be brought into action.

In this particular case the area ex-

* "Tests on the Inlay Cement Problem," by J. Head, D.D.S., DENTAL COSMOS, 1905, vol. xlvii, p. 779.

† "The Cement Problem in Inlay Work," by G. W. Poundstone, D.D.S., DENTAL COSMOS, 1905, vol. xlvii, p. 756.

posed is small, nevertheless solution will no doubt go on at first as rapidly as with a plain cement filling in the same mouth. In a short while the exposed edge of the cement will come to lie at the bottom of a narrow and relatively deep chink in which the saturated solution will tend to stagnate, especially as the chink will get more or less choked up with all sorts of insoluble débris. In most cases solution will go on with less and less rapidity, and in many will after a time practically come to a standstill altogether; in any particular case the rate will depend on several different factors, such as the chemical and physical characters of the cement, the composition of the patient's saliva, and the position of the joint in relation to the bite. In this connection it is, I think, a well-established and remarkable fact that although the cement does wash out to some depth, the tooth very frequently remains free from fresh attacks of caries.

The rate of solution may possibly be affected by the nature of the material forming the inlay. Thus it is conceivable that a gold inlay, owing to its relatively large conductivity and coefficient of expansion for heat, might be subject to frequent small changes in bulk, and so tend to help the renewal of solvent in the joint: there may also, under some circumstances, be a slight amount of electrolytic action going on at the surface of a metal inlay.

INFLUENCE OF CEMENT ON SHADING OF INLAY.

The influence of a layer of opaque cement on the appearance of a porcelain inlay deserves perhaps a brief consideration.

Both porcelain and tooth substance are translucent materials, and, as with all other bodies, their "shade" will depend both on their own nature and on the illumination they receive; moreover, the light they send to our eyes comes not only, nor in this case even mainly, from the surface, but also from layers which lie deeper down, and in their passage through the porcelain or tooth substance the light rays are broken up and reflected many times.

Under ordinary circumstances the "lighting" of the teeth is from above downward and backward, and the apparent shade varies considerably with the raising or lowering of the upper lip. If, now, a central tooth has its tip restored with porcelain, and an opaque line, although thin, and it may be quite invisible, runs horizontally across it, the relative shades of tooth substance and porcelain will alter with every alteration in the level of the upper lip. The reason of this is that the opaque layer prevents the basal part of the tooth from receiving any light from the occlusal part, so that each gives back just the light it receives from the outside source, and while the porcelain tip remains constantly much the same "shade," the base looks light or dark according to the position of the lip. If instead of a transverse layer there is a vertical one running from before backward, the raising or lowering of the lip will affect both halves of the tooth in the same way, hence a porcelain restoration with a vertical join can be so matched that it looks well in all conditions of lighting, whereas one with a horizontal join will only be at its best if one particular set of conditions is realized, and especially with one particular position of the upper lip.

The same principles govern the lighting of porcelain inlays in other positions; in the case of interstitial cavities in canine teeth for instance, except that the conditions of illumination are not so changeable, the front part, whether it be porcelain or tooth substance, tends always to throw the back part into shadow, so that mesial inlays have to be made darker and distal ones lighter than the original color of the tooth.

CONCLUSIONS.

(1) The cement lute confers on inlays all the advantages of cement except facility of manipulation.

(2) The thickness of the film at the edge can by suitable choice of method be theoretically reduced to the size of the grains of cement.

(3) Such a film is in most cases practically immune from solution and altogether immune from mechanical wear.

(4) With an opaque cement the character of the lighting of a porcelain inlay depends on the direction of the plane of the join.

THE PATHOLOGY OF THE DENTAL PULP.

By RUSSELL W. BUNTING, D.D.Sc., Ann Arbor, Mich.

(Report presented to Section II, Sixth International Dental Congress, London, 1914.)

AS we review the contributions to the pathology of the pulp we find that relatively less is known of the morbid anatomy of that organ than of any other component of the tooth, save perhaps the pericementum. In fact, those who have made a special study of the subject admit that they do not fully understand the normal structure and histological complex of the pulp, so that they often find it difficult to determine the degree of variance of a pathological condition from a histological norm. This is due in large measure to the fact that they have met with great difficulty in perfecting a technique by which they may prepare the pulp for microscopical study with a minimum amount of change. Incased as it is in the hard dentin wall, with which it has an intimate relation, the pulp offers numerous obstacles in the process of fixation and sectioning.

Students of the subject have met with a second difficulty when they have attempted to link the various pathological conditions of the pulp with the symptoms which accompany them. It is true that few tissues of the body offer equal opportunities for antemortem examination, it being possible to catch the pulp in any stage of inflammation or degeneration, but the symptomology of this organ is so obscure that great difficulty has been experienced in synchronizing the symptoms with the pathological conditions which produce them.

STUDIES ON THE MORBID HISTOLOGY OF THE PULP.

But in spite of the many difficulties much valuable work has been done upon the pulp, and many beautiful preparations have been made which faithfully depict the morbid histology of that organ. The most comprehensive and complete contribution which has been made in America is that given by Dr. G. V. Black in vol. i of the "American System of Dentistry," by Litch. The text of this treatise, with the illustrations which accompany it, has formed the basis for many other works upon the subject which have appeared since the time of its publication.

Dr. Black, in the treatment of this subject, first describes the histology of the pulp, and dwells at some length upon its sensory functions. As to its symptomology, he speaks of the pulp as being a true internal organ, having no tactile sense. He goes on to say that it has a "resentment to heat and cold which is a special sense of the dental pulp; under normal conditions it has none other whatever." He reviews the symptomology with regard to the sensory functions, and cites cases illustrative of referred pain of dental origin.

He speaks of the physical conditions which surround the pulp, which in times of hyperemic disturbances prevent swelling, and are a restraint to edema and the migration of the leucocytes from the

bloodvessels to the surrounding tissues. He states that he has not found secondary inflammation and swelling of the periapical space as a result of hyperemia and inflammatory conditions of the pulp, but that they occurred only when the pulp was badly affected or nearly disorganized.

HYPEREMIA.

Among the various pulp diseases, hyperemia is first considered. In his presentation of this subject Dr. Black reviews in detail the methods of his observations, and the technique by which he prepared his specimens for study. He gives many illustrations of pulps in the various stages of disease, and detailed descriptions of the conditions found, by which the reader is led through the phases of hyperemia, thrombosis, and inflammatory conditions of the pulp. He further says that all pulps which are exposed to the action of the saliva are inflamed, but that inflammation seldom occurs when there is no exposure. As to the sequelæ or prognosis of such inflammation, he says, "The dental pulp has a considerable power of recuperation from the inflammatory state. It is certain that moderate extravasations of blood are disposed of successfully, and that a considerable bulk, considering the size of the organ, of inflammatory lymph is tolerated without destroying it, and would undoubtedly be disposed of by the tissues if the case were placed under favorable conditions. . . . Of the ability of the dental pulp, when placed in good hygienic conditions, to recover from inflammation there can be no doubt whatever."

The author then considers the Infections, with special reference to ulcerations and abscesses of the pulp. He has found that abscesses are far more common in the multi-rooted teeth than in those having a single root.

CHRONIC PULP DISEASES.

Of the chronic diseases, hypertrophy is first described, and cases are cited in which the hypertrophy was accompanied by absorption of the dentin. Under Degenerations the deposition of calcoglobulin in disease conditions and the formation of pulp-stones is reviewed. The hard formations within the chamber are described as follows:

(1) Secondary dentin.
(2) Dentinal tumors in the pulp chamber.
(3) Nodular calcifications among, but not of, the tissues of the pulp.
(4) Interstitial calcifications of the tissues of the pulp.
(5) Cylindrical calcifications of the pulp.
(6) Osteodentin.

The author makes the statement that very frequently slight chronic affections of the pulp will cause the destruction of a portion of the layer of odontoblasts. In case a secondary deposit of dentin is formed in this region, it is devoid of tubuli or dentinal fibrillæ. Also, that under certain conditions these odontoblasts which have been lost may be regenerated.

In his conclusion Dr. Black says that all secondary calcific formations within the pulp result in exhaustion and final death of that organ. In view of this fact he decries the practice of stimulating secondary dentin and urges the use of non-conductive materials beneath all fillings which are in proximity to the pulp.

CONTRIBUTION TO THE PATHOLOGY OF THE PULP.

Eugene S. Talbot has reviewed the work which he has done upon the pathology of the pulp, in his book entitled "Developmental Pathology." Chapter xxviii of his work treats of the dental pulp and opens with a general statement as to its evolution and development. The author then considers the possibility of the existence of a lymphatic system in the pulp. He states that he has been unable to demonstrate the presence of lymphatics, but describes oval spaces, without walls, in the pulp tissue, the nature of which is not clear. Whether there be lymphatics or not, the author

is very certain that the pulp has a good regenerative process by which diseased and abscessed areas are repaired and restored to health.

After describing the vascular and nervous systems of the pulp, Dr. Talbot takes up the consideration of its pathology. He states that the causes of pulp disease are changes in the blood stream which are due to poisons circulating in the blood. These poisons are, in the opinion of the author, the result of degenerative conditions, and may produce in the pulp a faulty metabolism and auto-intoxication which make it susceptible to any of the pulp diseases. Such a pathological degeneration begins as soon as the apex of the root of the tooth is closed.

Because of its structure and physiology the pulp is very susceptible to inflammatory changes. According to the author, in cases of obstruction the intravascular pressure alone is sufficient to produce rupture of the capillaries and marked diapedesis. The absence of lymphatics and collateral circulation causes the pulp to pass quickly from hyperemic states, through inflammation, to death by coagulation, stagnation, neurosis, or thrombosis.

In the consideration of pulp abscesses it is stated that they may occur at any location. A number of excellent photomicrographs are shown in which abscesses may be seen in their various stages, from that of areas of small cell infiltration to large abscesses and complete dissolution of tissue. The sections show degenerating odontoblasts and nerve fibers, and thickened arteries. One particularly fortunate section, "Figure 330 shows A, a circumscribed area of acute inflammation about to liquefy and form an abscess, C, a fully formed abscess, and B, the cicatricial tissue of an old abscess showing conclusively that restoration of a diseased pulp is possible." These illustrations are followed by several showing nerve-end degeneration, with cases of specific Wallerian degeneration.

The author then takes up the discussion of the various pulp diseases, and illustrates many with sections. He speaks of the pulp as being an end-organ, without collateral circulation or lymphatics and having but a single exit for its venous circulation all of which renders it susceptible to thrombosis. The thrombi are described as being due to the embolism of the products of degeneration, fat droplets, tissue fragments, tumor cells, air, etc.

Inflammation of the arterial coats is spoken of as being very common. He calls the pulp "a unique end-organ whose arteries are susceptible to obliterans and arterio-sclerosis, which predispose to degenerations and necrosis." The causes of this condition are stated as being auto-intoxication, and drugs taken systematically which may become irritants, syphilis, gout, rheumatism, Bright's disease, alcoholism, and metal poisons.

As a result of arterio-sclerosis in the pulp, cloudy swelling and fatty degeneration occur, which conditions are often associated with typhoid fever, septicemia, and other acute infections and toxic diseases. Amyloid and hyalin degeneration is described as well as the various calcific concretions which so readily form in degenerating pulp tissues.

In his conclusions Dr. Talbot states that the causes of pulp diseases are changes in the blood current due to circulating poisons which result from degenerative conditions occurring at the stress periods of life; that pathological degeneration of the pulp begins when it has ceased to form dentin and the apical end is nearly closed; that inflammatory processes of the pulp may pass through all stages from infection to abscess without pain; and that all forms of degeneration, together with the pathological processes of evolution, are the direct causes of tooth decay.

NEOPLASMS OF THE PULP.

Some very valuable contributions to our literature of the dental pulp have been made by Dr. Vida A. Latham. Of these there are two which deal with the pathology of that tissue, the first of which is an article entitled "Neoplasm of the Pulp," published in the *Journal*

of the American Medical Association for 1904, p. 535. In this the author describes a case of tumor growth in the pulp of a tooth, and shows a number of very beautiful slides made from photomicrographs of the diseased tissue.

After having reviewed the literature upon these growths and having shown how little has been written upon this class of pulp diseases the author describes the case in hand. The patient was an elderly woman age fifty-six, stout build, neurotic type, who had had two sisters die of cancer. She complained of a neuralgia about the right side of the face. There were but few teeth in the mouth, among which the upper right first premolar and canine alone showed any peculiarity. The former of these had a reddish color, while the canine was of a greenish-white tinge which made it very conspicuous. Both pulps were alive and there was no evidence of caries. The teeth were extracted and the pulps of each were examined. That of the canine had a firm hard appearance like that of a fibroid tumor, and was spongy to the touch like a myxoma.

In the sections made there were (1) evidences of granulation and pulpitis; (2) slight sclerosis; (3) slight hyaline degeneration; (4) vessels surrounded by a fibrous thickening; (5) many polynuclear cells scattered in the tissue and massed in areas like round-cell infiltration; (6) cancer-like nests of cells, and hyaline areas near the periphery of the pulp.

In a discussion of these new tissue formations, Dr. Latham asserts that they were carcinomatous, of epithelial character. She offers no explanation of the origin of these epithelial cells, occurring as they did in a mesoblastic tissue. The statement is made that the odontoblasts are readily affected in pulpitis, they being found in every stage of degeneration. They are often exfoliated and atrophied like the ciliated cells of the bronchi. The author makes the suggestion that the epithelial origin of the cancer cells might easily be explained if we could but show that the odontoblasts were developed from the epithelium. The only other possibility of epithelial anlage is that of the nerve tissue in the pulp.

Among the conclusions of the paper attention was called to the fact that there were no prominent symptoms in the case aside from a slight neuralgia; that neoplasms of the pulp are rare and the literature upon the subject very scarce; and that studies should be put upon these neoplasms with reference to their significance and the possibility of metastases.

INFLAMMATORY DISEASES OF THE PULP.

In a second paper, entitled "Some Pathological Features of the Pulp," which appeared in the *Journal of the American Medical Association* for 1906, p. 916, Dr. Latham has reviewed the inflammatory diseases of the pulp, giving illustrations of the various phases of pulpitis. In opening the discussion of the subject the author deplores the fact that the normal histology is not well understood and that the symptomology of the various pathological states of the pulp is not clear.

In the study of the inflammatory conditions of the pulp the following data are suggested for consideration: (*a*) the delicate structure of the pulp is apt to undergo rapid secondary changes after an inflammatory attack, whether from constitutional or local causes; (*b*) its location and poor methods of egress for exudations and dangers from compression; (*c*) fissures and lesions of dentin and enamel are not always able to recuperate for perfect repair; (*d*) if a pulp has been exposed it is difficult to disinfect and hermetically seal; (*e*) the liability of entrance of bacteria through cracks in the dentin even before the pulp has been exposed by decay; (*f*) abnormally large and irregular pulps in some teeth; (*g*) the absence of a lymphatic system in the pulp.

The article then takes up the etiology and symptomology of inflammation in general. The various infections are discussed in regard to their avenues of entrance to the tissues, and the resistance which is offered to them by the tissues. The avenues of entrance of irritation to

the pulp are stated as follows: (1) by direct exposure as a sequel to caries, erosion, abrasion, fracture, etc.; (2) exposure of dentinal tubuli through trauma, fillings, etc., and transmission by the fibrils of irritating stimuli such as acids, metal fillings, etc., too close to the pulp; (3) through the apical foramina as a sympathetic depression from some other source; (4) by contact with the periodontal membrane when it is diseased.

In the discussion of the pathology of pulpitis the author shows sections of pulps in which slight irritation has given rise to a mild inflammation, which has subsequently been reduced by early resolution. Other sections are shown in which the inflammation has gone on to the formation of arterio-sclerosis and thrombosis, which condition is frequently associated with chronic inflammation of the periodontal membrane and pyorrhea. The author describes similar cases in which there is a marked change in the odontoblastic layer, which has been replaced by a thick membrane-like layer containing giant cells. Dr. Latham further states that these cells destroy portions of the pulpal wall of the dentin to enlarge the pulp chamber, and may later replace the lost tissue with a poor grade of dentin or osteodentin.

It is the belief of the essayist that a large number of inflamed and diseased pulps may recover if the cavities and the cracks in the teeth be sterilized and if the patient be in good health. As to the occurrence of pulpitis, it is stated that the upper premolars, canines, and incisors are more susceptible than the corresponding lowers, but in the molars the lowers suffer more than the uppers.

In conclusion the author says: "The loss of control of the vascular system of the pulp and obstruction in vessels followed by inflammation are probably factors in interstitial gingivitis which may be the cause of the gingivæ losing their normal function and so aiding in the progress of the disease. The interference with the vascularity of the bone, the arteritis obliterans in the pulp and peridental membrane produce venous hyperemia of the gums (acute or interstitial), changes in the mucous glandular structure, and finally atrophy and osteomalacia."

LESIONS IN VITAL PULP DUE TO GOLD RESTORATIONS.

Two papers have appeared which treat of the resultant pathological conditions in the case of living pulps beneath gold shell crowns and other large restorations. Both of these articles condemn the practice of leaving vital pulps beneath such extensive gold operations. The first paper, entitled "Pathological Lesions of the Living Pulp under a Gold Shell Crown," by M. L. Rhein, appeared in the *Items of Interest* for 1909, p. 561. In this paper Dr. Rhein calls attention to the pathological conditions which may be found in pulps under gold shell crowns, especially degenerations going on to calcifications of the pulp. As an illustration he reports a case in which the pulp was removed from a tooth which had been crowned, and sections were made of the tissue thus obtained. The photomicrographs show a marked degeneration and a tendency to calcification throughout the pulp.

The second paper, a more comprehensive treatment of the subject, appeared in the Dental Cosmos for 1910, p. 389. It was entitled, "The Adventitious Effect of Large Masses of Gold in Contact with Tooth Tissues," by I. N. Broomell. He first reports a case in which two pyorrhetic teeth which had served as bridge abutments were removed and an examination was made as to the condition of their pulps. In these are shown changes in the odontoblastic layer and an atrophy of the pulp cells. The bloodvessels were enlarged and sclerotic, while the dentin was largely disintegrated with the formation of interglobular spaces. All of these changes the author attributes to the adventitious effect of the mass of gold used for the attachment of the bridge to the tooth. The writer of this report is struck with the marked similarity between the sections of this case and the sections shown by Dr. Latham

of pulp changes as the result of pyorrhea. This leads us to inquire as to how much of the pulp change in Dr. Broomell's case was due to the gold, and how much to the pyorrhetic condition of the teeth.

Other cases are cited by Dr. Broomell, in which a more specific effect of the irritation of gold is seen. In one case suppuration of the pulp had been produced beneath a large gold filling. The dentinal fibers of this specimen showed club-shaped enlargements and a large amount of calcific degeneration had taken place. Still another case was that of a woman about forty-five years of age, of highly nervous temperament, with teeth which were hypersensitive under normal conditions. A gold shell was placed on a lower bicuspid which was free from caries with but little cutting of the enamel. After setting the crown an acute pulpitis resulted immediately, and it became so marked as to require the removal of the crown. The crown was reset after ten days and a little later the tooth was extracted because of pain. An examination of the pulp showed a marked increase in the number and size of the odontoblasts, and characteristic hyperemic and acute inflammatory conditions of the pulp. It was evident to the author that "The disturbance in the pulp was due to the thermal influence of the gold casing upon the terminal branches of the dentinal fibers, notwithstanding the fact that they were shielded by a layer of normal enamel." He also states that one of the most probable sequelæ of crowning a tooth with a live pulp is that of dry gangrene. He cites a case in illustration of that view, and shows sections of the pulp which have become shrunken and structureless.

VALUE OF THE PULP TO THE TOOTH.

In the *Dental Forum,* a journal published by the dental alumni association of the University of Buffalo, on p. 12, vol. i, an article is published by Dr. L. M. Waugh, entitled "Some Influences which Affect the Functions and Structure of the Dental Pulp." In this the author reviews the structure of the pulp and its pathology with especial reference to the calcific degenerations and their significance. In a discussion of the value of the pulp to the tooth, Dr. Waugh advocates the removal of the pulp in the following cases:

(1) When decay has so progressed that all of the overlying dentin is decalcified, except in young subjects.

(2) When prolonged pulpitis occurs beneath fillings of some years' standing. This seems especially true of gold.

(3) When operative measures are necessary upon teeth either much abraded or much eroded.

(4) When much dentin has to be removed, in elongating or inclining teeth in preparation for shell gold crowns, especially metallic.

(5) In treatment of advanced pyorrhea.

(6) In facial neuralgia when associated with or superinduced by pulp degeneration.

SECONDARY CALCIFICATIONS OF THE PULP.

In an article entitled "Secondary Calcifications of the Tooth Pulp," which appeared in the DENTAL COSMOS for 1912, p. 157, the writer of this report reviewed the various forms of pulp calcifications and gave illustrations of each. In that article the author has shown that certain forms of calcification which have been slowly laid down and of a good order may be of service to the health and vitality of the tooth, while those calcifications which are formed rapidly in response to a severe irritation are of a poor order and are more of a menace than a boon. They interfere with the circulation of the pulp and tend to produce its degeneration and death. The article also calls attention to the severe irritation which is given to the pulp whenever a live tooth is covered with a gold shell crown. If the tooth be properly prepared for crowning, practically all of the enamel must be removed. The cutting of the dentin on the lateral surfaces of the tooth and the subsequent flowing of the cement over the cut surfaces produce a profound irritation upon the pulp through fibrillæ which have not undergone sclerotic changes. "The ex-

cessive stimulation to the pulp in a large number of such cases results in degeneration and death of that organ, so that, although occlusal or approximal fillings may be inserted relatively near to the pulp in teeth which have been affected by abrasion or slow caries, the operation of crowning these vital teeth is unsafe and hazardous in a large percentage of cases."

As a conclusion to a discussion of the value of the pulp to the tooth economy the following statement is made: "From the foregoing we may conclude that a healthy pulp is a valuable asset to the tooth which is to endure direct stress such as mastication or the support of a filling. In teeth, however, which are ground down and entirely covered with crowns, little crushing stress is brought to bear upon the dentin, and the danger of fracture is reduced to minimum; in such cases the pulp is not essential to the welfare of the tooth, and may therefore be removed."

PRESENT STATUS OF THE STUDY OF PULP DISEASES IN THE UNITED STATES.

From the *résumé* which has been given, it will be seen that relatively few American investigators have made a detailed and scientific study of the pulp diseases. Much has been written of the symptomology and therapeutic treatment of the various forms of pulpitis, but it has been done from a subjective standpoint, dependent largely upon external and clinical observations. Perhaps that form of inflammation which results in partial or total calcification of the pulp is best understood. This is due to the ease with which sections may be made of these hard concretions and to the abundance of material to be obtained for study.

As to the other forms of pulpitis which involve histological changes in the pulp tissue, but few have mastered the technique of the microscopy of that tissue or studied its diseases from a pathological standpoint. Although much valuable work has been done, there is need for further inquiry into the reaction of the pulp tissue in response to the various stimuli to which they are subjected. In these days of extreme and extensive tooth restoration, a large part of which is being done upon vital teeth, we should look closely into the effect which our large fillings, inlays, and crowns have upon the pulp of the tooth. If their insertion is a source of severe and permanent irritation to the pulp, secondary changes will take place, many of which will result in cases of tic douloureux, septic pulps, and apical abscesses.

We know that the pulp readily undergoes hyperemic and inflammatory changes in response to irritation. We know also that when these irritations are mild and of short duration, the pulp may subsequently recover from the injury and return to normal. But in those cases in which the pulp has undergone more severe inflammatory and degenerative conditions we are very uncertain as to our prognosis. Some believe that no pulps which are seriously affected will ever recover their normal vitality, and should be removed. Others claim that the pulp tissue has great powers of recuperation, and, if properly treated, does recover even in cases of marked pathological disturbance. We need, then, a thorough and systematic study of the pulp degenerations and regenerations, these to be correlated with the irritations by which they are produced and the symptoms which accompany them. Such a study would give us information which we need, and should make our treatment of the pulp more intelligent and effective.

RADIO-ACTIVE SUBSTANCES AND THEIR THERAPEUTIC APPLICATION IN DENTISTRY.

By HERMANN PRINZ, A.M., M.D., D.D.S.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, SCHOOL OF DENTISTRY, UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, held October 27, 1914.)

FIFTEEN years ago nothing was known of radium, polonium, actinium and other interesting substances belonging to this group. In 1896 Roentgen made the world-renowned discovery that certain rays obtained from a Crookes tube would penetrate substances which, under ordinary conditions, are known to be opaque. In the same year the late French physicist, Henry Becquerel, observed that uranium salts, when brought into contact with a photographic plate protected by a tight-fitting cover of black paper, become sensitized. Certain substances are known to possess the power of emitting light rays, *i.e.* they cause fluorescence or phosphorescence. It should be borne in mind, however, that these latter substances have to be exposed to sunlight or artificial light for some time before they re-emit some of this stored-up energy in the form of light rays. On the other hand, minerals which contain uranium will bring about the same phenomenon without being previously exposed to light rays.

Light is a form of energy; it cannot be completely destroyed nor can it be created out of nothing. Since uranium salts produce light rays apparently indefinitely, it was supposed that they must contain certain specific substances which possess, as an inherent property, the power of light emanation. The isolation of these substances was finally accomplished, and their discovery is primarily to be credited to the late Professor Pierre Curie and to his wife, Mme. Curie, *née* Sklodowska, of Paris. Both experimenters worked with crude uranium minerals and from it they isolated radium—the radiant—and polonium, so termed in honor of Mme. Curie's native country, Poland. Shortly after the discovery of these two elements, Debierne of Paris isolated a third radio-active element from the crude uranium, which he named actinium.

SOURCES OF RADIUM.

The chief minerals from which radium is derived are carnotite or chalkolite, and pitchblende. Carnotite is found in several of our western states, especially Colorado and Utah, while the chief source of supply of pitchblende is Joachimstal, a mining town of Bohemia. It is from the latter substance, pitchblende, that practically all the available radium of Europe—and, to a large extent, of our country as well—is obtained. The quantity of radium present in the various minerals is extremely small, about five million parts of pitchblende containing one part of radium. A ton of pitchblende, containing about fifty per cent. of uranium, furnishes about two grains (0.13 grams) of radium. To extract this small quantity, tedious mineralogic processes are necessary. The present available amount of radium throughout the whole globe, expressed as the bromid salt, may be estimated at about an ounce and a half (45 grams), which represents a value of about five million dollars. One milli-

gram, *i.e.* about one-sixty-fourth of a grain, is listed at one hundred dollars. Speaking of dollars, it is of interest from an etymologic point of view that our American dollar owes its name to this little town of Joachimstal.*

RADIO-ACTIVE SUBSTANCES.

These may be classified in three distinct groups: Actinium, thorium, and uranium. Each primary element, by transmutation, transforms itself into a number of other substances. According to Rutherford and Soddy, all radio-active substances are continuously undergoing transformation. During the transformation of a radio-active element, another element is created whose atoms possess less power of emanation than is possessed by the one from which it is created. Restricting our discussion to uranium and thorium only, the following substances derived from the respective mother substances may be enumerated: Uranium, Uranium X, Ionium, Radium, Radium emanation, Radium A, Radium B, Radium C, Radium D, Radium E, and Radium F. Thorium, during the process of transformation, produces the following so-far-known substances: Thorium, mesothorium, radiothorium, Thorium X, Thorium emanation, Thorium A, B, C, and D. Incidentally, the products of transformation possess a variable period of "life," *i.e.* time of existence. A specific quantity of radium decomposes by about one-half in seventeen hundred years, radium emanation in 3.8 days, radium A in three months, radium B in twenty-six minutes, radium C in nineteen minutes, radium D in twelve years, radium E in six days, and radium F in one hundred and forty days.

Radium is an element closely related to barium in its chemical behavior. It is a white metal, melting at about 1316° F. (700° C.), and energetically decomposes water. Aside from the ordinary properties possessed by the barium group, it is endowed with three remarkable additional functions: It emits heat continuously at a constant rate, it is the source of radiation, and it generates a gas which is radio-active. The amount of continuous heat produced by one gram of radium equals about 135 calories per hour, or, to put it in other words, the total amount of heat given off by one pound of radium is about equivalent to that produced by the combustion of 250 tons of coal.

RADIATION ENERGY.

The transformation of one radio-active element into another is accompanied by the liberation of various rays, which are known as the alpha, beta, and gamma rays. Alpha and beta rays are not true rays; the alpha rays are positively charged ions of helium given off by the element, while the beta rays are negatively charged ions. The gamma rays are true rays; they do not contain free ions and are very similar to the Roentgen rays. The gamma rays are not distorted in a magnetized field, while the other two rays are turned to the right or left respectively. The power of penetration of these various rays differs markedly; the alpha rays are least active, the beta rays are slightly more so, while the gamma rays pass through a sheet of lead one centimeter thick, the human body, the walls of a house, etc. The relationship of the radiation of these various rays may be expressed by the equation, 1 : 100 : 10,000.

METHODS OF ESTIMATING AND MEASURING RADIO-ACTIVE EMANATION.

Until recently, the strength of radio-active substances has usually been expressed in Mache units—a Mache unit representing 0.001 electrostatic unit as measured by the amperemeter and mul-

* During the sixteenth to the eighteenth centuries, the mint of Joachimstal furnished a coin known as a "Joachimstaler," which on account of its high grade of pure silver content was the favorite means of exchange through western Europe and the Levant. Later, the "taler," as the coin is familiarly known, became the standard of exchange in the German-speaking districts of Europe, and from its Low-German derivative, daaler, the American "dollar" derived its name.

tiplied by 1000. At present, to standardize this somewhat arbitrary method, the term "curie" is employed. A curie represents the amount of emanation in equilibrium with one gram of radium; a "microcurie," *i.e.* one millionth of a curie, is the amount of emanation in equilibrium with 0.001 milligram radium. A microcurie equals about 2500 Mache units. The various rays emanated by radio-active substances act upon photographic plates, they produce fluorescence in certain bodies, they electrify gases, and they produce measurable quantities of heat. Upon these factors are based the various methods of measuring the radio-active emanation, *i.e.* the radiographic, the fluoroscopic, the electric, and the thermic. Various ingenious apparatus have been devised to accomplish these purposes.

CHEMICAL ACTION OF RAYS.

The chemical effect of the rays is manifold; their action upon silver salts present in a photographic plate led to their discovery. Especially easily affected are the simpler salts. Rock salt assumes a yellow color, while melted borax turns blue. Glass in which radio-active compounds are kept becomes variously affected. At first, it assumes a light blue color, which in time changes to a dark violet blue. Most interesting is the effect of emanation on precious stones, *i.e.* amethyst changes to deep violet, sapphire to yellow, diamond to a bluish or brownish hue, etc. An interesting observation is related by Bordas. He obtained some corundum stones of a cheap kind from a jeweler. After keeping these stones in a closed box containing some highly active radium salt for a month, all the stones had changed their color: the colorless corundum had become yellow like topaz, the blue ones had changed to a rich green, and the violet stones had taken on the color of the sapphire. The coloring was so perfect that the same jeweler was willing to buy back the same corundum stones as genuine precious stones at twenty-five times their original price. Alpha rays decompose water into free hydrogen and oxygen, the beta rays produce hydrogen from water, while the remaining oxygen unites with some of the water to form hydrogen dioxid. Many other chemical changes are known, *i.e.* water may be produced from free hydrogen and oxygen, etc. As yet, nothing definite is known regarding these peculiar chemic effects of radio-active substances.

BIOLOGIC AND PHYSIOLOGIC ACTION OF RADIO-ACTIVE SUBSTANCES.

Every living cell, when subjected to radium emanation, is influenced by it; however, the reaction of the cell depends upon its specific nature and upon the kind of rays employed. In consequence, certain tissues are more easily amenable to the rays than others. Nervous tissue reacts most energetically, while intestinal and serous tissues are far less strongly influenced. Muscle tissue is the least reactive. Connective tissue, when subjected to the rays, is readily stimulated to proliferation. Histologic examination indicates that the typical phenomena of inflammation, with their long chain of changes, *i.e.* from an early hyperemia to the final necrosis, may be produced at will. The internal organs react in various ways; readily influenced are lymphoid tissues, especially the spleen, less so the kidneys, and still less the salivary glands and mucous membrane. No living tissue will stand the prolonged exposure to the rays without showing some definite change, and it is immaterial whether the tissue is of animal or vegetable origin. Ferments, on an average, are slightly activated. Saliva ferments are usually at first slightly paralyzed and later activated; the results obtained, however, are so very variable that little significance can be placed on these observations. Low-type organisms, *i.e.* bacteria, protozoa, etc., are comparatively very slightly influenced by radiation. Upon pathological tissues the effect of the rays is much more pronounced than upon normal structure, hence the great significance of the rays

in the treatment of diseases. As stated by Sticker, pathological tissues react to the gamma rays according to the following scale: Leukemic tissues, mycosis, eczema, sarcoma, carcinoma, lupus, tubercular ulcers, lipoma, myoma, and fibroma. The physiologic effect, as Von Norden expresses it, results in an internal electric ionization of the tissues. So far, no danger from the application of small doses of emanation have been observed; large doses are productive of destructive results. From a therapeutic point of view, innumerable diseases have been subjected to the effects of radium emanation. In due time it was found that specific results were obtained in certain forms of skin diseases, including neoplasms, in disturbances of metabolism, especially gout, and in painful alterations of the nervous system, *i.e.* neuralgia, locomotor ataxia, etc.

METHODS OF APPLICATION OF RADIO-ACTIVE SUBSTANCES.

Of the various radio-active substances, radium and mesothorium in numerous modifications are the principal elements employed therapeutically at present. The salts of these elements may be preserved in small metal, ebonite, or other suitable containers, covered by a filter usually consisting of a thin sheet of mica or aluminum. Various-shaped tubes, boxes, sounds, compresses, etc., are available so as to conform to the various types of body surfaces and cavities. If a radio-active substance is to be administered in the form of gas emanation, it is preferably carried out in an inhalatorium. Many of the well-known sanatoriums of Europe and the United States are at present provided with such radium emanation inhalatoriums. For the internal administration of radium emanation, water artificially charged with radio-active gases or with the dissolved salts, or natural springs containing radio-active substances are chiefly employed. For the charging of water with radium emanation, various methods are in vogue. The water may be charged by direct solution of a soluble radium salt, *i.e.* the bromid or the chlorid, or by submerging a very finely powdered insoluble salt, *i.e.* the sulfate. To present as large a surface as possible, the insoluble radium salts are employed in various modifications. They may be precipitated upon asbestos in a porous cell, they may be mixed with charcoal and formed into slabs, they may be mixed with cement and formed into balls, and lastly, they may be mixed with clay and fired. Most of these processes of subdividing radium salts are protected by patents. The "life" of these various modifications of radio-activity is usually very prolonged; the fireclay rods, it is estimated, may be used seventeen hundred years, and still have one-half of their radium content available.

For many centuries it has been known that the water of certain mineral spas is endowed with peculiar therapeutic qualities which cannot be attributed to the organic or inorganic constituents of these spas. It was found that certain artificially compounded mineral waters prepared according to formulas obtained from most carefully conducted analyses will not produce the same therapeutic effects as the water employed at the respective spas. While climatic conditions, change of environment, and similar factors no doubt play an important rôle in balneologic therapeutics, the fact remains, however, that the water of certain spas, when drunk at the springs, exercises some peculiar beneficial effect on the sick. To explain these curious properties, folk-lore has endowed certain springs with mystic spirits, the "Brunnengeist," the "spirit of the spring," as it has been appropriately designated in bygone days by the Germans. Soon after the emanation of radium had become an established fact, investigation was carried on in the hope of finding similar possibilities possessed by the various spas, and it was discovered that many of the famous watering resorts owe their renown in a large measure to the presence of radium emanation in their spas. The more important watering resorts of Europe containing emanation are: Bath, Baden-Baden, Gastein, Landeck, Joachimstal, etc.

THE APPLICATION OF RADIO-ACTIVE SUBSTANCES IN DENTISTRY.

Radium was introduced into dental therapeutics in 1912, by M. Levy of Berlin. Aside from his numerous publications, the writings of Walkhoff, Trauner, Mamlok, Léger-Dorez, Warnekros, and many others are available to the inquiring student. According to Levy, the following oral diseases have been subjected to radium emanation: Psoriasis of the oral mucous membrane, pyorrhea alveolaris, loosening of the teeth without the presence of pus, marginal gingivitis, leukoplakia, chronic aphthæ, fistulas, and ulcerative stomatitis caused by gout. The therapeutic application of radio-active substances about the mouth may be accomplished by utilizing the following methods and means: The drink cure, mouth-washes, tooth-pastes, compresses, injections, irrigation, inhalation, and finally, variable combinations of these procedures. The drink cure and the application of the mouth-washes are probably the two most prominent means of utilizing radium emanation for such purposes; the other enumerated methods are of questionable value. The technique of the various methods is comparatively simple. As a drink cure, Levy recommends the following procedure: Water charged with emanation, or water containing a specific quantity of a soluble radium salt may be used. The radium content should correspond to about a thousand to 3000 Mache units per day, although higher concentrations have been used with no deleterious side-effects. Every twenty to thirty minutes during the two or three hours following the three main meals, a small quantity of the charged water should be taken. The object is to furnish the organism with small quantities of the products of decomposition of radium, which are slowly absorbed. In due time they reach the blood current and finally are eliminated, primarily through the lungs and to a less extent by the urine, the skin, perspiration, and the saliva. Within twenty minutes after partaking of 600 Mache units, radium emanation has been shown to be present in the saliva. As a gargle, Trauner recommends the following procedure: A quart of water containing about 375 Mache units forms the basis of the mouth-wash. Of this solution, the patient uses two glassfuls (about 10 fluid-ounces each) per day as a mouth-wash, observing the following precautions: Every dose of the solution—which should not be too large, so as to find ample room in the mouth—has to be worked forcibly between the cheeks and the teeth for at least a minute and a half, so as to de-emanize the water. The water should then be removed from the mouth slowly and in a thin stream. The emanation will separate from the water and precipitate itself upon the mucous surfaces of the mouth. From twenty to thirty minutes are necessary to use up the content of a glassful of the solution. After the gargling, the patient should not eat or drink, and if possible should not speak, for at least one or better two hours, to retain the gaseous emanation in the mouth. With this simple procedure Trauner claims to have obtained most remarkable results. The formation of pus and subjective symptoms are checked in two or three days, remaining only, and to a milder degree, upon those places where accumulations of calcarious deposits are present. The tartar has to be removed thoroughly, and at future sittings careful examination has to be made for remnants of tartar, which represent a constant and sure source of pus production. Large-sized pockets are successfully treated by syringing with two cubic centimeters of a concentrated emanation solution.

If one wishes to obtain a comprehensive view of the present state of radium emanation in therapeutics, one is at once confronted with the enormous mass of accumulated literature. Within the last three years, aside from numerous exhaustive treatises, more than a thousand articles have appeared in current professional journals. The early glowing reports of 1912 and 1913, which in many

instances bordered on therapeutic hysteria, fortunately have been superseded by the more sane and unbiased observations of broadminded practitioners. Radium treatment is slowly settling down to the specific phase in medical practice to which undoubtedly it is entitled. During the year's sojourn in Europe (1913–14), the writer had the opportunity to familiarize himself with the present status of the application of radio-active substances as employed in the alleviation of dental diseases. The two dental institutes which have primarily investigated radium therapy are the two institutes of the University of Berlin and of Graz. At the Berlin Institute, Zahnarzt Mamlok, and at Graz Professor Trauner, have carried out extensive investigations on the subject, and both gentlemen have been most courteous in furnishing patients and offering their experience to the writer, which he hereby gratefully acknowledges. Parenthetically, it may be remarked that both gentlemen are close observers and sound in their judgment. Trauner is still an ardent advocate of radium therapy, and he is convinced that its influence is very marked in the treatment of inflammatory conditions of the oral mucous membrane. On the other hand, Mamlok is rather skeptical at present, and he sums up his experience by stating that the prolonged utilization of water charged with radium emanation has a tendency to lower the virulence of the ordinary pus bacteria usually found in inflammatory conditions of the mouth. He has obtained good results in the treatment of pyorrhea alveolaris by combining the following procedures: Careful removal of all tartar deposits, establishing perfect occlusion, splinting of loose teeth, application of radio-active substances, and rigid oral hygiene. It was observed that patients who suffered with pain in connection with their dental ailments were unanimous in their statements that washing with radium-charged water relieved this condition, like "magic," as they expressed it. Of the many other benefits claimed by dental practitioners and patients alike relative to the therapeutic effects of radium mouth-washes, pastes, etc., the writer is extremely skeptical. He has not been able to observe any special value derived from such procedures. In a number of counter-tests, in which a warm physiologic salt solution was substituted for the radium preparations, the comparative results obtained were equally as good. At the meeting of the German National Dental Society, the Central Verein, held in May 1913, the enthusiasm relative to radium therapy probably had reached its zenith. It had leaped up in sky-rocket fashion, and, following the law of gravitation, came down at an equally rapid rate. At the 1914 meeting of the same society, aside from a few derogatory remarks, one noticed a conspicuous absence of discussion on this supposed panacea for all bodily ills. As the writer has stated above, radium seems to be entitled to a legitimate place in general therapeutics. So far as its application in the treatment of oral diseases, especially pyorrhea alveolaris, is concerned—for which it has received the bulk of its indorsement—at present no positive results can be recorded.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

NITROUS OXID ANALGESIA IN GENERAL DENTAL PRACTICE.

By E. B. PRENTISS, D.D.S., New York, N. Y.

(Report of the Correspondent, presented to the Dental Society of the State of New York at its annual meeting, Albany, May 14, 1914.)

FOR a great many years, nitrous oxid has been employed as an anesthetic in the extraction of teeth. For such operations it has justly earned a great reputation, because of the comparative ease of its administration as well as the lack of any ill-effects upon the patient. It has been known as the safest of all general anesthetics. The general surgeon has made more or less frequent use of it for minor operations, especially short ones; also, during more recent years, he has come to use it quite generally as an easier, quicker, and more pleasant method of beginning the anesthesia when ether is to be used in continuance during long operations.

During the last five or more years the attention of the dental profession has been called to the possibilities of nitrous oxid combined with oxygen as a means of producing a condition of analgesia, which may be continued for a considerable period of time, sufficient, at least, for performing all ordinary operations about the mouth and teeth.

THE OPERATOR'S RESPONSIBILITY.

Very little seems to be known about its action or effect upon patients by the average dentist, and I think the majority of us feel that it has not had a sufficient test to warrant us in assuming the added responsibility for the safety of the patient which its use imposes upon us. This responsibility seems to be considerably out of proportion to the importance of the average dental operation in which its use is indicated.

Within the past two or three years, especially, there has been great activity on the part of the manufacturers of different machines. I feel that nearly all, if not all the knowledge which most dentists have of nitrous oxid and oxygen has come through the *so-called* "Special Courses in Anesthesia and Analgesia" conducted by men who are paid to advertise these machines. These men, being graduated dentists and having spent a great deal of time in perfecting themselves in administering nitrous oxid, have been able to convince a good many practitioners throughout the country that it is a "very simple matter for anyone to become proficient in its use after a few trials."

A comparatively few have become proficient in its use, and have found it of great benefit in their practices. To hundreds of others, however, it has undoubtedly been a disappointment, while in the hands of a great many other operators, it is a source of great danger to the patients who intrust their lives to their care. In conducting my investigation on this subject, I have carefully avoided obtaining information from anyone who is known to be interested personally in the manufacture or selling of any apparatus.

INQUIRIES ADDRESSED TO DENTISTS AND PHYSICIANS.

I have tried to conduct this inquiry along purely scientific and professional lines, and hope that this report will be entirely free from all commercial influences.

Two forms of letters have been sent, one to dentists and another to physicians or surgeons. The following is a copy of the letter sent to dentists:

My dear Doctor,—As Correspondent of the New York State Dental Society, I am seeking information upon the subject of "Nitrous Oxid Analgesia in its Relation to General Dental Operations."

Will you be kind enough to state your personal opinion, if possible based upon clinical experience, regarding the following questions:

(1) In about what proportion of your operations do you find nitrous oxid analgesia of benefit either to your patient, yourself, or both?

(2) Do you find that the present-day equipment is perfected to such a degree that it incurs no great inconvenience to the operator in his work? And is an assistant required to handle the apparatus?

(3) Do you consider that the dentist should take any special course in anesthesia in order to qualify for the safe administration of nitrous oxid in operations of considerable duration?

(4) In what proportion of cases have your patients experienced bad effects from its use?

(5) Considering the subject from all possible angles, is it your opinion that nitrous oxid should form a part of every dentist's equipment?

An early reply will be appreciated, in order that I may incorporate it in my report to be given at the annual meeting of the State Society in May.

Thanking you in advance for any information you may be able to give,

Very truly yours.

The letter sent to physicians was the same, except the questions, which were as follows:

(1) In administering nitrous oxid and oxygen for continued analgesia as required in ordinary dental operations, what are the probable or possible ill effects, if any, upon the system?

(2) Do you consider that the dentist should take any special course in anesthesia in order to qualify for the safe administration of nitrous oxid in operations of considerable duration?

(3) Considering the subject from all possible angles, is it your opinion that nitrous oxid analgesia would be a safe adjunct to the average dental operation?

The replies received, except in two or three instances, were brief. They are as follows:

REPLIES FROM DENTISTS, FAVORABLE AND UNFAVORABLE.

(1) Dr. T. B. Hartzell, Minneapolis, Minn.:

My dear Dr. Prentiss,—In answer to your first question, would say that I find nitrous oxid analgesia of advantage in all minor operations upon the teeth where the matter of avoiding pain is a consideration.

In reply to question No. 2, would say that my answer to that question depends on the character of apparatus used.

There are three types of apparatus in use for the administration of nitrous oxid: The first is one in which there is no attempt to control the dosage, in which the patient is given full inhalations of nitrous oxid until he reaches the condition of anesthesia; then there is nothing to be done but to cease administering and operate. That is a very old type of apparatus.

The next type of apparatus seeks to control the flow and mixture of the gases, and in this type the manufacturers usually provide two bags, each holding about a gallon, oxygen being discharged into one and nitrous oxid into the other, and allowed to mix according to the symptomatic needs of the patient and the judgment of the anesthetist.

The gases in this type of apparatus, coming in some cases directly from the cylinders to the bags, are held in moderate restraint by pressure regulators, which roughly indicate the amount of gas flowing. Of this type of apparatus there are several on the market, notably the Teter, Clark, McKesson, and others.

The third type of apparatus, the most perfect of all, is so devised that the gases can be administered in known quantities and the percentage of each gas accurately controlled, and this control is so perfect that the operator can, after arranging his anesthetizing machine to deliver a certain mixture of nitrous oxid and oxygen, depend on that mixture remaining constant, thus giving an even, satisfactory anesthesia in which it is impossible to overdose the patient, because the machine will not permit of the patient's receiving more than a certain accurate flow of the combined gases. In this type an assistant is not required to handle the apparatus, and any change in the proportion of the gases flowing is indicated by delicate gages, which instantly record that fact in full view of the anesthetist.

In answer to your third question, would say that I do consider that everyone who at-

tempts the matter of general anesthesia should have special instruction in general anesthesia from a man who thoroughly understands the science of anesthesia; *not from some traveling salesman* who is out to sell the apparatus.

In reply to the fourth question, would say that when the gases are accurately proportioned and carefully administered there are no bad effects, if the individual to whom the gas is being administered has been properly prepared for the anesthetic. If, on the contrary, the anesthetic is administered immediately after eating, there will be a certain amount of nausea and depression in many cases, and this is just as true of nitrous oxid and oxygen as of ether, chloroform, or any other anesthetic. Proper time and condition of the administration is important in anesthesia as well as analgesia. The digestive processes are inhibited under general anesthesia, and if the stomach contains a mass of partially digested foods, fermentation and nausea will ensue under any anesthetic.

There is still another factor in the preparation of the patient which is vastly important in any type of anesthesia, whether it be produced by gas, ether, or chloroform; this is the existence of fear or anger on the part of the individual being anesthetized. During fear or anger, the physiological action of certain glands of the body produces substances which in exaggerated amounts vastly increase the danger of the anesthetic to the individual.

In regard to the last question, would answer, No. The nitrous oxid equipment should form a part of every man's equipment who is capable of using it, and who has work that demands its use. I would like every dentist to equip himself with a microscope, but how many dentists do you suppose would use a microscope, if they had one? I will say this, however, that every dentist who desires to practice painless dentistry and who will train himself in anesthetic matters will be given increased comfort and so will his patient, if he does make such apparatus a part of his equipment.

Very cordially yours.

(2) Dr. Chas. F. Ash, New York City.

My dear Dr. Prentiss,—Replying to yours of March 28th, in answer would say:

(1) I suppose I use nitrous oxid in 20 per cent. of my cases.

(2) Equipment is not perfected to a degree where it incurs no inconvenience to the operator, and I believe the equipment is capable of much further development; I believe also that an assistant should be a graduate nurse, and that such an assistant is absolutely indispensable for satisfactory results.

(3) I believe any person administering nitrous oxid or any other anesthetic should make a special study of anesthesia in order to qualify for its safe administration.

(4) I believe I have not seen any bad effects from the use of nitrous oxid. I have seen but one patient who had any disagreeable symptoms after the operation, but that was directly attributable to other causes and not to nitrous oxid.

(5) In answer to question No. 5, I am not prepared to say that it should form a part of every dentist's equipment by any means. I believe that nitrous oxid, while satisfactory in the hands of some people, will be more or less unsafe in the hands of many others.

Very truly yours.

(3) Dr. J. R. Hasbrouck, New York City.

My dear Doctor,—I have been most derelict in disregarding an immediate reply to your letter, and apologize for my rudeness.

Herewith is expressed my observation based upon five years' experience with $N_2O + O$.

In ninety per cent. of cases it ameliorates the unpleasantness of painful operations both to patients and myself.

The modern apparatus seems to me to be faultless, but the necessary efficiency can only be realized when an assistant is employed who is sensitive, alert, and possesses a physiologic and psychic understanding. I consider the services of a qualified assistant absolutely necessary both for the safety and sequential administration of the anesthetic, whether it be carried beyond analgesia or not.

In cases of prolonged anesthesia, I consider it most presumptuous and hazardous for anyone to administer $N_2O + O$ unless a special training and experience has been had.

I can report no conspicuous ill effect save an occasional slight headache or lassitude.

In justice to one's patients and self, I deem $N_2O + O$ a most necessary adjunct in the practice of dentistry, but its intelligent and conservative use should be observed.

Appreciating the honor of your inquiry, I am,

Most faithfully.

(4) Dr. Weston A. Price, Cleveland, Ohio.

My dear Dr. Prentiss,—Your communication of the 28th is received, with its list

of questions relative to nitrous oxid analgesia. Without repeating the questions, the answers I would give would be as follows:

(1) Less than ten per cent.

(2) (*a*) Present-day equipment is very satisfactory; (*b*) an assistant is not required to handle the apparatus, but should always be present.

(3) Yes, if he has not had experience.

(4) Probably twenty-five per cent. of cases are short of satisfactory.

(5) No, not if he is skilful in using other available methods. A great help for a few patients, however.

In regard to your postscript, I would recommend that you write to Dr. George N. Wasser, New England Bldg., who is an enthusiast in its behalf, but not interested, so far as I know, in any machine.

With best wishes, I am,

Yours very sincerely.

(5) Dr. George T. Gregg, Pittsburgh, Pa.

(1) About 2/3, but am using less nitrous oxid; using conductive anesthesia instead.

(2) The apparatus could be improved, especially inhalers. An assistant is essential.

(3) Should take a course.

(4) About 10 per cent.

(5) $N_2O + O$ should be in any office equipment, but I think conductive anesthesia is going to replace it to a very great extent.

(6) Dr. J. D. Hertz, Stamford, Conn.

My dear Dr. Prentiss,—In answer to your inquiries of March 28th, regarding the use of nitrous oxid, I shall be very glad to give you whatever information I can as to my use of same. We have a record of over 700 cases since November 1, 1912; previous to that time we kept no record.

In answer to question No. 1, I would say that I find nitrous oxid analgesia of benefit in at least one-third of my cases, and most decidedly think it of benefit to my patients and myself.

(2) In the great majority of cases I find the equipment of very little inconvenience, and an assistant is not required to handle the machine, as it is seldom that it needs much attention, if it is once set at the analgesic point. But I would not think of using nitrous oxid or any other anesthetic or analgesic without the help of an assistant.

(3) While I think that all the information the beginner can get in the use of anesthesia and analgesia will help him in its administration, on the other hand no amount of theory will give him that proficiency which he can gain only by experience.

(4) Our record shows 21 cases of vomiting and 12 that did not feel normal for from one to several days, and we have had about half a dozen cases that we could not handle at all under either analgesia or anesthesia.

(5) At the present time I am very partial to nitrous oxid, and think that analgesia and anesthesia should be practiced in every office for the alleviation of a great deal of pain that it is otherwise impossible to relieve.

Trusting that the above may be of some slight service to you, I beg to remain,

Yours very truly.

(7) Dr. Geo. N. Wasser, Cleveland, Ohio.

My dear Doctor,—In answer to your questions on "Nitrous Oxid Analgesia in Its Relation to General Dental Operations," contained in your letter of March 28th, would say:

(1) Over 75 per cent.

(2) (*a*) Yes. (*b*) Not necessary, but advisable.

(3) Not necessary for analgesia, but advisable for anesthesia.

(4) Have been giving it over five years, and have never had an unfavorable symptom, and but four cases of nausea.

(5) The dentist who does not make use of nitrous oxid and oxygen is missing the greatest boon that has come to the profession, with the possible exception of the casting process. It gives me great pleasure to answer these few questions, as it gives me an opportunity to express my appreciation of nitrous oxid and oxygen, and tell in part of the beneficial results to both patient and operator.

Sincerely.

The following letter coincides so nearly with my own view of the matter and sounds such a timely warning that I have placed it at the end, where it will leave a lasting impression:

(8) Dr. Henry W. Gillett, New York, N. Y.

Dear Dr. Prentiss,—The following is in reply to your questions concerning nitrous oxid analgesia:

(2) (*a*) No. (*b*) Yes.

(3) Yes.

(5) No, not in its present stage of development.

I have not made enough use of the process to answer questions Nos. 1 and 4.

In spite of the safety of nitrous oxid as an anesthetic, I remain unconvinced that it is right for any operator to assume, as regular practice, the responsibility for the management of an anesthetic, and at the same time carry on an operation that ordinarily requires all his faculties to bring to a successful issue.

Analgesia may at any moment become anesthesia; in fact, the advocates of the practice state that they frequently induce anesthesia at difficult or critical moments.

It is my belief that the fact that an operator has at hand a trained attendant or trained nurse will not provide legal protection for him in case of unfortunate results with an anesthetic used as recommended by the advocates of nitrous oxid analgesia apparatus. If his legal obligations are not safeguarded, then his moral obligations are surely in a precarious situation.

It is a well-recognized principle in surgical practice that the administration of anesthetics and surgical operations are not to be carried on by the surgeon at one and the same time. It is also a recognized principle that the anesthetist should be competent to care for and safeguard the life of his patient in any emergency arising from the use of the anesthetic. I feel that these two points have been minimized by the commercial advocates of nitrous oxid analgesia.

It is to be borne in mind that the present interest in the practice is chiefly commercial —that it is a part of a skilfully organized and sustained selling propaganda on the part of people interested solely in the financial returns, and that, of the thousands of analgesia outfits sold to the profession, not twenty per cent. are in practical use.

It is an unfortunate fact that it seems possible for any manufacturer to command the services of professional promoters, equipped with a high degree of skill and efficiency in the practice of almost any special process, who will gravely assure the profession that duplication of the results—which they have spent years in training themselves to demonstrate so easily and perfectly—is readily possible for any dentist of "ordinary skill." No matter how complex the process, it is only necessary to take a course with the demonstrator at $50 per course, and—presto! throngs of grateful patients and eager competition for a place on the waiting-list!

I believe the ultimate outcome of this commercial effort will be to leave the profession hundreds of thousands of dollars poorer with only some handsome junk to show for it, and to again demonstrate that the professional man, who sells his services to the supply houses as a promoter, either openly or secretly, should be barred from all professional association.

In writing this I do not forget that a few men have given the requisite study to equip themselves for this work, and I realize that they are giving good service. Neither can I forget that, regardless of their efficiency and knowledge, if they assume responsibility for both anesthetic and operation, they are violating recognized surgical standards. Under these conditions, if by any mischance a fatal accident occurs as a result, the expert testimony of the professional anesthetists of the highest standing, so vital to their defense, is likely to be highly critical if not flatly condemnatory.

Yours very truly.

REPLIES FROM PHYSICIANS.

The following replies were received from physicians and surgeons:

(1) Dr. Edward M. Foote, New York.

Dear Dr. Prentiss,—You can find my views on the subject of nitrous oxid gas in the last edition of my book on "Minor Surgery," in which there is a chapter on the different anesthetics.

Answering your questions specifically, I do not think there are any probable ill effects from its use in dental operations, subsequent to the period of the anesthesia. There is, however, a certain amount of danger attendant upon its use, and for this reason, in answer to question No. 2, I should say positively, Yes.

I should say in answer to question No. 3, Yes, if the gas is properly administered by a competent individual.

Incidentally, one might remark that taking a course in medicine does not qualify one to give an anesthetic properly. If such were the case, the hospital interne would never have gained his unenviable reputation for poor anesthesia.

Sincerely yours.

(2) Dr. Alexander Lambert, New York City.

Dear Sir,—I am in receipt of your letter of April 2d asking me to furnish certain information as to "Nitrous Oxid Analgesia in its Relation to General Operations."

Being a medical man, I am not competent to answer all your questions, for they come

under the head of surgical experience and of experience of men who give the anesthetic. There is one point, however, in the second question, as to whether a dentist should take a special course in anesthesia in order to qualify for the safe administration of nitrous oxid. I think there is no question whatever, in answer to this, that he should take such a course. The mere fact that the greater the ignorance the greater the self-confidence in giving the anesthesic is not conducive to the greatest safety to the patient. I have seen a great deal of anesthetics given, both before there were special anesthetists in this city and since then, and I have noticed an enormous difference in the resulting effect upon the patients since anesthetists have come into vogue. There have been less accidents, the patients have recovered more quickly, they have needed less anesthesia, and in all ways it has been better for both patient and operator.

Yours truly.

(3) Dr. Robert T. Morris, New York City.

My dear Doctor,—Answering your letter of April 2d: Dr. R. C. Coburn, of Broadway and 86th st., is perhaps our best authority on the subject of nitrous oxid and oxygen anesthesia. Answering your questions, however:

(1) The chief danger appears to consist in the patient's coming out from under the influence—while we are at work—sufficiently to suffer from the effects of the strong stimulus or shock being sent into the centers of consciousness from the field of operation.

(2) I should consider it by all means desirable for the dentist to take a special course in anesthesia, in order to qualify for the safe administration of nitrous oxid or its combination anesthetics.

(3) Nitrous oxid anesthesia is perhaps the safest adjunct among anesthetics for the average dental operation.

Yours truly.

(4) Dr. Karl Connell, New York City, assistant surgeon, Roosevelt Hospital.

My dear Doctor,—In reply to your questions, it is my belief:

(1) That continued analgesia will have no detrimental after-effects except occasional headache and nausea, providing that the gases be pure, and nitrous acid poisoning be avoided.

(2) Nitrous oxid for prolonged operations is far more dangerous in unskilled hands than ether and chloroform; high training is essential.

(3) Nitrous oxid analgesia, with a percentage of from 8 to 20 per cent. oxygen and allowing some dilution with air, will be a safe adjunct for dental practice. At present, proper control of amount and percentage is not obtainable except by the experienced administrator.

Sincerely yours.

(5) Dr. R. C. Coburn, New York City (of whom Dr. Morris speaks).

Dear Dr. Prentiss,—Replying to your letter of the 6th inst., I would make the following answers to your questions:

(1) The *probable* ill-effects resulting from nitrous oxid and oxygen in continued analgesia, if the blood is kept well oxygenated, are nearly *nil.* There are, however, some *possible* ill-effects, especially in those suffering from cardiac disease and arterio-sclerosis. Cyanosis increases the blood pressure, thereby throwing extra work upon the heart. Any increase in blood pressure, in some subjects, renders cerebral hemorrhage more probable, and, by throwing extra work upon the heart, functional failure may be induced. Patients suffering from advanced stages of such diseases, however, are not ordinarily dental subjects. Very much, if not all, depends upon the skill with which nitrous oxid and oxygen is administered. Finally, the aspiration of vomited material must not be wholly disregarded.

(2) and (3) Yes.

Sincerely yours.

The last two gentlemen, Drs. Connell and Coburn, are especially qualified to speak on this subject, having had a great deal of experience with anesthetics of various kinds, and lately having been doing a great deal of special work with nitrous oxid and oxygen.

SUMMARY.

I wish to take this opportunity to thank those who have so willingly and thoughtfully replied to the letter of inquiry sent. Judging from the proportion of answers received, this report is the most successful of any during the three years in which I have served as your Correspondent. Of eleven sent to dentists, eight replies were received, and

of eight letters sent to physicians, five replies were returned.

The letter from Dr. Hartzell is especially valuable, because of the detailed information it gives. There seems to be such a difference of opinion in regard to most of the questions that it would be difficult to attempt to condense them in such a manner as to draw any definite conclusion.

However, as nearly as I can judge from careful perusal, the majority seem to think that $N_2O + O$ is of benefit in quite a number of the very painful operations; that a capable assistant should be at hand if not actually needed; that special training is absolutely necessary for its safe administration; that ill-effects are produced in about 10 per cent. of the cases operated on, and that the apparatus should be in the offices of only those who are perfectly competent to use it intelligently. I would call special attention to the statement of Dr. Karl Connell, assistant surgeon at Roosevelt Hospital, New York, a man who has made a very special study of all anesthetics. He says that *"$N_2O + O$ in unskilled hands is more dangerous than either ether or chloroform."*

There are a few points, as yet not mentioned in the report, which I hope the discussion will bring out.

One, which it seems to me is very important, is the liability of cutting beyond the safety point while the patient is under analgesia, thus bringing about the subsequent death of the pulp.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

ANESTHESIA AND ITS RELATION TO OPERATIVE DENTISTRY.

By W. D. DELONG, D.D.S., Reading, Pa.

(Read before the Pennsylvania State Dental Society, at its annual meeting, Philadelphia, Pa., June 30, 1914.)

BY virtue of discovery, Anesthesia is the historical property of the dental profession. The victory over prejudice, doubt, and opposition, which followed the introduction of this great boon to patients who had to submit to surgical operations, whether of a major or minor character, was obtained only after a hard-fought battle. In this fight the dental profession played no inconsiderable part. Time must not dim the glory of this discovery and conquest, nor detract from the honor of the discoverer and warriors. Horace Wells discovered surgical anesthesia. Morton discovered the anesthetic properties of sulfuric ether. Both these men were dentists. Their names should be forever enshrined upon the walls of the Hall of Fame.

TARDINESS OF THE DENTAL PROFESSION TO ADOPT ANESTHESIA.

Until the advent of analgesia, *i.e.* that condition in which the sense of pain is either partly or wholly obliterated while consciousness is retained, dentists, with comparatively few exceptions, did not avail themselves of the great service anesthetic agents are capable of rendering to patients.

In the past, many members of our profession had, and probably at present more still have, an aversion to the administration of anesthetics so as to produce complete anesthesia. This aversion had a twofold tendency—to create a class of specialists who became skilled in the administration of these agents, and second, to drive this part of practice

into the hands of advertisers and charlatans. The former effect of this aversion is a laudable one, while the latter is no small factor in the apparently large "business" done by the dental parlors and dental institutes of the country.

Nitrous oxid outfits, until recently, were found in relatively few dental offices, or, if installed, were shortly afterward discarded. Ether and chloroform were seldom administered by the dentist. For the extraction of teeth and an occasional minor operation in the oral cavity, where anesthesia was decided upon and the case was not sent to a specialist, a physician was called—and this is still the case—to administer the anesthetic.

Has this practice created and fostered the impression so prevalent in the public mind, and maybe in the medical mind as well, that the dentist is not as capable, by reason of lack of training and inexperience, as his brother, the medical practitioner, safely to induce anesthesia? Moreover, may I ask, Is there truth in this opinion which the public so largely entertains? Not everyone can be a skilled anesthetist. But surely there ought to be in every community one or more skilled dental anesthetists who could be called in case of necessity.

SKILL IN THE ADMINISTRATION OF ANESTHESIA A PARAMOUNT REQUISITE.

The introduction of the mixture of nitrous oxid and oxygen for the induction of anesthesia and analgesia in operative dental practice seems to have revived the interest of the dental profession in no small degree. According to a canvas of two hundred dental offices, over 37 per cent. are equipped with nitrous oxid outfits of the later models for the administration of nitrous oxid and oxygen combined. Manufacturers, aided by numerous members of the profession, are vying with each other in improving and perfecting apparatus, each manufacturer making great claims as to the superiority of his make of machine. We can rest satisfied that the ingenuity of dentists and manufacturers will sooner or later, and soon at the latest, produce the perfected machine; but we must not forget that no machine will ever take the place of the man, the operator, the anesthetist. Let not the perfection of the apparatus replace for one moment the necessary knowledge and skill. Sight and hearing, analysis, judgment, decision, and action enter into every act of inducing anesthesia. No inanimate object, however ingenious and perfect, can possess these functions. Anesthesia is no plaything. The *Medical Times,* a few years ago, said in an editorial: "The reason why the patient so rarely goes beyond the borderline lies not so much in the agent employed as in the skill of the experienced anesthetizer, who knows the properties of the drug he uses; who, after a thorough examination, has taken all precautions, who foresees all possible accidents; who will not trust to luck; and who remains vigilant throughout, and until the patient returns to consciousness." These requirements should not make the dentist shrink from the use of anesthetics, but be a stimulus to so inform and fit himself that he can take up the practice with confidence and skill.

INDICATIONS FOR NITROUS OXID AND OXYGEN ANESTHESIA.

While ether and chloroform have frequently been employed for difficult extractions and other operations requiring more than one or two minutes, the combination of nitrous oxid and oxygen administered by the nasal inhaler is less frequently used. What follows refers to nitrous oxid and oxygen anesthesia only.

Complete anesthesia is of great value in several operations other than extraction. In opening up a pulp chamber, when acute pericementitis is present—an operation which almost invariably is excruciatingly painful—most happy results are obtained, and the patient's blessing is bestowed upon the operator's head as part of the remuneration. In these cases, the patient after having suffered intensely for several hours, and

sometimes a whole night, is in a condition of fever and lowered vitality, if not slight shock. To submit him to the painful ordeal of drilling into a tooth so sore that the merest touch is almost unbearable, might be termed cruel, when in a few moments this operation can be done painlessly under the influence of nitrous oxid and oxygen anesthesia.

It is good surgery to thoroughly curet an infected alveolus immediately after extraction. It is remarkable that so little general infection follows the extraction of septic roots. Occasionally, however, we see no little trouble, local and systemic, as the result of an extension of an infection, or a reinfection; curetment under complete anesthesia will remove the foci of infection, and healthy granulation will follow. The opening of alveolar abscesses and the scaling of the roots of teeth affected with pericemental abscesses are other conditions where general anesthesia may be indicated, and where thorough work can be done by its employment. It is not the administration of nitrous oxid and oxygen for inducing complete anesthesia, however, that has caused the profession to receive the introduction of this combination so extensively and so enthusiastically in many quarters.

THE BENEFITS OF ANALGESIA.

Analgesia is a word of common occurrence in the dental literature of the last few years. Many means and methods have been employed in the past to relieve pain in cavity preparation, with but indifferent success. We all meet with cases where it is practically impossible to prepare a cavity according to our ideals without inflicting severe pain and the production of shock to the patient. Fortunately, in analgesia we have a means of combating both these effects in our operations upon patients of this type. The practitioner who has familiarized himself with this method of practice no longer dreads the appointments with this class of sufferers. "No more dread for the dental chair now!" was the exclamation of one of the writer's patients, after her teeth had been filled—while, before, temporizing only had been possible. This, I believe, is the experience of all users of the analgesic method.

Its benefits need argumentation no longer. It is the method *par excellence* in all cases where pain-elimination is indicated. It can be safely stated that when the operator has the confidence of the patient, and when the gases are properly administered, this condition of painlessness can be produced quickly and surely in practically every case with little or no bad after-effects.

DISCRETION ADVOCATED IN THE USE OF ANALGESIA.

In what per cent. of cases is the use of analgesia indicated in operative work? Here a great difference of opinion exists among practitioners. Some men recommend its employment in nearly all cases. In my own practice it is resorted to only occasionally, because I am not in harmony with what seems to be an indiscriminate use of the gases. Is the elimination of all pain in our dental operations desirable? May we not consider pain as a normal physiologic function serving a useful purpose even in the operation of preparing a cavity in a carious tooth? I quote from Dr. DeFord's book on "General Anesthetics in Dentistry" the following paragraph: "Bold in other directions, commendably progressive in all that relates to manipulative ability and artistic development, the dental surgeon shrinks from anesthetics. He cuts into living tissue, lacerating the nerves themselves, performing laparotomies upon the teeth, so to speak, and the anesthetic usually employed is that of witty speech or an amusing story, while the patient suffers, cringes, agonizes, almost to the state of collapse." Is this a picture common in your practice? If so, by all means employ analgesia! Much has been said about shock produced by pain inflicted during cavity preparation. It is a question, however, whether prolonged analgesia will not make a greater impression on the nerv-

ous system than the slight degree of pain which accompanies the larger number of operations upon the teeth. Therefore, just objection may be raised against the indiscriminate use of this agent.

A patient in a state of analgesia is not in a normal state. Some patients are very susceptible to the influence of the gases. It has an exhilarating effect upon them. The desire to inhale the gases grows upon them, and they ask for their administration when no painful operation is done. In such cases we should be careful not to create an appetite such as may result, because of our treatments, in other drug habits. Discrimination and discretion should be the watchwords to guide us in the use of analgesia, and we should shun the abuse of this most desirable aid in our work.

ETHICAL AND UNETHICAL PROPAGANDA FOR ANALGESIA.

A great deal of credit and gratitude is due to Hewitt, Teter, and others, for bringing the value and the method of the administration of a mixture of nitrous oxid and oxygen to the attention of the dental profession. Apparently, so the writer views it, manufacturers are making an undue and possibly harmful effort to introduce this practice into our offices, and so-called courses are being given in anesthesia and analgesia by itinerant teachers and lecturers. All of you have no doubt received circulars inviting you to take courses of instruction in the use and administration of nitrous oxid and oxygen analgesia. No valid objection can be found against this method of teaching, if it is done in a spirit of professional dignity and integrity. Some of the circulars sent out broadcast, however, savor very strongly of the commercial spirit; and this society, in the opinion of the writer, would do well to put its stamp of disapproval upon such conduct. Exaggerated claims are made, and the dollar mark seems branded upon most of the topics taught. Let us not be trapped by the transparent veil of professionalism that is intended to hide the true motive of pseudo-teachers. Increase of financial returns is the slogan with them. To receive a professional fee commensurate with the services rendered is strictly ethical. But to use a new apparatus, or a new method of practice, as a subterfuge to increase one's financial income is contemptible professional graft.

POSTGRADUATE INSTRUCTION IN ANALGESIA NEEDED.

Postgraduate instruction in the analgesic method of practice is needed, owing to the want of experience with anesthetics on the part of the majority of dentists. The relation of the dental profession to the supply houses is probably closer than any similar relation of the medical profession; yet it is hardly questionable, from a professional standpoint, whether these houses or depots are entitled to any teaching rights.

Reports have come to my notice where representatives of commercial houses not only have instructed practitioners in the use of the apparatus which they sold, but also taught them how to induce anesthesia. A week of clinical lectures in anesthesia and analgesia under the auspices of the State Society, local societies, and dental colleges in various cities of the state would supply this instruction in a manner not open to objections. Let every dental office be equipped with a gas outfit; let every dentist familiarize himself with the technique of its operation, and then apply it with intelligence, judgment, and professional honor—and our profession will have acquired a most valuable addition to its armamentarium.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

DENTAL EDUCATION.

By ALFRED OWRE, B.A., M.D., D.D.S., Minneapolis, Minn.,
DEAN OF THE COLLEGE OF DENTISTRY, UNIVERSITY OF MINNESOTA.

THE subject of dental education is not new. It has been brought to our attention so frequently that some of us would perhaps prefer a discussion of some interesting phase of dental practice, leaving the problems of the education of the dentist and management of the dental colleges to those few men now in charge of the work. It is because the schools need suggestions and help from the rank and file of the profession for the upbuilding and uplifting of the standards of dental education in this country that I present this subject at this time. There is no more vital question in all our modern complex civilization than that involved in the one word, Education. Institutions large and small, public and private, state and secular, are grappling with it as never before, and we, as dentists, if we would attain to the high professional standing in the community which we covet and which we have a right to expect, must in a large measure attain it by recruiting our ranks with graduates educated and trained in the best possible manner for their chosen field of work.

DEFINITION OF EDUCATION.

The chief object of this paper is to emphasize the value of proper education, hence a definition or meaning thereof should stand out before us throughout. Herbert Spencer defines it as follows:

"Education tells us in what way to treat the body; in what way to treat the mind; in what way to manage our affairs; in what way to bring up a family; in what way to behave as a citizen; in what way to utilize those sources of happiness which nature supplies; how to use all our faculties to the greatest advantage of ourselves and others; how to live completely. And this being the great thing needful for us to learn, is, by consequence, the great thing which education has to teach. To prepare us for complete living is the function which education has to discharge."

Our effort should be to function maximally in society; we should practice our profession as a duty toward humanity. All this involves responsibilities which extend in many directions.

The man who remains inactive in regard to state and social questions was referred to in early Greek society as harmless, but it was soon found that the adjective was inadequate, and henceforth he was referred to as useless. His life was too incomplete; he was not vitally interested in the world's improvement. What is this world and society to me? and, What am I to the world and society? are questions that every man should have before him, instead of the predominating materialistic substitute—which, simply stated, is only concerned with What can I get out of it?

BROAD INTERESTS A REQUISITE FOR EFFICIENCY.

Dentists should not consider themselves as separate from general activities. This is often an unfortunate accompaniment of specialization, and is more often true in those instances where the specialization was not preceded by a broad general education.

The present status of things should be vividly before us in whatever we do. Some knowledge of the aims and ideals of our age and of the country in which we live is not only interesting and illuminating, but is absolutely essential to

attain to the highest efficiency in our efforts in our various specialties. And it is not difficult to obtain this. We are perpetuating in slightly lesser degree pretty much the same traditions which have dominated and oppressed the world for centuries. Briefly stated, this is to ignore nature's essential demand upon us for "work," and as soon as possible to live without working, or simply to idle because somebody else works.

We strive to accumulate wealth of some kind, and there is no wealth which does not represent human labor;—ease and luxury on one side, and servitude on the other! It is either interest, rent, dividends, or some income from position without real work—and in all of this colossal material struggle we forget the human being and his rightful lot! We claim we are better off as a result of science and the application thereof, but has the result really been an increase in human welfare and happiness? It seems that the opposite is continually being emphasized; there is a wider gulf established between the profit-takers and the oppressed toilers. *We have entirely forgotten to aid humanity to do what nature seems to suggest all the time, namely, to become more and more perfect mentally and physically.*

This is our environment. Many of us never know any other aim than that which is predominant in the minds of the unthinking mass. We are not practicing dentistry because we find in it joyful expression, an ever-increasing satisfaction in realizing our ideals, and through this the greater vision of higher and higher possibilities, the infinite through the finite. It is a rather drowsy existence, which poisons our efforts, and real progress is almost hopeless. We want to be left alone in the pursuit of the lower ideals.

A nation is the sum-total expression of its individuals; no man lives alone; he contributes unconsciously to the group; so after all it is the individual character with which we are concerned. Henceforth, if the predominating aim is to accumulate wealth, we must ask how this leaven works and affects the various institutions, government, life, and activities of the people and the individual citizen. In other words, we must have a true perspective, a true understanding of what is and what is not, before we can functionate efficiently in the social structure. In this connection the educational forces are most important, especially those institutions which give the tone to the general education and atmosphere of the period.

UNIVERSITIES AS THE POTENTIAL STRONGHOLDS OF IDEALISM.

It is often said that universities establish the intellectual horizon of a given community. If they were left unhampered by the material forces of the particular community, they probably would soar to the highest star. Unfortunately, however, this ideal condition does not exist; more often we find that the prevailing or materialistic environment perpetuates its ideals through the educational avenues. This is never proclaimed, not even in a whisper. The audible remarks are chiefly in the direction of higher and greater attainments, blessings to the reaper, contentment, happiness, etc. Thus universities can be effective weapons in the propagation of ideals of whatever kind.

If education is the means by which we learn to adjust ourselves to the world, should it not be uncontaminated and untrammeled by the ideals of the materialistic and greedy elements? State universities usually reflect the ideals of the community; if the latter is democratic, we may find this ideal more or less realized, according to the sincerity, morality, and intelligence of the people. Privately endowed institutions are apt to be influenced by those who contribute to their maintenance. Nevertheless, it is to the universities that the world is most deeply indebted for its intellectual development. The universities have preserved the thought and knowledge of the past, and it is to these institutions that we look for education and guidance in all great movements. How well these institutions have accomplished their mis-

sion can best be studied by an examination of the results in the various regions—and be it also said that their influence is not only local. The universities are charged with a great public trust, hence a deep interest should be taken in them by all who are concerned with the perfection of man.

THE ULTIMATE AIM OF EDUCATION.

These institutions have stood for the higher things, although, for subtle reasons, they have not always emphasized certain items in some places. Generally, their aim is to develop normally all the faculties of man and point to the happiness which insures therefrom. An education should fit a man for complete living; he should be able to earn his own living, not be a drag to the community; furthermore he should be able to contribute something toward the perfection of the world. Again, if an education does not fit a man for the appreciation of the beautiful things of the earth, it is a failure; there must be something in the curriculum which will give him a vision, a presentiment and foretaste of higher destinies. There is nothing so sad in this world as a limited outlook; it antagonizes the very basis of organic life. It is therefore clear that a civilization which ignores that something which will carry the mind upward to the sublimest intellectual heights, as well as that fundamental principle of nature which demands work from all, must sooner or later disintegrate. The ideals of the nation must include the welfare of the largest number, a just social organization without slavery in any form; whenever this did not maintain in ancient democracies, they perished. It follows, then, that the government must not lend itself to any individual triumph which does not include the mental, moral, and physical well-being of all its people.

To realize one's self, to externalize the depths of one's soul or inner self, is the great aim of life. To the extent that the greatest number of individuals realize this, can a nation be called successful. We are indebted to the Greeks for that part of our training which developed the physical man or sound body as well as the intelligence, but it is in the Christian religion that we find duty toward our fellows emphasized; these influences have molded our educational systems rather effectively to the present day. We must also analyze the effects of modern science and industrialism. Perhaps other words could be used to bring out a discussion, such as individualism and its tendency, capitalism and its operations, etc.

PRESENT STAGNATION IN DENTISTRY.

The foregoing remarks ought to give us a perspective so that we can appreciate what may be the central conception which explains and justifies the movements of a given time in any special calling, such as dentistry. They cannot hang unsupported in the air; they must have support or root in some kind of soil, to be of permanent value in the great scheme of things. This is true in regard to dentistry. If it can prove its right to live with other useful and necessary pursuits, then it should show signs of life, like other living things, by sloughing off that which is useless and assimilating that which is new and useful; in other words, dental education must readjust itself to the ever-changing conditions of life and modern progress in general.

There has been no such response, and the present activities for better things seem somewhat stagnant, and remind us of a harmonious prelude to a future more quiet still, a sort of gentle preparation for disintegration. Of course, it must always be borne in mind that there are a few men in nearly every period of history who labor insistently for the higher things, and their work resists disintegration.

UNFITNESS OF MANY DENTAL STUDENTS.

One reason for this general stagnation is that we have had a rather spectacular dental educational performance in America for the last quarter of a century.

It has kept pace with the masquerade of other large carnal appeals to which the human family often responds. The product gives us a fair test of the work done by our schools. On discussing the product of our dental schools I know I shall be criticized. Yet it seems to me that a man who has observed carefully, with impartiality and objectivity, should give expression to his innermost thoughts on things as they are, as well as suggest some remedies. This partakes of constructive suggestion. No one can deny that the dental profession has a rather large number of unfit men in it, unfit because of a lack of special native talent or bent for this particular calling; these have drifted into dentistry as a result of improper vocational guidance or no guidance at all, save that limited vision of childhood which depicted the neighborhood dentist in all his glory. This, then, must be a defect partly chargeable to dentistry, since so many schools take all applicants, continue them whether unfit or fit, and finally graduate them. Being in the wrong occupation, the individual is of course unable to find expression, and is at war with himself; he keeps on drifting without a rudder. Life is unsatisfactory and meaningless; instead of harmony and unity we have chaos and disintegration. The suggestion of a readjustment to such a man is always resented; he has his investment, and according to the spirit of the times, it must be made to pay. To build up the future with such a man is more hopeless still; he is usually without any other vision than that supplied by the prevailing commercial atmosphere.

THE QUALITY OF MODERN DENTAL EDUCATION.

To the foregoing must be added the most important item of all, namely, the quality of the education itself. Let us pause for a few minutes to gather courage; we need it, because when it is keenly analyzed, there will be very little left of the whole business.

The early period of dental education. Organized dental education began with the first school about three-quarters of a century ago in this country; there was a desire for more systematic and effective teaching of dentistry than could be given under the direct tuitional system of office instruction. The medical schools at first refused to co-operate in this movement. It was a critical period, all told, because general education was about to pass from the old and more or less simple ways to meet newer and more complex demands; all this as a result of the ever-increasing industrial problems and material wealth. In the early days of the century our problems were not so intricate, and the education of that day was adequate for their solution.

Whatever general education was offered at that time, the special callings did not always demand very much preliminary work. Many good men were produced, however. It could not be otherwise in a new country where rapid changes took place, and where opportunities were freely open to talents waiting for expression. The educational systems of many technical schools of those days were more or less crude and somewhat superficial, owing to lack of funds and also to lack of real pedagogs, so the production of good men was probably due as much to the student's former preparation and native ability. Nevertheless, we can still respect this early period of dental education, because it was primarily a sincere effort. Our more recent development can be foreshadowed when we remember what has happened in the last forty years, socially, economically, politically, and otherwise. It was an age of intense industrial expansion, buried in material greed and exploitation; tremendous fortunes were made in brief periods of time; the earth was so easily skimmed, and often men succeeded with very superficial attainments. During this period capital was found for every enterprise conceivable, and furthermore there were no geographical limitations and gospel of humanity considered, or if there was some religion extant, it was not thoroughly applied to the trade operations of the time. It would be strange indeed if anything

could escape untarnished from such an atmosphere, but let us refer to this period as a temporary phase of our civilization—a period of strong, positive conditions with resulting negative relations—and eventually hope for readjustments to the nobler ideals of which we are capable.

Exploitation of dental schools for purely materialistic purposes. Dentistry came in for its share of exploitation. Schools were organized, factories sprang up, things (mere matter in the eyes of the exploiters and dictators) had to be marketed, and in this scramble the welfare of the people was forgotten and ignored. We were all so well fed we went to sleep, and from this sleep we have not even now half awakened. Students were enrolled and graduated by the hundreds—a college which could not boast of this quantity was not respected. Dental chairs and other equipment were produced in large quantities, and men had to be supplied to operate the equipment. Laws were modified by the dictators so that the whole should increase in value and profit. This was the chief consideration. The aim of the colleges was to attract students, and to this end as many modern weapons as possible were used. It was a rather easy field to plow; men of low commercial ideals were attracted to it more forcibly than those of spiritual power and genuine pedagogic ability. Students were regarded as impersonal things, like mere receptacles into which some superficial information was to be poured, rather than as living organisms, which having digested suitable food are stimulated into healthy activity. The whole process was unable to initiate mental activity. It was the aim of the promoters to perpetuate their ways. The subtle agencies resorted to for this nefarious business were often of a persuasive order, and the sleep of the rank and file was contributory to the perpetuation. It must also be noted, however, that the whole scheme of vocational education was somewhat chaotic in its makeup. To go into detail in regard to the curriculum would occupy much time; generally speaking, high ideals did not prevail in the large majority of dental schools, and what is worse, they do not prevail at the present time. Many of us do not appreciate the real conditions on account of nearness to the movement; we often require distance in time, to get at the real truth of things. In this instance we cannot allow this traditional principle to operate too much, because, in the meantime, a great deal of harm is and will be done to the whole population of this country as well as to others beyond our border.

Shortcomings of modern dental educational institutions. Educational institutions of the ideal modern, democratic type are endowed. Education, whether general or vocational, must be regarded as a serious thing in the life of a nation. When it degenerates into a money-making affair, an industry for profit solely, then it is unworthy of the good name which it so proudly uses, and the degree is a mockery. The scathing criticism of American dentistry in other lands must be recognized, and should be interpreted by us in a constructive sense, rather than resented with storm and indignation. It is undoubtedly true also that we can show a more perfect plant, but in the hustle and bustle of the circus-like performance of dentistry the slow and sincere reconstruction going on here and there is not noticed—it is not in the limelight. It behooves us as a profession to intensify ourselves in our investigation of what is really going on in our dental schools. It behooves us as a progressive, organized body to prove our right to such appellations, making stepping-stones of our dead selves, going on to something higher and better. However, we must not be forgetful of the few sincere and real benefactors of dentistry, and that many good all-around men have emerged from the system—but this is more like the lily growing out of the mud. And, indeed, we can acknowledge that some good shall come from the present makeshift—namely, that it shall act as a fertilizer for the growth of a better and larger body of men.

A BROADER AIM OF DENTAL EDUCATION WANTED.

There are simple duties of honesty and thoroughness in all work, and if education is the most serious item in the immortalization of a nation, we should apply our efforts to it first.

Our early educational efforts were directed toward making men of character and strength; men able to solve the problems of the day. As we have progressed, our problems have become more and more intricate, and the former education is inadequate; specialties are entered upon early, and the result has been a narrowing of the individual's outlook. The readjustment is slow, and the technical schools, dentistry included, are from the very nature of things consciously preserving the *status quo*. They are almost criminal in laying hold of anything that presents itself which will maintain them in the old routine. We must produce men capable of entering into the larger life of the community, men who can functionate maximally as citizens, because every man is responsible for the tone of the society in which he moves, and for the influence which he spreads around him, hour by hour. The future dentist must be able to live in the real interests of the day; he should have broad views upon the whole range of questions that are vital to the hour. The isolation of any man from these things make him a machine, an automaton, and an irresponsible being. This points to the fact already indicated, that a better preparation before entrance to the dental school is needed, as well as a thorough reconstruction of the curriculum and the methods of instruction. The dental teacher must be developed; state aid must be had to give financial support, as no college can adequately teach dentistry if it is obliged to work on a self-supporting basis. Let us again emphasize that perfection for man consists in the full development of all his forces, physical and intellectual, and of all his emotions, his family affections, his love of humanity and duties to his fellows, his sense of the beautiful in nature and art. And to this Dr. Babylon replies that dental schools *per se* are not concerned with anything but just the teaching of dentistry; and the same man keeps on shrinking in his dental ideals until the product is so withered that it reminds us of a huge tree gradually dying, branches falling, and the trunk yielding to decay from within and without.

DENTAL TEACHERS OF HIGHER IDEALS NEEDED.

Something can be done in all technical schools by way of establishing an atmosphere of a higher and more spiritual kind than these schools have hitherto been able to produce. We are influenced as much by the unconscious as by the conscious. But this requires a different order of teacher in the dental school than is generally employed; in many instances our dental teachers were experts in their specialties, and at the same time were totally lacking in the great human qualities, or as Bosanquet says—"A man may be a good doctor or a good painter, or a good engine-driver, and yet be a brute, a liar, or a cheat." Our first great step to remedy these many wrongs is to acknowledge the real condition, and the next genuinely to desire a betterment. We must get out of our narrow horizon, and insist that the entering portals of our profession shall give society the class of men who will perform rightfully and manfully the duties expected of them. There are too many machine men in our profession already, and these usually have no heart in their work. If they had had in all their preliminary training instilled into them the idea that we are all working together for the common good; if in the technical school this idea had prevailed in everything that was done, the product would be a class of men who would practice dentistry as a duty toward their fellows. Geo. H. Palmer says—"It is from the management and temper of a school that its formative influence proceeds." Buildings, chairs, and fountain cuspidors bound up with the capitalist

organization seeking to enlarge its dividends as the chief aim cannot produce great spiritual human beings who are interested and enthused in the common good of man. For this we need wise men of large social and altruistic selves, men who live and strive after an ideal. The teacher, the man, the leader, the organizer, who is in any way connected with our educational forces, must have the large human qualities and relationships, especially the man who works with the student daily.

It seems strange that in America, where we have really done so much for education, the vocational teacher is not yet to be had in sufficient numbers—our national neglect, of course. One of our faults is that we have been satisfied to practice dentistry as a trade, aiming largely at personal gain, and not as a profession, which is concerned with larger things. One attracts the materialist, the other the altruist. The dental teacher must in all probability be made; briefly summarized, he should teach because he loves it, should find expression in service, should intuitively adjust himself to others, and especially to the student mind. He should grow larger and wealthier year by year through contact with the spiritual possession of the world; this expands his personality and enriches his experiences. These accumulations are reinterpreted through him, and applied unconsciously to the work in hand. The ideal teacher uses the thought of the world at the bench, wherever it is; he must be a resourceful man, always ready with a chest full of great and stimulating ideals to connect with the concrete work, in order to prevent the narrowing tendency of a specialty. He should at all times watch his pupils and prevent them from becoming mere recipients of facts; he should arrange his work so that the students are continually grasping the abstract through the concrete—this enlarges the mind. We are often criticized for a lack of ethics—this must be recognized by the teacher, and unconsciously and yet concretely he can encourage the development of the moral habit. On this point I want to quote G. H. Palmer,* who emphasizes the value of human relationship as follows: "As human beings, however, pupil and teacher are akin and removed from one another merely by the degree of progress made by the elder along a common path. Here, then, the relation is one of fellowship, but a fellowship where the younger is largely dependent on the older for an understanding of what he should be. By example, friendship, and personal influence a teacher is certain to affect for good or ill every member of his school. In any account of the school as an ethical instrument, this subtlest of its moral agencies deserves careful analysis."

It is the teaching by example that is so powerful in many instances; the teacher must be instinctively good, and not a classroom sham. "When good has been clearly perceived, it never abandons the mind." I have forgotten who spoke these words, but the truth of them tenaciously remains in my memory. And we must go still farther. The teacher must look upon life as the great expression; he must look upon dentistry as a connecting link in the realization of our true selves. From the very inherent characteristics of the present system, this sort of teacher could not be produced; he simply cannot grow in the trade environment.

ESTABLISHMENT OF STATE UNIVERSITY DENTAL SCHOOLS ADVOCATED.

This means first, then, that we must demand the establishment of state university dental schools, and encourage them wherever they are. The universities need your constructive criticism and moral support; they need to be dealt with equally with other callings under state supervision. Furthermore, the situation is not hopeless in regard to the ideal teacher; we have him, but at present he is not allowed to expand or evolve

* G. H. Palmer, "The Teacher."

to ripeness. In the proper environment, plants yield the greatest fruitage. The dental teacher, like other vocational teachers, must be chosen, first, because he is efficiently equipped in his vocation, then according to his aptitude for teaching, and last, but not least, according to his cultural and spiritual attainments. The latter may come, after the first two important requirements have been met. In no case should a teacher be allowed to go on, however, without the third or last requirement. It is the larger and nobler life we want to emphasize in the future, and this is obtainable through literature and art. We have had too much of Dr. Babylon, whose life has exaggerated the importance of material conditions. It is bread and butter with Dr. Babylon. If his technique is good and brings a bellyful of food with it, that is the end of things, as far as he is concerned. But there are other aims which intensify the hopes and preferences of man, which mean greater human happiness, and all of these were not included by the pompous Dr. Babylon in his considerations. Shall we allow the latter with his pinching and materialistic views to hamper the true progress of dentistry? We have difficulties to overcome in trying to get state aid. Dr. Babylon will prevent the establishment of state schools; they yield him no direct profit. He will discourage the development of the ideal teacher, the greatest leaven of our future work. He will dictate our standards to us through legislative bodies; he will control our society expression and effectiveness by the use of many subtle weapons. All of his work will easily be seen through, when the greater spirit of the rank and file has been aroused; the latter we depend upon for constructive action.

CONCLUSION.

To sum up, it seems to me that education, the greatest and noblest of all missions, cannot be intrusted to the "industry for profit"* element. We must use our most united effort to have the state universities take over all dental education, but not on a niggardly basis. This is the first and most important step; this in itself will insure the balance, the development of the ideal dental teacher as pictured. Better methods of instruction, higher standards of entrance and fitness of students will soon come thereafter. The state can, according to its interpretation of community welfare, adjust the length and intensity of the course, and insist upon ideals and standards to be legally maintained.

We must strive eventually for a more general realization of the fact that dentistry is a great boon to mankind, and that it is intimately connected with general happiness. Furthermore, we must increase the possibilities for the man who enters our ranks to find joyful expression in dentistry.

Let me conclude by saying optimistically, and with all the enthusiasm that I possess, that it is the rank and file we depend upon. No reform ever comes from above. Dr. Babylon is the self-satisfied and contented drag to real progress; he has directed the whole movement. We have been turned from the true path of our development by the insincere pursuit of what was foreign to our temper, but our great hope is that, by sincerely desiring it, we may be restored to that dignified and exalted position which it is our birthright to hold.

* Expression used by J. H. Henderson in his book "Pay Day."

SURGICAL LESIONS DUE TO ORAL SEPSIS, AND THEIR TREATMENT.

By W. J. ROE, M.D., D.D.S., Philadelphia, Pa.

(Read before the Pennsylvania State Dental Society, at its annual meeting, Philadelphia, June 30, 1914.)

THE term *sepsis* is here used in its widest application, and includes so many surgical lesions that a textbook could be written upon the subject. It is evidently impossible, within the space allotted, to attempt a connected and detailed presentation of this subject. The title of the paper does not necessarily include the etiology, symptomatology, or diagnosis of these surgical lesions, and I shall but briefly mention them and offer some suggestions in regard to treatment which, I believe, are not generally applied in practice.

PYOGENIC AND SAPROPHYTIC INFECTIONS.

The following lesions represent the earlier stages and manifestations of pyogenic and saprophytic infections, with their toxins and ptomain poisoning: Cellulitis, myositis, ductitis, lymphangitis, adenitis, periosteitis, osteitis, resulting in resolution or suppuration, abscess, and necrosis, and occasionally in sapremia, septicemia, or pyemia.

These are lesions due to pyogenic or saprophytic infection, or both. When they are of pyogenic origin alone, the clinical symptoms are invariably less severe or fulminating than when saprophytic infection is added. Saprophytic infection is necessarily secondary to pyogenic infection or devitalization from other causes.

The specialized lesions are so numerous that to mention the more frequent will suffice: Cellulitis of the lips, cheek, soft palate, floor of the mouth, tongue, fauces, and palatal pillars, the tonsils, and often extending widely, causing myositis of the muscles of mastication, expression, speech, and deglutition.

The salivary glands and their ducts are frequently involved by contiguity with the cellulitis, and rarely by continuity along their ducts and tributaries, except in prolonged and exhausting illness where the secretion is much altered or reduced, causing ductitis and parotitis, submaxillaritis or sublinguitis—which, in these cases, develop suppuration, abscess, and frequently septicemia and pyemia.

SUPPURATIVE LESIONS.

If the normal and acquired resistance of the tissue cells and fluids is not sufficently strong to destroy the invading bacteria and their products, then suppuration in its common acceptance occurs, with accumulating products in local areas, known as abscesses, or in wider areas, called suppurative cellulitis.

The specialized lesions due to suppuration are also numerous, the more frequent being alveolar abscess, ossifluent abscess of the maxillary bones, abscess of the floor of the mouth, superficial and deep cervical abscess, and are frequently further distinguished by the cervical triangle in which the suppuration is developing, such as a deep cervical abscess in the submaxillary triangle, or a superficial cervical abscess in the submental triangle, or abscess of the lip and cheek.

Lymphangitis is not often recognized, owing to the thickness of the skin and fascia, but the lymphadenitis is easily recognized, especially early, before much

cellulitis or the induration of a rapidly forming periadenitis develops.

Periosteitis may extend equally in each direction, but it rarely extends beyond the midline of the maxillary bones in unilateral infection. It is necessarily associated with some degree of osteitis and cellulitis, and when it involves the periosteum of the angle and ramus of the mandible, myositis is frequently a prominent symptom. Also arthritis and synovitis of the temporomaxillary articulation in some degree is usually present.

Osteitis refers to the maxillary bones, as they contain only red bone marrow; the term osteomyelitis I prefer reserving for the bones containing both red and white bone marrow. It is practically always secondary to periosteitis, and invariably begins in the alveolar process, reaching the body of the bone by continuity; as in periosteitis, it rarely involves the opposite maxilla or half of the mandible in unilateral infection.

PREVENTABLE LESIONS DUE TO ORAL SEPSIS.

The surgical lesions due to oral sepsis are practically all preventable, and therefore prophylactic measures are of first importance. With the intelligent co-operation of the patient, this should be the ideal of the dentist and patient alike. Such results are in the majority of cases obtained even now if the patients co-operate, but the increase should be continuous until practically all obtain the same protection.

The ideal or standard which I would place before the profession and public would be normal occlusion, with early repair of caries maintaining the early vital forces of the dental organs, and the prophylactic remedial treatment of pyorrhea alveolaris or extraction, if results are not preventive of infection.

INFECTIONS INCIDENT TO ERUPTION OR CARIES OF DECIDUOUS TEETH.

This, therefore, requires the dentist to assume full care of the dental organs during the lifetime of the patient. The infection incident to the eruption of the deciduous teeth is very frequent and severe in results. It is due, as in the eruption of the permanent teeth, to the invasion of the space between the crown and gum tissue by pathogenic bacteria, which are introduced with the food and salivary secretion, and being retained, develop and produce infection. This occurs more frequently during the eruption of the deciduous teeth than of the permanent teeth, with the exception of the third molars. The early and careful artificial eruption of these teeth by the excision of a quadrangular section of the gum, providing a self-cleansing surface of the crown during the inflammatory stage, will prevent pyogenic infection very largely, and also probably pathogenic infection such as tuberculosis of the regional cervical glands.

Tuberculous cervical lymphadenitis is more frequent during the first five years than at any subsequent similar period, and when it involves the regional glands which are primarily supplied by the tributary lymphatic vessels from the alveolar regions, the portal of entry for the invading tubercle bacilli is provided by the previous lesions of the gums or those produced by caries of the deciduous teeth. The same assiduous care in repair of the deciduous teeth, to preserve their vital forces, is necessary to prevent infection if for no other reason—which of course is obvious.

One of the important functions of the deciduous teeth concerns the normal occlusion of their successors, but if they are allowed to be destroyed by caries and become devitalized or necrotic, the question arises as to whether they are to be maintained at the probable risk of infection, in order to maintain or promote normal occlusion in the permanent teeth.

The dentist is then called upon to decide which is the greater evil, infection, which is so frequent in such cases, with all its serious possibilities, or the possibility of disturbed occlusion of the succeeding teeth and its consequences. From what I have seen of both condi-

tions, I am persuaded strongly that the danger of infection is greater, and I feel it my duty to advise extraction, notwithstanding the frequent objection of the dentist or orthodontist.

CONTRA-INDICATIONS TO EXTRACTION OF LOWER THIRD MOLARS.

The same watchful care is necessary during the eruption of the permanent teeth, especially the molars, owing to the extent of masticating surface which is to be uncovered before the danger of infection is passed. The position of the lower third molars is frequently such that, although they are in normal position and have advanced to the level of the occlusion of the second molars, they are only partially erupted, and remain so for long periods, causing frequent infection. These normal and useful teeth are frequently sacrificed by extraction, in the belief that their removal is necessary to relieve the infection, when all that was necessary and proper was the uncovering of the crown.

Not only are these third molars very commonly ruthlessly extracted, but the often severe traumatism to the soft tissues and exposure of otherwise uninvolved bone and periosteum invites and promotes a severe and extensive infection. The only cases in which the removal of these teeth is justified are those of malposition that cannot be corrected by ordinary means. I have yet to see a single case of an unerupted tooth in normal or malposed position causing any clinical symptoms, either local or reflex, until the tissues by which it was surrounded had become infected and inflamed. It is not the presence of the tooth, but the occurrence of infection, that produces the untoward result. Unerupted malposed or impacted teeth deeply protected in the maxillary bones, when discovered by the Roentgen rays, do not call for removal unless they be invaded by infection. The extraction of such teeth, for the supposed benefit to the patient, is often a serious expenditure of energy to him, while in reality only some necessary treatment is required for relief.

AVOIDANCE OF TRAUMATISM AND INFECTION IN EXTRACTIONS URGED.

In general surgery we have come to recognize the urgent necessity of performing every operation with the greatest gentleness, avoiding every possible traumatism, in order to conserve the vital energy of the patient, prevent infection, and promote repair. The same principle applies to oral surgery with equal or even greater force. In the extraction of teeth, great care should be exercised to prevent as far as possible all traumatism to the gum tissue, periosteum, or bone. This is necessary to limit infection and promote repair, to conserve the tissue for future function, to shorten convalescence, and thereby to lessen the waste of vital energy. The present methods are questionable in several ways, which I think it prudent to call attention to. When a patient has to have several teeth or roots extracted, and only one or two of these are infected and give trouble, the extractor should make it his practice to remove at the first sitting only the infected teeth or roots, and the others at a subsequent sitting, when the danger of infection to the periosteum and bone of these teeth is reduced to a minimum.

Many dentists have the careless practice of extracting indiscriminately teeth with severe infections as well as those which are practically free from infection at one and the same time, and of making the operations with the same forceps, thereby inoculating otherwise healthy portions of the mucous membrane and gum tissues. In order to avoid these surgical lesions or infections, it is necessary, I contend, to extract at one time, only the infected teeth or roots, and to remove the other teeth or roots at a time when the infection has been overcome, and the mouth is in a hygienic condition. If one is compelled to extract all of the teeth, infected or not, at one time, the non-infected ones should be first extracted, while the forceps are clean; or even better, a different and fresh pair of forceps should be used for each tooth. Then, before the infected

teeth are removed, the alveoli of the extracted healthy teeth are protected, temporarily at least, from gross contamination and rapid dissemination of pus and fluids which invariably follow the removal of badly infected teeth. While I do not want to appear as an alarmist, I want to call attention to the danger of the present method of extracting teeth. My first experience in dentistry was gained under a preceptor in Canada, whose practice it was to separate the gum tissue from all the teeth to be extracted, and then very carefully to loosen the teeth and remove them, leaving no laceration whatever, but clean, healthy sockets. At the present time, the habit is—and it is often a habit among those considered to be expert extractors—to see how many teeth one can tear out of the mouth in the shortest period of time. That, to my mind, is absolutely wrong. The expert extractor of today should remove teeth with the least possible traumatism, avoiding what would otherwise naturally and inevitably result in a grosser infection. There is no one factor, in my opinion, that tends so much to prevent infection of the gum tissue and alveolar process, and often the body of the bone, as careful application of the forceps and careful dislodgment and removal of the tooth. I have seen some of the worst infections in mouths in which the evidence showed that the gum tissue was torn and the alveolar process destroyed as the result of traumatism from the extracting forceps. I have thought a good deal of this wholesale butchery in the extraction of teeth, and have seen much of it. Instead of trying to extract the greatest possible number of teeth under one administration of the anesthetic, which attempt is inevitably followed by serious traumatism and infection, it would be much safer to administer the anesthetic several times, and extract the teeth at different sittings. If it is necessary to extract several teeth at one sitting, the gum tissue should be very carefully detached and the teeth carefully removed without laceration or damage to the surrounding tissues or the alveoli.

TREATMENT OF MAXILLARY SINUSITIS.

In concluding, I wish to speak very briefly of the treatment of maxillary sinus infection. Contrary to the opinion of many, I believe that the greater majority of infections of the maxillary sinus are secondary to infections adjacent to the apical portion of the roots of teeth. This, I believe, is much more common than any of us probably appreciate. Many of the infections following the perforation of the floor of the maxillary sinus become spontaneously cured almost synchronously with the treatment instituted within the root-canal, the natural drainage through the ostium being quite sufficient to cause the sinus to clear up. Further, I believe that practically all cases of chronic empyema, myxomatous degenerations of the mucous membrane, and polypoid excrescences that fill up the spaces in the maxillary sinus, are practically all due to the continual pouring-in of pus products through the alveolus, and these cases can practically all be sufficiently treated by good root-canal work, which will prevent further pouring-in of the pus through the floor of the maxillary sinus. When this is done the normal recuperative power of the tissues will clear up the infection in a few days. It is different, however, with chronic suppurative antritis. No drainage of any kind through the root-canal or alveolar process will suffice to cure these cases. The diseased membrane has to be removed from the whole maxillary sinus, which, during the formation of new mucous membrane, must be tamponed to maintain a reasonable amount of pressure. This treatment, in my opinion, should be applied only through the outer wall of the maxillary sinus over the anterior teeth which are in relation to the sinus; we know that the maxillary sinus rarely extends anteriorly to the first bicuspids, and practically never reaches the region of the canine, but in a large number of cases is in relation to the molars. Dr. Davis, of this city, has recently shown conclusively, in a series of splendid experiments, that the floor of the maxil-

lary sinus at about eight years of age is on a level with the floor of the nasal cavity, and previous to that time is on a higher plane, probably five millimeters above the floor of the nasal cavity, but in later years a great deal lower.

I am opposed to any method or operative treatment by which the maxillary sinus is made to drain through the nasal wall. I know this to be considered as good practice by laryngologists and nasal specialists, but I have witnessed many unpleasant and unfortunate results in cases where the nasal wall had been opened too extensively, so that the secretions of the nasal cavity had flowed into the maxillary sinus for months and years and had to be removed mechanically, the sinus becoming a receptacle for all kinds of secretions, pus, and débris which collects on the nasal mucous membrane. Such practice I cannot but denounce. The proper and to my mind conservative treatment consists in opening the outer wall through the buccal cavity, curetting away entirely the diseased mucous membrane and tamponing the cavity with iodoform gauze. If this treatment is instituted, and the tampon is renewed every three or four days, new mucous membrane will re-form in the course of three or four weeks, when the tamponing can be discontinued; in nine out of ten cases the opening will close spontaneously, and recurrence of the trouble rarely occurs.

THE NORMAL FUNCTION OF THE CHILD DENTURE IN ITS RELATION TO DEVELOPMENT OF THE JAWS AND OTHER FACIAL BONES AND THE PRESERVATION OF THE TEETH.

By H. E. KELSEY, D.D.S., Baltimore, Md.

(Read before the Pennsylvania State Dental Society, at its annual meeting, Philadelphia, June 30, 1914.)

THE subject of the care of children's teeth, in its most obvious aspects, has been receiving so much attention as to make further elaboration superfluous. That phase of the subject, however, which is indicated in the title of this paper seemed to me worthy of further consideration, relating as it does to nature's own methods for establishing and maintaining the health and usefulness of the organs, and through them contributing to the health of the individual.

VALUE OF HYGIENE MEASURES.

I do not in the least degree mean to minimize the value or importance of all the artificial hygienic measures which have been so ably set forth in the many papers that have been presented and through the oral hygiene movement which has been so justly attracting the attention of both the profession and the public generally, for they are absolutely necessary to the civilized individual in proportion to the degree to which he has been allowed or encouraged to depart from nature's physical processes in the preparation of the food for the stomach; or to express this idea in another way, in proportion to the degree to which food has been premasticated before being taken into the mouth, thus eliminating the function of mastication and insalivation, which maintains not only in this

way its health and cleanliness, but as well prepares the food in the only proper way for the further digestive processes—for by this natural retention of the food in the mouth, together with the natural act of mastication, is produced the first of that sequence of secretory stimulations which provides in advance each division of the digestive tract with the proper ferments to take care of the particular kind of food which has been received at its beginning.

If we lived in an absolute state of nature, none of these artificial means would be necessary to the maintenance of perfect health. But we do not so live, nor is it necessary to do so to enjoy good health, for we can employ these artificial hygienic measures as adjuncts to nature's fundamental physical processes; yet we cannot interfere too radically with those fundamental physical processes without interfering with development, and therefore health; and of all our physical organs we have interfered with the functions of none so much—especially in childhood—as with those of the dental organs, and of them all none are of greater importance to the individual's health.

IMPORTANCE OF FUNCTIONAL ACTIVITY OF THE MASTICATORY APPARATUS.

It is strange but true that the acquisition of a certain amount of definite scientific knowledge relating to the nutrition of the body should have led us into a grave error regarding the manner in which that nutrition should be administered, apparently on the assumption that, if we were smart enough to discover something of the manner in which the invisible stomach performed its work and what food was most suitable for it, we could afford to ignore the mouth function in the preparation of that food for assimilation, substituting instead artificial comminution, especially in the child; for it was probably argued that, as he is so weak in many other ways in comparison with an adult, he must also be weak and inefficient in the use of his digestive apparatus, and especially that part of it which is under voluntary muscular control, the mouth. Then, too, the opinion has always seemed to prevail that the mouth was merely an orifice through which food might be introduced into the stomach, and that the teeth and mastication were only designed by nature to comminute the food sufficiently to permit of its being swallowed, ignoring insalivation, reflex secretory stimulation, etc. Acting on this hypothesis, it is not surprising that, in this age of machinery, it was decided that no matter if adults were usually able to masticate their food sufficiently not only to extract some pleasure from its flavor, but also to make swallowing a safe and practicable operation, at least no chances should be taken with children; and we all know the parental fear of choking which does not permit the baby to have the much-coveted bone to gnaw, or solid food upon which to exercise and stimulate its jaws and teeth and the structures in which the teeth are implanted. What was the use, they argued, of risking the child's life by allowing it to attempt to reduce its food by mastication to a swallowing consistence, when we have at our command such ingenious machinery for pulverizing anything from wheat to meat, or extracting its essence, which might be diluted with water? In fact, so great is the misconception regarding the use of the teeth that many people believe that they are thus preserving the teeth to longer life and greater beauty, not realizing that one year of vigorous chewing is worth more to a child than many tooth-brushes.

Fortunately, we have in the last ten years, through the careful study and research of a great many thoughtful men who have been studying the problem of nutrition from the mouth toward the stomach and intestines, instead of from the intestines and stomach toward the mouth, acquired a better understanding of this complex process, so that we now know the function of the mouth to be as important, if not more so, than that

of any succeeding organ, inasmuch as it initiates that sequence of secretory stimulations which, as before mentioned, is so necessary to normal digestion and assimilation.

As a matter of fact, while a child at birth is a helpless little mass of humanity so far as locomotion is concerned, it has nevertheless certain well-developed muscles which are associated with the function of nutrition, and which enable it to extract its natural food from the breast with as much tireless energy as it will ever exhibit later in life in any other capacity. And during this period of its life, it never suffers lack of development in the oral region if fed in the natural way.

By the time, then, that a child has reached an age when it exhibits an instinctive tendency to begin to take food other than milk and in a manner other than by sucking, it should have become manifest to its parents that nature's methods should be continued in its feeding, and that as teeth have been provided, the child should be allowed and encouraged to use them.

Among most mammals—and there is no reason why the human race should be an exception—there is a period during which the young take both milk and solid food, their size gradually making the supply of milk no longer adequate for their needs, even did not nature, after a certain time, begin to diminish the supply of milk preparatory to casting the new creature upon its own resources. And it is during this period that its instinct to reduce solid food by long mastication and mixing with saliva to almost the consistence of the liquid milk to which it has been accustomed is strengthened into a habit, and thus the inclination to masticate properly is acquired and fixed so that it will not be lost later. It is the writer's conviction, supported by such investigation as he has so far made, that if the habit it not formed at this time, it will never, or only in rare instances, be acquired later in life by a mere exercise of the will through the individual's knowledge that it is good for him.

TESTS REGARDING THE HABIT OF FOOD-BOLTING.

Some very interesting and instructive experiments were reported by Dr. H. C. Ferris before the Eastern Association of the Graduates of the Angle School regarding what he calls food-bolters. After experiencing the difficulty—which we all encounter in trying to secure reliable data—as to whether or not his patients properly masticated their food, he argued that a person who could readily swallow an object similar to a large pill without chewing could and would swallow his food in large and unchewed pieces. He therefore had six sizes of chocolate-coated bread pills made which he would instruct his patients to swallow, and the results showed that, while some could not swallow without chewing even the smallest, others could without the least difficulty swallow the largest, which was about three-eighth inch in diameter. On the face of it this experiment would seem to prove without further investigation that his hypothesis was correct, but Dr. Ferris supplemented it with the best information he could get on the habits of the patients subjected to this test, which all tended to confirm it.

When the writer heard Dr. Ferris' report he commended the work, but since making a more detailed study of this subject, he believes that its benefits were not by any means fully appreciated, and now thinks that it may become a diagnostic aid of much value not only to the dentist and orthodontist, but also to other specialists by furnishing a reliable index to the habits of a patient in this respect.

FUNCTIONAL ACTIVITY OF THE JAWS IN CHILDREN A PREVENTIVE OF MALOCCLUSION AND DENTAL CARIES.

A consideration of the mode of life of primitive races furnishes further evidence that the habit and inclination to masticate thoroughly before swallowing is acquired in childhood, and begun almost in infancy. Dr. Hrdlicka, curator

of the division of physical anthropology of the United States National Museum at Washington, states that among the Indians as well as other primitive peoples, children are given solid food as soon as they show a desire for it, and therefore at a much earlier age than our children, so that from infancy the jaws are receiving their natural developmental stimulus through the action of the muscles upon them. On the other hand, breast feeding is continued to a much later period than among more civilized races, so that the child receives abundantly those natural activating food properties which are so essential to normal development, and which cannot be provided in any artificial food, and at the same time it is acquiring the ability to prepare other food properly for digestion when the parent milk food is entirely discontinued. It is significant too that among primitive races, after breast feeding is stopped, the child must rely solely upon this acquired ability, for he is not furnished with the cows' milk substitute as are the children of civilized parents, and Dr. Hrdlicka also states that, during his observations of children among the Indians, except in some modern boarding schools, he found malocclusion and caries of the teeth so rare as to be really negligible, and I think we may reasonably assume that this is due in a great measure to functional activity of the jaws.

INCREASING REFINEMENT OF FLOUR AND ITS DELETERIOUS EFFECT.

Let us compare, for example, the manner of preparing corn for use as a food, which is an article common to both the civilized and the primitive child. In the case of the primitive child, the corn is prepared in two ways, one of which is by pounding it in a stone mortar into a coarse meal, after which it is made into cakes; the other consists simply in parching it, leaving the entire act of pulverization to the teeth—and what better mill could be devised for the needs of one individual than the magnificent dentures found in the skulls of the original inhabitants of this country and in the mouths of their descendants today, especially when they live under natural conditions?

Dr. Hrdlicka speaks of trips of several days' duration made with Indians, during which almost the only food was parched corn, and of which, under those conditions, he himself tired less than of canned foods.

The writer, during his childhood spent in the mountains of North Carolina, was particularly fond of the parched mountain corn—which, by the way, was neither sweet corn nor the large yellow corn of the North and West, but a much smaller white variety, doubtless much nearer to the original maize of the Indians, and which was at that time, when ground into a coarse meal in the little water mills of the country, the chief and almost the only material for making bread.

But this is much changed, and the introduction and use of the fine-bolted wheat flour now common is no doubt to the great detriment of the masticatory organs, if not in other ways. On the other hand, the child of civilization living in what is known as modern or up-to-date environment, instead of having to eat his corn parched, has a new kind propagated for him that will pop open and become soft so that little chewing is required, or it may be rolled into flakes and soaked in milk, or else it will be ground to finest flour, cooked into mush and eaten with milk or butter, or if it is to be made into bread, it will be mixed with other finely ground flour and so prepared that still little or no chewing will be required. What is true of corn is true of meat and all other articles of food that are common to both primitive and civilized man.

ERRORS IN MODERN CHILD DIET.

The sedulous care which civilized parents exercise over the diet of their offspring is commendable in so far as it does not interfere with, or tend to alter, nature's methods; but usually it does this—often even in infancy, and more

frequently from then to maturity. As mentioned previously, the fact that a child will occasionally choke, or, if left to its own devices, will choose food that will make it ill, is undoubtedly one of the reasons why parents get the notion that anything the child wants to do regarding its feeding must of necessity be wrong, and most of its instincts come to be regarded with suspicion.

A very scientific and in other respects excellent mother who had brought her child for the treatment of a malocclusion, when told that the child had not too many teeth, as she had supposed, but that its jaw had failed to develop sufficiently to accommodate them, said that this was very discouraging, since, if she had been conscientious about one thing more than another, it had been the nutrition of her child; then recounted an excellent diet, so far as materials went, which she had supervised for it since breast feeding—the only natural feeding, by the way, it had ever received. The list contained the usual fruit juices and but little fruit, beef juice but hardly any beef, and then only when it had been ground, and the same was true of other meats; milk and prepared cereals were important items, and some special child's food taken with milk was used for a time. A number of always fresh vegetables were also on the list, but nothing at any time to stimulate really effective chewing. I told her that she had undoubtedly furnished the child with sufficient nourishing food, but that, in attempting to supplant nature in the preparation thereof she had defeated both her own and nature's ends. Through lack of function, the jaws and all associated structures had failed to develop, and nutrition had been below normal in spite of the excellent food, because the first important digestive process had been neglected. At the same time, this mother recognized the necessity for the general exercise of the body and limbs, and had insisted that the child should have plenty of it. How strange that she, like so many others, should not be able to carry her understanding a little farther, and realize that one organ just as much as another must have functional exercise to insure development.

This case seems to me typical of a majority of those met with in the ordinary course of the dentist's and orthodontist's practice, while there are many others in which the child would be permitted to chew, but owing to some defect in one or more teeth cannot do so with comfort, and is therefore worse off than the former, in that its food has neither natural nor artificial comminution.

Finally, there are some who supply a wholesome common-sense diet for their children, and not only permit but encourage them to chew their food well. This, if applied to the whole race, while it might not eliminate malocclusion and caries, because there are other definite factors concerned in the etiology of these disturbances, would nevertheless greatly diminish them.

CONCLUSION.

This is not a paper on Fletcherism, which has been so often and so ably expounded, and which means proper preparation of food by mastication for further digestion, whether it requires ten minutes per mouthful for the dental cripple, or only twenty or thirty seconds for the individual with a good masticating apparatus.

The mouth-hygiene movement, if broadened to include a popular knowledge of the foregoing facts, will do much within the next few years toward enlightening the public generally; but are we as a profession exerting ourselves sufficiently to instruct our patients with whom we come in daily contact along these lines?

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE TECHNIQUE AND RELATIVE VALUE OF GOLD FILLINGS AND INLAYS.

By J. V. CONZETT, D.D.S., Dubuque, Ia.

(Read before the Dental Society of the State of New York, at its annual meeting, Albany, May 14, 1914.)

A DISCUSSION of the subject of the comparative value and technique of the gold filling and the gold inlay is both timely and profitable. The gold inlay has been in the hands of the profession long enough to allow of some definite judgment of its value as a preservative of the dental organs when used as a filling material.

When the cast gold inlay was first given to the profession it was hailed with delight, and a stampede ensued for machines with which to make it. Conservative men of the profession predicted disaster and went as far as saying that the method had no merit of permanent value. Others of equally high standing were loud in their assertions that the ideal method of the restoration of lost tooth tissue with gold had come. Today we again find an alinement of the operators of our profession for and against the gold inlay, and now their arguments are not *à priori* but *à posteriori,* for we are in possession of the results of six years of trial. There have been failures, multitudes of them, and we shall try, within the brief space of time allotted, to draw some conclusions from the failures that we have observed, and see whether they militate against the method itself, or whether they have been the result of a failure properly to grasp the fundamental principles upon which the inlay system rests, or to apply them if understood.

GOLD FOIL FILLINGS.

First let us take a hasty survey of the method of filling cavities with gold foil. Ever since dentistry has been a profession, the ability to fill a tooth properly with gold foil has been the measure of an operator's professional standing, and all dentists have been ambitious to excel along that particular line. Down through the ages of dental development, operator after operator has bequeathed to the profession some improvement in the methods of cavity preparation, the making and the use of the gold foil, the instruments, and the methods for the better and easier use of this king of filling materials. The method as used by the best operators of the present time is not the work of any one man or set of men; it is the result of the evolution of the art as it has been developed in the brains and by the hands of earnest, devoted men in all parts of the dental world; but it remained for one man of great genius and indefatigable energy to collect, harmonize, eliminate, and add to the methods of the best men of all time and then give to the world of operative dentistry that which his admirers have been pleased to call the "Black system." Dr. Black does not claim originality in the methods he teaches, and all that we will claim today is that he developed a system with which we may work to better advantage.

Those of us who ardently admire and love him, as I confess to do, are not content to give him so small a part, but for the sake of the advancement of the profession, and for harmony, we are willing to lay aside our personal opinions and work in harmony with anybody who is willing to take the good, come from where it may, and eliminate the bad, come from where it may.

THE BLACK SYSTEM OF CAVITY PREPARATION.

The Black system of cavity preparation teaches certain definite measures of procedure, each step having a logical reason for its existence. After a study of the case under consideration, and when ready to begin our cavity preparation, we follow this plan: First, obtain the outline form. Second, the resistance form. Third, the retention form. Fourth, the convenience form. Fifth, the cavo-surface angle. Sixth, make the toilet of the cavity.

The outline form contemplates the obtaining of extension for prevention and the esthetic form.

EXTENSION FOR PREVENTION.

Extension for prevention means the carrying of all the margins of the cavity into areas of relative immunity to dental caries. It will not be possible for us to make an extended observation of this principle, nor indeed of any of the principles that we predicate, for time will not permit. Suffice it to say that there are areas of immunity and susceptibility upon the surfaces of the teeth, such immune areas being those which are naturally kept clean by the excursions of food over the teeth during mastication, and the movements of the lips, tongue, and cheeks. The susceptible areas are those which lie in places protected from the frictional movements referred to, and thus harbor the organisms which make for decay, for we know that decay cannot take place unless the organisms of decay are able to attach themselves to the teeth, and there remain in undisturbed quietude to prey upon the dental tissues. All pits and fissures must be followed out to their full extent, so that the margins of the inlay or filling may lie in smooth territory, for if this were not done, and a fissure were allowed to remain in part, the remaining part of the fissure would harbor the organisms, and a recurrence of decay would occur about the filling. The buccal and lingual margins must be carried far enough out of the embrasures that the margin of the filling will not be in contact with the approximating tooth. The gingival margin should be carried far enough so that the margin of the finished filling is covered with the gum. In short, all margins must be in territory that is automatically kept clean.

ESTHETIC OUTLINE OF CAVITY.

The esthetic form is that which we give to the outline which will, to the greatest degree, conserve the beauty of the tooth. It is our duty not only to save the teeth, but to do so with the least possible interference with esthetic appearance, and in order to do so we must be artists as well as artisans. The filling should be as unobtrusive as is consistent with safety, but I should hesitate to sacrifice safety to beauty, unless it were the express wish of the patient. All external lines should be gently curved, for a curve is always more beautiful than an angle, and lastly, the original form of the tooth must be as perfectly restored as it is possible to do, for there is nothing that detracts from the appearance of a denture more than a lot of misfit teeth, one filled to one form and another to quite a different form and size.

RESISTANCE FORM OF CAVITY.

The resistance form is that which is given to the cavity in order to cause the filling to resist the forces brought to bear thereon. The depth and width of the resistance form must be determined by a study of the conditions obtaining in the case under consideration. Some individuals exert a force of from 250 to 300 pounds upon their teeth during mastication, while others of weaker muscular physique and possibly a sensitive peridental membrane as a result of a pyorrheal tendency, exert a force of but from 50 to 75 pounds. It would obviously be foolish to cut as broadly and as deeply in the latter individual; yet, if we did not cut sufficiently well in the former individual, failure will soon re-

sult by reason of the filling being forced out by the stress brought to bear upon it. The resistance form is best obtained by making cavities with flat seats, for a flat foundation distributes the forces that are exerted upon it in the most equable manner. If the foundation were rounded, the filling would have a tendency to rock under the stress of mastication, and this tendency frequently resisted would in time cause a movement in the filling that would make for failure. We insist, therefore, on placing fillings upon bases that are as flat as it is possible to make them.

RETENTIVE FORM.

The retentive form is that which is given a cavity that will resist the pulling forces that have a tendency to lift the filling out of the cavity. Pits, grooves, and deep undercuts were the methods that obtained in the practice and the teaching of too many of the older practitioners, and unfortunately have not been completely banished from the practice of very many operators of the present day. These means of retention are not only unnecessary, but positively harmful, as we might show if time permitted. The only retention necessary for a well-condensed gold filling is parallel walls deep enough to afford sufficient grasp of the gold upon the walls of the tooth. In making a gold foil filling, it is permissible to make a slight undercut, but this should never be deep, and it is scarcely necessary to add, such practice is obviously contra-indicated in the making of a gold inlay. I said that the cavity should be deep enough, and I wish to emphasize that statement, for many of the failures that it has been my privilege to study have been caused by a too shallow cavity preparation. Often the cavity is scarcely cut through the enamel. The cavity must be made deep enough to afford sufficient grasp upon the axial walls to afford a sufficient frictional resistance. Just how much that must be cannot be stated, for all cases are not alike, and the preparation of the retentive form must be made with an intelligent perception of the conditions that the finished filling is to meet.

CONVENIENCE FORM.

The convenience form is that which is given to a cavity which enables the operator to adapt his filling material perfectly to the walls of the cavity. Again it is not possible to set down any fixed rules; indeed, the form which it would be easy for one operator to fill might be an absolute impossibility for another. So the only rule that we can make is always to prepare a cavity in such a manner that the operator will be able to fill it perfectly with the material which he has chosen for the case in question. It is much better to sacrifice a portion of a good tooth in order that a perfect filling may be made, and thereby to save the tooth permanently, rather than to leave a doubtful portion and render it impossible to make a perfect restoration and thereby cause a failure with perhaps the loss of the whole tooth, or if not, certainly with the loss of a greater part than would have been lost if the original filling had not been a failure—to say nothing of the inconvenience caused the patient and the chagrin occasioned to the operator.

PREPARATION OF THE CAVO-SURFACE ANGLE: REASONS FOR BEVELING.

The cavo-surface angle should be beveled all around the cavity. I know that some operators advocate the butt joint, but I do not believe that they have any scientific evidence upon which to base their recommendations. The margins should be beveled—

First: To protect the enamel rods. We know that enamel is one of the strongest tissues in the body when its continuity is unbroken, but, by reason of its histological structure, once there is a break in the enamel surface the rods immediately contiguous to the break will be unsupported, and upon the slightest stress will fall into the ditch caused by the absence of the rods concerned in the break. Moreover, any rods that do

not reach from the surface of the enamel to the dentinal junction are very weak in their resistance to stress, and fall out very easily; therefore no short rods should be left unprotected upon the surface of the cavity. This can only be prevented by properly beveling the surface of the enamel, or by having such an intimate knowledge of the enamel that all of the enamel preparation will be so made that there will be no short rods left at the surface. We are willing to admit that this can be done, but it is much easier and safer to bevel the margin and thus be sure that all rods are perfectly protected. We should have an intimate knowledge of the histology of the enamel, for we cannot intelligently operate without it.

Second: The beveling of the cavo-surface angle causes a flange to be cast upon the margin of the inlay which can be burnished to perfect contact with the tooth immediately after cementation, thus making an hermetical joint, and minimizing the cement line to the greatest possible degree. If the butt joint is used, it will be impossible to burnish the inlay to adaptation; indeed, it would be unwise to attempt it, for the burnisher would come in contact with the unprotected enamel rods at the margin and cause a checking thereof;—so, if for any reason one persists in the use of the butt joint, he must not attempt to burnish the inlay to the tooth.

Third: In the butt joint there is an end-to-end adaptation of gold and tooth, and, be the fit ever so perfect, we know that it is impossible to compress cement to a thinness of less than the one-thousandth of an inch; therefore we will have a thin plate of cement between the inlay and the tooth which has no protection, and the constant pounding of the forces of mastication upon the inlay will be transmitted to the thin plate of cement, which will be disintegrated and eventually fall out and leave a wide-open ditch for all sorts of invasion. The flange upon the inlay, however, can be burnished down to the tooth, the cement line pinched off to the greatest possible degree, and what cement is left will be protected from stress by the flange which seals it in.

TOILET OF THE CAVITY.

The toilet of the cavity comprehends the thorough cleansing of the cavity from all chips, residual decay, or débris of any kind. In the making of a gold filling, the freshly cut dentin, prepared under the protection of the rubber dam, offers the best condition for the adaptation of the gold, and any wash is therefore contra-indicated. If the inlay is to be used, and the cavity has been prepared without the rubber dam, then the cavity should be thoroughly rinsed out with warm water immediately before the cementation of the inlay, and should then be washed with alcohol.

The preparation of a cavity is practically the same for an inlay as for a gold filling, the only possible difference being that in the preparation for a gold filling some undercut retention is permissible, while for an inlay this is, of course, absolutely prohibited.

PERFECT ADAPTATION OF THE FILLING MATERIAL.

No matter how perfectly our cavity has been prepared, if the filling material that is to make the restoration is not perfectly adapted to the tooth, so as to seal it hermetically and protect the dentin from the incursion of moisture and micro-organisms contained therein, the operation will be a failure. The perfect adaptation of gold to the tooth so that it will permanently save the tooth is a fine art. The gold must be so inserted that it will be in perfect adaptation to the walls of the tooth at all points, for a filling is no more perfect than its weakest point. No matter how perfect may be the rest of the filling, if it is imperfect at one point and fails at that place, the whole filling is a failure. In the adaptation of gold to the cavity, a plugger of medium size should be used, one about 1 x ½ millimeter for cavities in proximal surfaces of incisors, and one a little larger for cavities in the proximo-

occlusal surfaces of the molars and bicuspids. If too large a plugger is used, too great a degree of force is necessary to condense the gold properly, and if the plugger is too small it will chop the gold and fail to condense it perfectly. In making the filling, the gold should be started in one of the angles, and then each succeeding pellet malleted toward the walls of the cavity. In condensing a pellet of gold the plugger should be started toward the center of the cavity, and in a series of steps the plugger should travel toward the wall of the cavity against which the gold is to be condensed. When the wall of the cavity is reached, the plugger should be lifted away from the gold and again seek the center of the cavity and again travel toward the wall, and never should the plugger travel away from the margin toward the center of the cavity, for in so doing we are causing the gold to draw away from the wall, and inasmuch as the malleting has tempered the gold and made it springy, it will be impossible to bring it again into perfect adaptation to the cavity walls. The filling should be thus built up by laminating the gold, or shingling it, to make the whole filling stronger.

DENSITY OF MALLETED AND CAST GOLD FILLINGS.

The life of a gold filling depends a great deal upon its density. We know that cast gold has a specific gravity of 19.2, and the closer we can approximate that density in a filling the better it will be, while a filling with a specific gravity of less than 14 will be a failure in a short time. This is due to two reasons: First, the filling will be too soft to resist the stress of mastication; second, by reason of the very high percentage of air-spaces the filling will be little better than a sponge, for the whole interior of the filling will contain air-spaces which will readily give up the air in exchange for moisture laden with all kinds of impurities. The ingress of the moisture will break up the cohesion of the pellets of gold, and in time it will be possible to pick out the filling with an excavator.

We do not have the problem of density to deal with in making a cast inlay, for the gold is at its highest density when cast, and there are no air-spaces with which to contend; but the problem of softness is very much in evidence. Pure gold has been advocated as the material to be used in the making of all cast gold inlays, for the argument has been advanced that, since in the cast inlay we have the gold at its highest density, we have it in its ideal form for the making of a filling. These advocates forget that gold is softened by heating, and tempered or hardened by malleting or beating. Consequently a gold filling of a specific gravity of 18 will be harder and much more resistant to stress than one of cast gold with a specific gravity of 19.2, because, in the making of a filling, each pellet of gold is beaten again and again so that it attains its maximum hardness, but in the gold inlay the gold has been annealed to its greatest extent, and is consequently at its softest state.

SELECTION OF GOLD FOR CAST INLAYS.

It is true that pure gold gives us a more perfect cast than any other material, but whenever stress is to be exerted upon it, its use is contra-indicated by reason of its softness and its inability to stand up under the strain of mastication.

In cavities in the proximal surfaces of incisors, pure gold is the best material to use, for here no particular stress is brought to bear upon the inlay; but in proximo-occlusal surfaces of molars and bicuspids an alloy should be used. For ordinary cases an alloy of 23-karat gold will be amply sufficient. I personally reach this karat approximately, by using half-and-half pure gold and S. S. W. 22-karat plate gold. This gives an alloy of sufficient resistance, of as good color as the pure gold, and one that casts almost as perfectly.

In cavities demanding a great deal of resistance, an alloy of gold and 5 per cent. platinum may advantageously be used.

METHOD OF MAKING WAX MODELS FOR INLAYS.

The problem of adaptation of gold inlays is of the greatest importance, and the success or failure thereof involves a knowledge and an intelligent use of the principles of the manipulation of the wax in model-making and casting of the inlay.

A wax should be used that is hard at mouth temperature, otherwise the wax will have to be hardened by the use of cold water, which will cause a shrinkage of the wax. This shrinkage added to the natural shrinkage of the gold will cause a discrepancy in the finished inlay that will greatly militate against its success. The wax should be brought to the proper temperature, so that it will not be too soft or too hard, by immersing it in water of the right temperature, or in an electric heater made for the purpose, or, if care is exercised, over the open flame. The wax should not be melted, and if too soft it should be allowed to harden before being introduced into the cavity. When ready it should be in the shape of an elongated cone and be introduced into the cavity with a steady pressure. The thumb and first finger of the left hand may be placed on the buccal and lingual surfaces of the tooth and act as a matrix if no matrix be used, and then with the forefinger or thumb of the right hand the wax is thoroughly and firmly pressed into the cavity, this pressure being maintained until the wax is hard. This is done for the purpose of forcing in additional wax as the shrinkage of the wax in cooling makes place for it. When the wax is hard, the patient should not be asked to bite into it, as is the custom with some operators, for the wax is thereby displaced from its adaptation to the walls of the cavity, and a distortion of the inlay will be the result. The wax should rather be carved to occlusion, and the artist will have the opportunity to display his skill to the highest degree in the reproduction of the sulci and occlusal planes.

The investment of the model, its burning-out, and the casting are problems that I dare not attempt to discuss in brevity. Suffice it to say that the model should be immediately invested, should not be burned out to such a degree that the investment is weakened by the heat, and should be cast in a cold mold.

CAUSES OF FAILURE OF CAST GOLD INLAYS.

In conclusion let us state that by far the great majority of the failures of the gold inlay are attributable to a faulty cavity preparation, which causes the inlay to fall out of the cavity. I have no doubt that such a preparation would be the cause also of recurrent caries if the inlay stayed in long enough for such recurrence, for in most cases which have come under my observation the extension form had been wofully ignored. This cause of failure can be corrected by a study of cavity preparation and the observance of the laws relating thereto as laid down by Black.

Another cause of failure is the omission of a proper beveling of the margins.

The third cause of failure is the use of pure gold in inlays upon which a great deal of stress falls; such gold will, as a result, often flow to so great a degree as to overhang the surface of the tooth.

I am a firm believer in the gold inlay as a means for saving a tooth in which it has been properly placed, so much so that the cast gold inlay is taking an increasingly larger place in my practice as time goes on and I have the opportunity of observing its beneficent office in the saving of the teeth of my patients, together with a degree of comfort in its insertion that was never remotely approached by the gold filling.

CORRESPONDENCE.

EMETIN HYDROCHLORID AND PSORIASIS.

To the Editor of the Dental Cosmos:

Sir.—In view of the great difficulty, if not the impossibility, of effecting a cure for the skin disease called psoriasis, I take pleasure in making the following report.

In treating pyorrhea by the emetin hydrochlorid method, as advocated by Drs. Barrett and Smith of the University of Pennsylvania, several phenomena well worthy of mention have occurred. The principal one, and the one with which this article will be concerned, is the apparent cure, or at least the disappearance during the course of treatment for pyorrhea with emetin hydrochlorid, of all symptoms of psoriasis in a patient who for fifteen years had been suffering from that disease.

The backs of both hands were completely covered with most repulsive-looking, inflamed, somewhat corrugated and scaly surfaces. This condition was also found in large patches on both arms and on some parts of the body. The disorder had been many times diagnosed as psoriasis. The patient had been treated for many years by different physicians, and informed me that he had used every known remedy that the physicians whom he had consulted could think of, to try to alleviate his condition or effect a cure, but with very little if any benefit, and he had finally become so discouraged that he had given up all hope of ever being cured of this very disagreeable malady.

In the treatment of his teeth for pyorrhea, I followed the course prescribed by the originators of the treatment already mentioned, and after the third treatment the patient voluntarily called my attention to the lack of itching and the apparent improvement in his skin disease, and voluntarily expressed a desire to have some of the emetin injected under the skin of the hand—indicating the benefit recognized, after the third treatment, by the patient himself. I did not comply with his request, but continued to treat the gums locally as before stated until the full course of treatment as prescribed was finished. At the present time, six treatments having been given—and it being now two weeks since the last treatment—every symptom of psoriasis has entirely disappeared.

It gives me great pleasure to report what seems to be a remarkable benefit, if not cure, of this very stubborn skin disease; and I hope that other practitioners, seeing this, may be able to afford other patients suffering from the same cause an equal benefit.

Respectfully,

Wm. R. Chaplin, D.D.S.

Savannah, Ga., January 4, 1915.

REQUIREMENTS FOR THE PRACTICE OF DENTISTRY IN BRAZIL.

To the Editor of the Dental Cosmos:

Sir,—As there appears to be considerable interest shown by dentists in America in the requirements for the practice of dentistry in Brazil, judging from the number of inquiries I have received on the subject, I shall be glad if you will publish the following for the information of those interested:

First. A diploma from a reputable dental college is required.

Second. The secretary of the college granting the degree must appear before a notary public and certify that the diploma is the identical document authenticating the degree conferred on the holder thereof on the date specified, the certificate being pasted to one edge of the diploma.

Third. The signature of the notary public must be certified to by the secretary of the state in which the college is chartered.

Fourth. The signature of the secretary of state must then be certified by the Brazilian consul. Fee $1.65.

Fifth. On arrival in Brazil the diploma must be presented to the department of Foreign Relations for certification of the consul's signature. Fee 550 reis. ($0.16½.)

Sixth. The diploma is then presented to the federal treasury, where stamps to the value of 1200 reis ($0.35) are attached.

Seventh. A petition is then made bearing a 300 reis ($0.09) stamp to the secretary to the Faculty of Medicine of Rio de Janeiro, to which is attached the legalized diploma, and the treasurer of the Faculty of Medicine's receipt for 200 milreis ($65.00), asking that the date and time for examination be set.

Eighth. The examination is in three parts—oral, written, and practical—and the language is Portuguese or French, covering subjects as covered by the boards in America. If the candidate fails, 100 milreis ($32.50) is remitted.

Ninth. Having passed the examination the candidate takes his diploma to the board of health in the place where he expects to locate, for registration. No fee.

Tenth. There are two yearly fees—federal, 40 milreis ($13.00), and a municipal sanitary tax.

Eleventh. The diploma so registered allows one to practice anywhere in Brazil, as the examination is a federal and not a state examination.

Marcellus Rambo, D.D.S.

Rua d'Assemblea 104,
Rio de Janeiro, Brazil.

Proceedings of Societies.

PENNSYLVANIA STATE DENTAL SOCIETY.

Forty-sixth Annual Meeting, Philadelphia, June 30, July 1 and 2, 1914.

(Continued from page 86.)

WEDNESDAY—*Afternoon Session.*

THE meeting was called to order on Wednesday afternoon, July 1st, at 2.30 o'clock, by the president, Dr. Howard S. Seip.

Dr. Seip announced as the first item on the program for the afternoon session, the reading of a paper by Dr. H. E. KELSEY, Baltimore, Md., entitled "The Normal Function of the Child Denture in Its Relation to Development of the Jaws and Other Facial Bones and the Preservation of the Teeth."

[This paper is printed in full at page 178 of the present issue of the COSMOS.]

Discussion.

Dr. G. L. S. JAMESON, Philadelphia. Dr. Kelsey's paper is an argument for the natural, simple life from the very beginning. It is an axiom in physiology that, in proportion as an organ is used or disused, it either develops or deteriorates. It is also an axiom in clinical medicine that it is very much easier to prevent disease than to cure it; and Dr. Kelsey has dwelt on these two phases. The first function of the child when it is born is crying, thereby opening up the respiratory organs, and the second function is the desire for food. The probability is that dental troubles start at the very beginning of life. I have in mind one family in which the three oldest children were fed with the bottle with a small nipple, but the fourth child was nursed by the mother. This child never had any adenoid or tonsil trouble, but the other three had hypertrophied tonsils and adenoids, and I have thought many times that the trouble with these children started at the very beginning of life.

If the child takes food in the normal way, the breast so fills his mouth that he either must give up the food which he is so anxious to take, or else must force the nasal passages open. The process of taking food occupies a considerable portion of the time in the early stages of life, and breathing through the nose during the taking of food opens up the nasal passages, and starts the child in breathing properly. On the other hand, if the child is given a nipple, it is very easy to take in air around it, and the child does not go to the trouble of breathing through the nose. I believe that this is the beginning of trouble with the breathing apparatus, which has a great deal to do with the proper development of the dental organs. If the child does not breathe properly, the organs of the mouth will not be developed properly.

Coming to the question of the child's proper use of the teeth, we all know that foods are now so prepared that children particularly do not use their teeth as they should, thereby losing the stimulation caused by mastication. When the teeth are properly used in mastication, the dental organs are stimulated, and consequently are better developed. The

essayist dwells on artificial foods. I have always thought that the nearer we keep to a milk diet in early life, the better.

As I said before, any organ that is used is developed, and any organ that is not used is not properly developed. In my practice I have made it a rule to have children taught to masticate as early as possible and to eat the crusts of toasted bread, or what we call Educator crackers. It is a good practice to give them bones to suck and bite upon, as these all have a tendency to stimulate the organs of the mouth. There are, however, cases in which, although the child is taught to breathe properly and is so fed that he uses the organs of the mouth, yet there may be some interference with proper development of the teeth and jaws, and these are the cases where the orthodontist begins his work. We can all recall having seen in years past many people with protruding teeth, receding chins, irregular teeth, etc., but in the future all well-bred people should be free from facial and dental deformities. The corrections that are being made by the orthodontists at the present time will make a decided impression on the generations to come. We will be a much better-looking people, and as the organs of mastication are enabled to perform their functions more normally, we should be a healthier race.

The essayist, of course, has been considering the question of digestion in its entirety, which is a mechanical and chemical process. If the child does not masticate, the food is not properly insalivated, hence the first step in the process of digestion is imperfect, and the whole process is impaired. It has always seemed to me that the process of digestion is much like the manufacture of some chemical in which we have to add certain substances in the beginning and others later on, until completion of the reaction, but if we make a false start, we shall have an imperfect result. The proper mastication of food, I think we all agree, is not only good for the dental organs, which it develops and stimulates, but it also renders the process of digestion more complete and thorough.

After thirty years of practice I have come to the conclusion that, in order to practice dentistry properly, we should see our patients at the very beginning of life. I make it a point to see my little patients as early as three or four years of age, to ascertain that they are breathing and feeding properly. In many cases I find that the child is not breathing properly, and then I feel it my duty to call the attention of the parents to this fact, and induce them to take such steps as to enable the child to breathe properly. If that is not done at the age of four or five years, there will probably be a more or less abnormal development.

Dr. S. Merrill Weeks, Philadelphia. To my mind this is one of the most encouraging papers that has come to my attention for some time, and I hope you will not pass it by without careful consideration.

I believe the principles put before us by the essayist have to do with the fundamental causes of faulty development of the dental organs and of parts even farther removed from the dental arches than we had supposed. It seems to me to be a glaring frailty of man to begin at the wrong end of all problems to arrive at a solution—in other words, to work backward.

The medical men were for years expending all of their efforts in the endeavor to cure disease rather than to find some means of prevention, and it is distinctly encouraging to know that they are now equally as eager in their efforts to find the causes of disease and to devise means of averting it. Thus it is with the difficulties under consideration. No matter how proficient we may become in the science of correcting oral deformities, our progress toward the millennium is slow indeed, if we can do nothing to prevent the occurrence of these deformities.

I so thoroughly agree with all the facts presented by the essayist that I can only emphasize what he has said.

I recognize that there are many and varied causes of oral deflection, but I am satisfied that the principal cause

of subdevelopment is the lack of use, brought about in the manner set forth by the essayist. An examination of many skulls of uncivilized people shows the percentage of undeveloped arches to be small, because their habits of diet are such as to insure much exercise of the teeth and arches. The teeth in these races are well worn by use, while, on the other hand, we find in the many undeveloped arches of the present time very little wear of the organs of mastication.

We know how necessary it is that any organ be used in order that it may properly develop. For this reason it is inconceivable why so many child-specialists almost invariably prescribe premasticated and predigested foods for children who are troubled with digestive irregularities. Many such troubles, I believe, could be overcome if the child were never permitted to acquire a distaste for thorough mastication which is persistent and pernicious through life. When Fletcher promulgated his scheme of mastication for man's benefit, he builded better than he knew, and if it could be applied to every child we could in time hope for a race that would have but little use for the orthodontist or the specialist in digestive disorders.

Dr. F. C. Friesell, Pittsburgh. After reading Dr. Kelsey's paper, which was sent to me some time ago, I realized that in agreeing to discuss it I had either underestimated his ability or overestimated my own capacity. Many of you will agree that the essayist has made statements that just invited questioning, and then quickly forestalled opposition by admitting the probability of limiting factors—which is good generalship.

The essayist has presented to us a message containing some important factors which are being overlooked or neglected by the dentist in his daily work.

Natural provision for the organs of mastication is made at a very early date in the embryo, the mandible being the first bone in the body to calcify, and the crowns of the deciduous teeth being well formed prior to birth.

While lack of enforced function of mastication may account for *some* cases of caries and malformation, I am inclined to believe that failure to clean the teeth and mouth properly may be considered as the cause for the greater percentage of carious teeth, while acquired habits of thumb or tongue sucking, nasal obstruction, mouth-breathing due to carelessness or laziness, also inherited physical inharmonies, intermarriage between persons of different nationalities, etc., will explain the larger percentage of malocclusion and deformities in the jaws and teeth of children.

Science and reason may argue for certain definite rules of life, but environment, custom, and conventionality may demand some departure from such rules in order that our idea of comfort and happiness may be realized. Ought we to refuse to ride by train, streetcar, or other conveyance, because, in so doing, we are not exercising certain muscles in the way nature intended?

We can advise the parents whose children come under our care, and impress them with the necessity for the proper mastication of food and oral hygiene, but do you believe that we can ever prevent the man of large stature from marrying the woman of diminutive size? Until such phases of eugenics can be controlled, we may not expect any appreciable decrease in the great number of cases of malocclusion and malformation that we now observe in the mouths of children.

Dr. J. V. Mershon, Philadelphia. Dr. Kelsey has very clearly pointed out in his paper a saying of Dr. Noyes, namely, that bone is built in response to mechanical stimulation, the chewing of food by the infant supplying the mechanical stimulation necessary for the development of the maxillary bones. The essayist pointed out particularly that the dentist's important responsibility does not begin after all the teeth are erupted, but starts practically at the birth of the child. It will be a tremendous step forward if the members of the dental profession start to send for the babies of their patients as early as they are fit to be brought to the dental office

for examination. The essayist has mentioned another fact in regard to which the dental profession has been taught wrongly, judging from many mouths in which the deciduous teeth are still present; and that is that malocclusion rarely exists in the deciduous teeth. I believe it is beginning to be generally accepted among orthodontists that a large percentage of malocclusion of the permanent teeth is only an exaggeration of that which already existed in the deciduous denture, and undoubtedly can be traced to a lack of proper mechanical stimulation, which the essayist dwelt upon so ably.

Dr. J. G. Lane, Philadelphia. The subject under discussion is certainly a very interesting one, and has been exceedingly well presented by Dr. Kelsey. I believe there is no other branch of dental science in which such beneficial results could be obtained by prophylactic measures as in the prevention of malocclusions. As has been stated by the essayist, Dr. Jameson, and Dr. Mershon, it is easily possible, by prophylactic measures and by precautionary methods, by having the functions of these various organs and tissues made normal early in life, to prevent malocclusions.

Dr. Kelsey (closing the discussion). I have very little to say in closing. Most of the discussion has been an elaboration of ideas contained in the paper. Dr. Friesell probably misunderstood some of the points I intended to emphasize. My paper was in no sense a discussion of the etiology of malocclusion, except as related to this one phase, which I consider one of the most important. If he could substantiate the theory that the intermarriage of persons of greatly different characteristics—such as size, race, etc.—is responsible for serious malocclusions, I am sure he will do a great favor to the profession. Fifteen or twenty years ago this question was being much discussed, but it has not been taken very seriously in the last ten years, though I am not willing to say that it may not be revived with some success, and if it does contain any truth, we would like to know about it.

Dr. Mershon. I move that a vote of thanks be extended to the essayist for his very valuable and instructive paper. [Motion carried.]

Motion was then made and carried to adjourn until the evening session.

Wednesday—*Evening Session.*

The meeting was called to order on Wednesday evening, July 1st, at 8 o'clock by the president, Dr. Seip.

The first item on the program for the evening session, as announced by the President, was the reading of a paper by Dr. W. D. DeLong, Reading, Pa., entitled "Anesthesia and Its Relation to Operative Dentistry."

[This paper is printed in full at page 162 of the present issue of the Cosmos.]

Discussion.

Dr. R. H. Riethmüller, Philadelphia. Whenever there is a new appliance, a new method, or theory advanced in dentistry, unusual enthusiasm is displayed. This of course is one unmistakable sign of the progressiveness of dentistry; yet, on the other hand, a progressive spirit is simply a duty of the up-to-date practitioner. The man who is behind the times to the extent that he does not familiarize himself with the latest theories, apparatus, and methods is nothing short of criminal. He is as criminal as the surgeon who does not follow the strictest rules of asepsis simply because thirty years ago—or during the time of "the war"—wounds healed and limbs were amputated without any rules of asepsis being observed,—and some of the victims still live to tell the tale. But enthusiasm in dental endeavors has sometimes overreached itself, and the general wave of disappointment is almost always associated with an absolutely injudicious condemnation of the very methods which, at the beginning, were taken up with such enthusiasm. We only need to point out, for example, the enthusiasm with which cataphoresis was practiced, and the disgust with which it was soon dropped, although there was

considerable merit in that method. The same applies to cocain. When Koller, in 1881, demonstrated the merits of cocain, the application of this alkaloid was taken up with excessive enthusiasm, but, alas, experiments had not been carefully carried out, and a great many disappointments, in fact a great many disasters, followed the early application of this drug in dentistry. I might mention other examples, such as processes of casting and casting appliances which were at first received with enthusiasm and then dropped with disgust. Celluloid plates, porcelain, and other similar methods have had similar experiences. Caution is also to be advised in the new field of local anesthesia. A great many anesthetists are taking up novocain-suprarenin anesthesia, but I for one would be the last person to advise the injudicious use of this most valuable method, unless the practitioner fully realizes the absolute necessity of a mastery of the pharmaceutic, physiologic, and anatomic principles upon which the method is based, and a full appreciation of the imperative necessity of absolute asepsis, without which local anesthesia can only do harm.

Our essayist justly emphasizes that the dentist is able to become an anesthetist, fully as capable as the medical man—for have not such men as Wells, Hewitt, Teter, Fischer, and others taught medical men a great deal that they did not know about anesthesia, both general and local? Yet if every dentist is supposed to be his own anesthetist, general as well as local, it would be advisable that he receive more efficient training in the diagnosis of cases before inducing anesthesia. The dentist, of course, in the short period of his training is hardly able to become a proficient diagnostician of lesions of the heart, kidney, and lungs, but he should be able to make a fairly thorough and reliable preliminary examination in every case in which general anesthesia is to be induced. If the dentist suspects systemic lesions, it is a very wise policy on his part to call in a trained anesthetist, and let him assume the responsibility of anesthetizing the risky patient.

Our essayist very justly emphasizes the fact that the machine will never take the place of the anesthetist. It is the operator's personal experience, his circumspect methods, his wide range of knowledge, and also his personality which are very important factors in regard to the safety of the anesthesia that is to be produced. The essayist very ably remarks that anesthesia is no plaything. Accidents will occur, but luck is usually with us; yet luck is not a scientific principle, and no method should be followed in which luck is relied upon as an important factor. How many dentists are there who daily induce general anesthesia, or analgesia—which is only the incipient stage of general anesthesia —who have more of a guard against accidents in their offices than a bottle of stale aromatic spirits of ammonia? And how many practitioners are thoroughly familiar with the methods of resuscitation? A great deal more caution is probably advisable, as the essayist says, in guarding against accidents, so that when they do occur—and, as most of you know, they will occur—the operator will be able immediately to combat any more serious sequelæ. This, of course, necessitates constant vigilance on the part of the anesthetist—who, in the case of the dentist, must assume the responsibility of the anesthetist as well as that of the operator. The surgeon's duty is considerably simpler than that of the dentist. The surgeon leaves the induction and control of the anesthesia completely to the trained anesthetist, who sometimes is not quite so well trained as he should be, because he is a green interne; yet the surgeon will not have his operation, no matter how simple or complicated it be, interfered with by the watch necessary over the patient's behavior under the anesthetic. Therefore, in any extensive or serious surgical work, I cannot see how the operator can do without a trained anesthetist.

The essayist has very well pointed out the cases in which anesthesia by nitrous oxid and oxygen is indicated, viz, especially inflammatory conditions and the excavation of hypersensitive dentin. In these conditions the application of this

method is almost ideal. There is no danger of carrying infection to deeper strata as there would be if local anesthesia by infiltration were applied, and no possibility of injuring the vital tissues underlying the hypersensitive dentin, because all that is necessary for the painless performance of the operation is superficial anesthesia, or analgesia.

The essayist says that painless excavation of hypersensitive dentin can be performed quickly, and in practically every case with little or no bad after-effects, which is true. It is also true, however, that there are contra-indications to nitrous oxid and oxygen anesthesia, as there are to other anesthetic agents, both general and local. In this connection I would point out an article by Dr. A. H. Miller which appeared in the *New York Medical Journal,* and was reviewed in the DENTAL COSMOS,* on "Gas-Oxygen Anesthesia: Indications for Its Use." He points out that it is absolutely unwise to make anyone believe that no deaths have ever occurred from nitrous oxid and oxygen anesthesia. From an observation and very thorough perusal of something like fifty papers on this subject, published here and abroad, he shows the following report of cases of death:

OBSERVER.	DEATH ASCRIBED TO—	
Teter.....	Shock and primary cardiac failure	1
Crile.....	Myocarditis, six hours after operation	2
Lydston...	Anesthetic	3
Allen.....	Uremia	4
Allen.....	No details	25
Allen.....	No details	25
Gatch.....	Hyperthyroidism	5
Gatch.....	Pericardial effusion	5
Gatch.....	Lymphatic diathesis	5
Olow.....	Diseased heart and arteries ..	6
Boys.....	Anesthetic	7
Miller.....	Suffocation (vomitus inspired)	8
Flagg.....	Anesthetic	9
Teter.....	Impure gas	10
Teter.....	Impure gas	10
Salzer.....	Anesthetic	11
Collins....	Impure gas	12
Buchanan.	Anesthetic	13

* See DENTAL COSMOS for May 1914, vol. lvi, p. 628.

These statistics probably could be corroborated, if more reliable statistical data were compiled in this country. The statistics quoted show that the safety of nitrous oxid and oxygen anesthesia, while it far exceeds that of any other general anesthetic, is not absolute. It should be pointed out that there are certain easily recognizable contra-indications in which no risk should be run.

The essayist wisely remarks that in his practice he resorts to nitrous oxid and oxygen only occasionally, and condemns its indiscriminate use. No further comment on that very judicious statement is needed.

He emphasizes the usefulness of pain as a diagnostic agent. Pulp exposures, for instance, are easily overlooked if the patient is in the anesthetic state, and a filling might be inserted thereupon, and very serious trouble arise afterward. In this connection, I would cite a few words from a treatise by Dr. Goldscheider in regard to pain as an aid to diagnosis:

> Pain makes us realize that some external danger is threatening which we may still avoid, or that harm has already been done to the body requiring our care if we would escape more serious consequences. Pain arises as a warning signal whenever we are exposed to such conditions of life as by their continued influence would involve general disturbances of health. Pain appears before or simultaneously with the outbreak of disease, warning man that his body is in a diseased condition and requires care. . . . Pain is the physician's most powerful assistant, whose demands the patient follows in blind obedience, and who saves the physician many an advice as to diet and conduct. . . . To wipe out pain entirely is an impossibility, and we cannot and would not do without it, since pain is necessary not only as a monitor in the combat against the hostile powers of matter, but also as an inspirer to ethical emotions. For it is chiefly in the reminiscence of one's own pain, both physical and mental, that love and active charity are rooted.

The essayist appropriately points out that nitrous oxid and oxygen anesthesia involves a general intoxication of the nervous system. This has been doubted

by some friends of general anesthesia, but how could anesthesia be produced, how could the nerve terminals be paralyzed, unless such a condition as general intoxication of the nervous system were produced? We could not obtain a condition of analgesia or anesthesia unless all the nerves were affected—therefore the term "general anesthesia"—and anesthesia is only possible by intoxication. Various theories have been propounded as to how the nerve cell is anesthetized, but the actual process of anesthesia is as yet unexplained. Possibly the fatty substance within the cell, or the respiratory or sensory centers, are affected individually or in combination. The fact, however, that general intoxication of the nervous system is induced by any and every general anesthesia has been demonstrated beyond a shadow of doubt, and every anesthetist has had many cases of laughing spasms, sexual excitement, or hallucination, which prove this contention. The possibility of such occurrences renders the presence of a third person, no matter whether general or local anesthesia is induced, imperative from a medico-legal standpoint. There are dentists who are serving terms of imprisonment because of *bona fide* accusations made by persons under persistent hallucinations due to the influence of general or local anesthesia. That general as well as local anesthetics produce intoxication of the nervous system is shown by the violence with which alcoholics often resist general as well as local anesthesia. Crying spells, involuntary micturition, vomiting, and sexual excitement show that general as well as local anesthesia—general more so than local—means the intoxication of the central nervous system.

The essayist has also very fittingly pointed out that nitrous oxid and oxygen can produce a habit. This is shown by the eagerness with which some patients take the chair because they like the sensation produced by the anesthetic. In some instances, office assistants have been in the habit of robbing their employers of nitrous oxid, because they liked to become intoxicated therewith. In one case that I know of, a laboratory man consumed in one week no less than three cylinders of nitrous oxid, because he liked the effect.

It is also difficult and great caution is necessary to determine whether a patient is really in the analgesic or the anesthetic state. The dividing line is extremely difficult to define, and in a great many cases when analgesia is claimed to be produced, anesthesia is really present. Temperamental conditions must also be reckoned with. We know that in the South American races, owing to their excitable temperamental makeup, due to influences of the hot climate, nitrous oxid and oxygen has a different effect from that observed in the more sedate races of temperate climates.

There are some technicalities which we have to consider in employing nitrous oxid and oxygen analgesia or anesthesia. Preparation of the patient for the anesthesia is most important, if the operator wishes to relieve him of the embarrassment of vomiting or other physical mishaps. The size and shape of the apparatus must also be taken into consideration. The operator's movements are often interfered with by the apparatus, and even with the nasal inhaler the field of operation is not always quite clear. Vision of the operative field is often obscured by blood, the aspiration of which must be prevented by all available means to avoid serious consequences. The operator himself or his assistant has to make changes in the position of the patient in order to obtain the most suitable situation without interference. After the operation the patient generally requires a shorter or longer period of rest.

It should be especially emphasized in regard to nitrous oxid and oxygen analgesia or anesthesia that there is an appalling lack of realization of the necessity for the sterilization of the mouthpiece or inhaler. We are doing everything we can to stamp out that most dreaded disease, tuberculosis, yet how many practitioners are in the habit of sterilizing their mouthpieces after every use?

Nitrous oxid and oxygen anesthesia has no doubt been one of the greatest boons to general surgery, for the reason that it has reduced danger to a minimum if the anesthesia is induced by a skilled operator. Crile of Cleveland has done a great deal of valuable research in this field, and he has at the same time pointed out its limitations and the folly of swearing blindly by one method. He believes in mixed anesthesia, and his whole theory of anoci-association, which tends to do away with surgical shock entirely, is based on the combination of general anesthesia by nitrous oxid and oxygen and local anesthesia by novocain-suprarenin, by which method a large operative field is eliminated, and shock of the central nervous system is avoided.

The essayist, strange to say, finds fault with dental teachers and manufacturers. It seems that all the iniquities of dentistry are habitually charged against the schools and the manufacturers. The dental schools, so far as I know, give very careful courses in anesthesia, but the dental student is supposed to familiarize himself with all methods of anesthesia and the administration of all anesthetics. It is practically impossible for the schools to have every student induce each kind of anesthesia say 12 times, and even then there would be some dullards who, though they had the opportunity, would not fully grasp the subject and become efficient in the administration of an anesthetic. In order to have proper training in the various methods of anesthesia, a special course is absolutely necessary, and if these courses can be given by men of proper intelligence, then they will be welcomed by the profession. The essayist suggests that the societies undertake to give such courses, and in this connection I would call attention to the fact that the Academy of Stomatology of Philadelphia has instituted such a course, and I think other societies have done the same, and it is hoped that their example will be followed all over the country. At the same time I wish to express the hope that these bodies will not stop short, that they will not favor one method of anesthesia, but be broad and progressive enough to give fair consideration to all methods which have been proved valuable. Although the dental supply houses are twenty-five years ahead of the rank and file of dentistry in this respect, they are again being blamed. To illustrate: Ask the proprietors of any supply house how much money they have spent in perfecting anatomical articulators, anatomical molds of teeth, investigating the amalgam question, and in similar important dental research, and what the returns have been, and your respect for the dental supply houses will be considerably increased. They know that in a few years the progressive practitioner will demand these things, that it is their duty to engage in conscientious scientific experimentation, and I think they deserve a great deal of credit for the sacrifices which they have made and are continuing to make. Since there are not enough teachers to demonstrate to their fellow practitioners the correct use of the method of nitrous oxid and oxygen analgesia and anesthesia, who is going to demonstrate it for the dental supply houses to their customers? Moreover, as you well know, most of the dental houses have these demonstrations performed by experts who hold diplomas from reputable colleges. The dental supply houses are business corporations primarily, and not charitable institutions.

These remarks have been made not in a derogatory spirit, or by way of unfair comparison, not in any hypercritical attitude, but in an effort to safeguard one of the most valuable accessories to the dental instrumentarium against unwise and injudicious use which would only spoil its usefulness in a great many practices, and to urge as emphatically as I can that all methods which have been proved valuable be given a fair trial. The element of personality also must be regarded, and what is the operator's fault should not be ascribed to the mechanism of the machine, and good luck should never be indiscriminately relied upon.

At the recent International Medical Congress of 1913, held in London, Eng-

land, the subject of anesthesia was for the first time included as a subsection, and the London *Lancet* in commenting on this remarkable fact—at least it seemed especially remarkable in England—published in the "Annus Medicus 1913" a report on the progress made in the field of anesthesia in medicine and dentistry, and in addition thereto a very important editorial, a review of which I will read to you:

"The whole subject during the generation which has expired between 1881 and 1913 has cast off much of its unscientific trappings, while its exponents from across the seas, equally with those who are British, can lay claim to pursuing their work along lines more or less scientific. The scope of anesthesia as we know it today is so far wider than it was in the times of Simpson and of Clover that an entirely different language is used in describing the results and the procedures. Practically, nitrous oxid, ether, and chloroform, given by the simplest apparatus or without any at all, formed the armamentarium of the whilom anesthetist. . . . At the recent International Congress of 1913 the subject was reckoned of sufficient importance to obtain its inclusion as a subsection, and to tempt into its arena such distinguished pioneers of new developments as M. Tuffier of Paris, Professor Heinrich Braun of Zwickau, Professor L. Burkhardt of Nürnberg, and that eminent scientist Dr. S. J. Meltzer of the Rockefeller Institute."

The methods of introducing anesthetics have been revolutionized, and in other directions progress no less gratifying has occurred. In the days of Snow and Paul Bert, as in our own, fierce have been the contests about the dangers of anesthetic agents. There have been those who delighted to say "I am of Paul," and in response we heard "And I of Apollos;" the chloroformists *versus* the etherists, the heart-failure men against those who believed dangers arose alone from respiratory failure. Today we find that such questions can be, and indeed are, put to the test of experiment. The anesthetist no longer confines his attention to the circulatory and respiratory systems; he recognizes that metabolism may be profoundly and deleteriously affected by his agents, and his endeavor is to obtain all the good he can from his anesthetics and rob them of their potential evils. All methods adopted to prevent pain, whether those connected with inhalation, with spinal anesthesia, or with local analgesia, are subject to the disadvantage that they may produce shock, even though in their intense action it may have been their beneficent rôle to abrogate shock due to surgical trauma. Alike as synergents to anesthesia and as a means of abolishing this shock are the employment of alkaloids and the combining of general anesthetics with local conductive analgesia; and these complex systems have found expositors in Dr. Crile and Dr. Gauss, both of whom are recognized as originators of special methods. Certain anesthetics are held provocative of shock, so that nitrous oxid associated with oxygen is preferred by some surgeons. The technique of their use in major surgery has been worked out by Dr. Teter, and his report and description of his modified apparatus proved how scientifically such schemes are now elaborated.

It has been my pleasure to read and review within the last year a large number of articles on this subject, and there is no doubt that nitrous oxid analgesia is one of the most valuable aids to the dentist, but its safe and judicious application cannot be too heartily insisted upon, for if it is used in a reckless way a valuable method is once more in danger of being consigned to the scrap-heap, where we have seen other valuable methods go before. I wish to close with a few words which I used in summing up a review of several articles on this subject in the DENTAL COSMOS (see DENTAL COSMOS, July 1914, vol. lvi, p. 881): "A study of the wonderfully generous harvest in the field of anesthesia of last year and the first months of this year will convince any fair-minded reader that there is a great deal of work yet to be done both in general and in local anesthesia; that both procedures have their definite places, and that the men who are endeavoring to create an artificial prejudice as to either one or the other method are wickedly and selfishly impeding progress and doing a great injustice to dental science, which has contributed so much to the present status of perfection of anesthetic means."

Dr. C. S. TUTTLE, Philadelphia. Many times have we heard the adage that "Discretion is the better part of valor," and it appears that Dr. DeLong has added "conservatism" as well. En-

thusiasm, at times, runs away with the best of us, and it is true that from time to time men come before us who are loud in their praise of something which sounds very good at the time, but which, when viewed more calmly and in a subdued light, proves valueless. The essayist relates not only the value of nitrous oxid and oxygen, but also points out cases in which its employment for the relief of pain is contra-indicated. There is no doubt that the combination of these two gases and their application in the dental office has done more to relieve the suffering which patients heretofore have been obliged to endure than any other agent which has been presented to us. It is also true, as Dr. DeLong tells us, that an indiscreet use of nitrous oxid and oxygen will eventually result in defeating our very purpose. All of us meet from time to time in our practice patients who do not tolerate an anesthetic well, and here it would be wise to avoid the administration of an anesthetic unless it is found absolutely necessary. On the other hand, we are told that less than twenty per cent. of the population of this country are, at the present time, receiving dental attention. Perhaps ten per cent. of the balance are situated in parts of the country so remote from a dentist as to render it impossible to reach him. It is reasonable, then, to presume that at least two-thirds of the remaining seventy per cent. neglect their mouths by reason of the fear of being hurt. Most of these we will find to be well educated, and it is among the educated that we have the highly strung type, who will not submit to any painful operation. Rather will they allow caries to form, and mouth infections to make such an inroad that they finally are forced to consult an exodontia specialist. It does not take long to imagine the wonderful good we shall be able to do for suffering humanity after we have succeeded in educating these *unattended* to the possibilities of nitrous oxid and oxygen for the alleviation of pain.

Much as I admire and appreciate Dr. DeLong's scholarly essay, I must take exception to his manner of expressing his disapproval of the postgraduate courses of instruction which are now offered to the dental profession. The men teaching this work have traveled from one end of the country to the other, reaching dentists in many localities so far removed from any of our colleges as to make it impossible for them to receive any such special instruction. While it may seem to the essayist that exaggerated claims have been made by these teachers, such is not the case, and it is most likely due to a lack of searching investigation on his part that he believes that these men teach the use of the new apparatus and the administration of this anesthetic for "professional graft." Among these instructors and those who have availed themselves of the advantages of this postgraduate work will be found men high in our profession, men of integrity and honor, members of our state societies, young and old, who seek knowledge which is not, up to the present time, to be found in the dental colleges, nor is it offered in any other way, with the possible exception of one or two isolated postgraduate schools, whose teachers themselves have most likely received their fundamental knowledge in this manner. History tells us that knowledge was first spread about by traveling teachers, who later settled in certain communities which have since become famous for their institutions of learning, such as Heidelberg, Athens, Rome, etc., and, as these reverend pioneers shed light into the dark ages of ancient history, just so are these young and wideawake dentists helping a sleepy profession to awaken to its full ability and true value. They have blazed a path of increased knowledge upon which none may fear to tread. The term "financial return" may seem harsh to the essayist, when placed beside the soft-sounding term "professional fee;" but do not both these terms convey the same meaning? One is plain and straight from the shoulder, the other puts the soft pedal on the almighty dollar, for which, no doubt, our essayist as well as the vast majority of those present are struggling

today. And why not? Is it not well, and do we not owe it to ourselves and to those depending upon us, not only to leave behind us a record of work well done, but also a substantial bank account upon which our families may lean, after we have entered into the Great Beyond? You will find very few Thomas Evanses among dental practitioners—their fortunes are not so great, and if someone comes along with helpful suggestions which will tend to shorten the long—and of necessity confining—hours of the dentist, I beg that he be received kindly and not called "pseudo-teacher." Were the dollar mark branded on most of the topics taught, I, for one, would rejoice to learn of it, for judging from the appearance of fifty per cent. of the medical and dental offices, it is high time that remuneration for services were assigned a more important part in our equipment. The decreased number of graduating dental students is almost alarming, and unless something is done along the line of financial return, dentistry will go out of business. The discouragement which the younger men are receiving from dental practitioners is deplorable. I related an incident in a paper read recently before the Southern Dental Society of New Jersey, which may bear repeating here: "A few weeks ago a young man about to graduate from the University of Pennsylvania called upon me. He was evidently much depressed, and finally admitted that he much regretted having taken up dentistry; was in fact disgusted with the profession, to say nothing of being discouraged. This was due to the fact that he had the day before visited the office of an older practitioner in our city, who had told him that, had he a son, he would not allow him to study dentistry; that there was no money in the profession, and that it was generally run down at the heel." When you consider that this boy had worked four years in high school, two in a preparatory school, and three at the university, you can well imagine that this statement, coming from one who had already entered the work, was disheartening to listen to.

"Business efficiency," too, may sound harsh, but how many of us really know its true meaning? How many professional men today are using their trouser pockets for a cash drawer? We would do well to change these methods and accept a few of the lessons from our brothers of the commercial world, upon whom, after all, we are dependent for our living, and to avail ourselves of the lessons given in postgraduate work along the lines of modern business efficiency, also of anesthesia, mouth infections, and the latest method of placing a gold inlay. Rather than have this society place its stamp of disapproval upon these teachers, let it join with the other state societies, who are not only giving these men their approval, but are gathering their members in classes for this work; and it has recently come to my knowledge that several of the state societies have already made some of these men honorary members. If we can but inspire co-operation and lay aside professional jealousies, our state societies and our colleges will take on new life, which cannot but spread throughout the cosmos of dentistry.

Dr. J. D. Thomas, Philadelphia. I do not know really what more can be said on the subject of nitrous oxid anesthesia. I think we have had one of the best dissertations on this subject that I have listened to for a long time. The time seems to be ripe for this subject to be well discussed and well understood. I have had some experience in nitrous oxid, but no experience with nitrous oxid and oxygen either in the production of anesthesia or that of analgesia—and I was almost going to say that I am glad of it. Nevertheless, this anesthetic mixture has its uses, and can be made to help in the work which the dental profession has to do today.

The other objection I could raise to Dr. DeLong's paper is that he did not go deeply enough into the subject, but Dr. Riethmüller has supplemented it to a great extent. There is nothing in what Dr. DeLong has said that I cannot give him high commendation for. I have always contended that nitrous oxid

is one of the most dangerous of all anesthetics, and yet it has the reputation of being the safest of all; and why? Simply because it has been *the* dental anesthetic, and many dentists have had their own apparatus for producing anesthesia for tooth extraction for years. The symptoms accompanying it are so perceptible that, when a person shows these symptoms, we simply cease giving the gas and allow the patient to breathe air, and that has been sufficient to bring about a recovery. We are depending upon the ideal effects of nitrous oxid, yet we must remember that it is not a life-saver, but an inert gas. As soon as the patient begins to breathe gas, oxygenation ceases, and the patient is on the rapid road to asphyxia. Asphyxia produces unconsciousness in the strongest men in sixty seconds, in a child in twenty seconds, therefore this condition may be serious for the patient. For this reason I am free to say that in my opinion nitrous oxid is the most dangerous of all anesthetics, because the anesthesia comes so quickly that unless the anesthetist is very familiar with it—and it requires a good deal of practice to become expert—we are liable to have serious conditions before we realize their presence, and it is a wonder to me that we have thus far escaped with so few fatalities. At the time when Dr. Litch wrote a chapter on this subject in the "American System of Dentistry," in all the thousands and hundreds of thousands of cases in which nitrous oxid had been given to patients by dentists throughout the country for the simple operation of tooth extraction, there had been only eleven fatalities; but at that time, viz, twelve or fifteen years ago, nitrous oxid was not used by the dental profession as it is today, for general operative work. Nine of these eleven fatalities were clearly proved to be due to causes other than nitrous oxid, and only two at that time could be legitimately charged to nitrous oxid. Therefore the profession and the public at large were justified in claiming that nitrous oxid was a perfectly safe anesthetic. The statistics cited by Dr. Riethmüller, however, corroborate my contention that nitrous oxid anesthesia is by no means free from risks. Why so? Is it because the operator is not sufficiently educated in its administration? Is it because he is careless? To my mind most fatalities are more due to carelessness on the anesthetist's part than to the gas itself. You know that in hospitals the internists are almost always entrusted with the responsibility of administering nitrous oxid, while ether and chloroform are administered by trained anesthetists. Training in the administration of nitrous oxid is just as necessary as in that of ether, and anesthetists should, as I have often tried to impress upon them, take into consideration the fact that there is no necessity for extremely profound anesthesia, but that there is a surgical zone, a zonal obliteration of reflex which, after it has once been reached, will require little ether, chloroform, or nitrous oxid to preserve for the operation. If this rule is observed, the patient will completely recover a very few minutes after the operation has been finished. I was some time ago present at an operation on a boy of fifteen years of age, in whose fingers fragments of a needle had become lodged, as the X ray showed distinctly. The operation was done under ether, and it did not require more than three minutes for the surgeon to remove the needle, but the anesthetist kept pouring on ether until the whole operation was completed and the wound bound up, and the boy did not recover from the anesthetic for forty-five or fifty minutes. There was no necessity for this anesthetic procedure, and I should not have been surprised if the patient had died, because he looked exceedingly white, and was not normal for a week afterward.

Dr. Riethmüller has referred to alcoholics. We know that the only difference between nitrous oxid and alcohol intoxication is that, in the one, anesthesia is produced by inhalation, in the other by ingestion. Suppose alcohol anesthesia is carried to the extreme, what is the process? First stimulation, then exhilaration, intoxication, stupor,

unconsciousness, and, if we go far enough, death. The same process goes on when anesthetics are given, but why should we carry anesthesia to that point? If a man falls down on the street and gets to the point of stupor and unconsciousness, there is no reason why we should want to keep him in that condition. After the surgical zone is under control, there is no reason to keep pouring on the anesthetic and continuing the condition for another twenty-four hours. We would then be running a risk with the patient, particularly so in the case of nitrous oxid.

A short time ago a physician who is well versed in administering anesthetics brought a patient to my office for the extraction of some teeth under nitrous oxid. I administered the gas, and began to extract the teeth. When I started, this physician told me not to begin yet, as the patient had not relaxed. After I had finished the operation, I told him that the patient did not have to relax under nitrous oxid. If I saw a patient relax under nitrous oxid, I would consider him very near death. After the anesthesia has been carried to the extent of the tonicity of the nervous system, anything beyond that stage will produce exhaustion, and finally collapse, and this we do not want to occur under nitrous oxid.

A great deal has been said tonight about the proper education and experience of men who are to give anesthetics, particularly nitrous oxid and oxygen. That is absolutely essential, of course, but as for danger, a great deal has been said of accidents under nitrous oxid anesthesia in cases of heart lesions, kidney lesions, albuminuria, diabetes, and different cases of inflammations or lesions of the vital organs; and yet I would rather administer nitrous oxid than any other anesthetic to a patient with heart disease or diabetes, provided the patient has enough vital force to bring him back to normal. This vital force is the guide I go by in administering nitrous oxid. The oldest patient I ever administered nitrous oxid to was ninety-two years of age. I have had hundreds of cases of from eighty to ninety years, and children of all ages, but I have never come so close to fatal accidents as with some of the strongest athletes, whose constitutions are ruined by the strenuous athletic activities of the present day. That may seem strange, but I contend that in running races as practiced at the present time, the nervous system, the vital force, is carried to such a point of collapse and exhaustion that the athletes cannot regain their normal vigor, and these men are the most dangerous patients for anesthesia, because we have nothing to guide us. The patient may be a fine-looking fellow, full of vigor apparently, but the anesthesia reduces his vital force to such a point that it is difficult for him to recuperate. Only a month ago I had such a specimen come to my office from Baltimore for the removal of an impacted third molar. He went through the operation as nicely as could be expected. After the operation, while he was rinsing the mouth, his face became very pale, and he quietly folded his arms and passed off into unconsciousness, and it required some three or four minutes of hard work at artificial respiration before I succeeded in getting the patient to breathe normally again.

Dr. Riethmüller spoke also of nausea. I received a letter from Dr. Teter some time ago which gave me an inkling of the frequency of this condition, and in which he asked me fifteen questions in regard to nitrous oxid and oxygen. I could not pretend to answer them all, because this would have required writing a book, but I attempted to answer those which were particularly interesting to me. He asked in the first place, "What percentage of nausea do you have following operations under nitrous oxid alone?" The next question was, "What percentage of nausea do you have following operations under nitrous oxid and oxygen?" I have not seen a case in twelve years, in over sixty-five thousand administrations. The next question was, "Have you had any cases remain unconscious unduly long after the discontinuance of the anesthetic, and if so,

how long have they remained unconscious?" I never saw anything of that kind. The next question was, "Have you had any fatalities, and if so, how many?" I never had any fatality in my office, that is, in any ordinary case. The only case I have ever had is one that could be explained by some other cause. A friend of mine, a strong man weighing one hundred and eighty pounds, for whom I had administered gas four or five times previously, presented for the extraction of two teeth. I administered gas and performed the necessary operation, the patient returning to consciousness normally. He rinsed his mouth, rose from the chair and walked across the room to the washstand about ten feet away, filled the water-glass and returned to the chair; all this time I was carrying on a conversation with him, not thinking that there could be anything wrong. He waited in the chair for twenty or twenty-five minutes, and after the bleeding ceased, he went to the mirror and put his hand to his mouth, but his hand came down like this [illustrating]. He said to me, "John, that hand seems numb." He looked a little pale, but went home a few minutes afterward, saying that he was feeling all right, but he died that afternoon. This was not a case of death from nitrous oxid, nor was the nitrous oxid any more responsible than any other excitement may have been.

This recalls to me another case: A man desired an operation performed under gas, and who, I saw, was not in good condition. I told him to have his physician examine him, and if he still wished to have the operation performed and his physician gave his authorization, to come back the next day. The following day I received word that the man had died at ten o'clock that night.

There is one point that I would like to speak of, that is, the history of nitrous oxid anesthesia. We all give credit for the discovery of nitrous oxid anesthesia to Horace Wells, we credit Dr. Morton with the discovery of the anesthetic properties of ether, and Dr. J. Y. Simpson of Edinburgh with the discovery of the anesthetic properties of chloroform. In a book published in 1894, which contains an account of the fiftieth anniversary of the discovery of anesthesia, celebrated in this city, these facts are on record. I want to mention this because history, as we understand it, is being placed in jeopardy. It is now twenty years since the celebration referred to, and in five years more it will be time to celebrate the seventy-fifth anniversary of the discovery of anesthesia, and it would be well for this and the National society to celebrate this event. Then we should put our shoulders to the wheel to have a statue placed in the Hall of Fame in New York city in memory of the discovery of anesthesia by Horace Wells. The reason why I am calling attention to this is that recently the credit for the discovery of anesthesia has been given to Dr. Long of Georgia, and the University of Pennsylvania has placed a memorial tablet on one of its buildings in memory of Dr. Long as the discoverer of anesthesia. I will read to you what was said in the history mentioned in regard to Dr. Long: "Dr. Crawford W. Long of Georgia used ether for anesthetic purposes three times during 1842 to '43, and now appears as a claimant to the discovery. But Dr. Long's connection with the subject was not mentioned until many years after the fact. He did not write a word in regard to his discovery, nor did any notice of it appear in print until 1849, five years after Wells' discovery, and seven years after he himself had administered the ether. How could anyone, after knowing of such a boon to suffering humanity, resist for even a day the impulse to 'fly on joyful wings, cleaving the sky,' to proclaim the coming of this great consolation to the afflicted?" Dr. R. M. Hodges wrote of this claim, "Not a physician or surgeon ever used ether because Long had used it; nor did mankind learn from him that anesthetic inhalation for surgical purposes was possible. His claim was made after the fact, and resting on no better foundation that those claims similarly made by other aspirants for distinction, a class

so numerous as to have been named by the London *Lancet* 'The class of jump-up-behinders.'" I speak of that, because I do not wish someone else to have the great honor which belongs to Horace Wells and to Morton. Dr. DeLong spoke of this, and I hope that some method or plan will be adopted by which we can definitely place the honor for this discovery where it belongs. A movement has been talked of, but it has not yet taken definite form. In Washington we have put in the hall of the army and navy medical museum a beautiful bust of Horace Wells in memory of his great discovery.

Dr. DeLong (closing the discussion). It is hardly necessary to say much in closing the discussion. My desire and my anticipations have been realized, that is, that I might be able to say something that would produce a discussion, which it has done, a discussion more interesting and more satisfying than the paper itself. I was particularly anxious to make this paper short, as I anticipated a good discussion because of the interest that is being manifested in this subject; and because of my efforts at brevity, I may possibly not have been as plain in my statements as I otherwise should have been.

I am sure that Dr. Riethmüller has misunderstood me when he found objection to my saying that nitrous oxid and oxygen anesthesia is the method *par excellence* in practically every case, and that its application is never followed by bad after-effects. When I made that statement, I had in mind cases where it is indicated. When I spoke about pseudo-teachers I did not have in mind teachers in the dental colleges; I had not in mind anybody who would in the spirit of true professionalism give postgraduate courses. I approve most heartily of postgraduate courses. I would, however, rather see them conducted in dental schools than by itinerant teachers. What I had in mind was the attempt to increase one's fees by means of a special method or machine instead of giving it in the open and charging a proper fee for the work. I love the almighty dollar as well as anybody, and I respect every man who gets a big fee; and I also realize that we are underpaid as a profession; but let us raise our fees openly, and not hide back of a method and say that because we are using a method or machine which our fellow practitioner does not use we ought to have a better fee. It was in that spirit that my statements were made; and because I feel strongly about this matter I used strong language. It is commercializing, it is belittling the profession not to raise our fees openly, for professional services rendered, instead of because of the fact that we may be skilful manipulators of a machine.

I have no quarrel with the manufacturers. I know that they have been and are doing a great deal for the profession, but I could feel a smile going over your faces, even if I could not see it, when Dr. Riethmüller referred to the labors that the manufacturers have been engaged in toward bringing out anatomical molds of teeth. I thought we would have to ask ourselves, Who labored the harder, we dentists in inducing the manufacturers to give us anatomical molds, or they in inducing us to use them?

The Secretary read a communication from the Panama-Pacific Dental Congress Committee urging a large attendance at the congress in San Francisco.

The Secretary also read a communication from the Research Committee of the National Dental Association.

Following this, Dr. T. P. Hinman, Atlanta, Ga., vice-chairman of the Research Commission, addressed the association in regard to the work of the commission.

Motion was then made and carried to adjourn until 9.30 Thursday morning.

(To be continued.)

DENTAL SOCIETY OF THE STATE OF NEW YORK.

Forty-sixth Annual Meeting.

(Continued from vol. lvi, p. 1273.)

FRIDAY—*Afternoon Session.*

The meeting was called to order on Friday afternoon, May 15th, at 2.30 o'clock, by the president, Dr. Smith.

The first order of business for the afternoon session was the report of the Committee on Scientific Research, by the chairman, Dr. W. B. DUNNING, which was followed by a paper by Dr. WM. J. GIES, New York, entitled "The Possible Influence of Internal Secretions on the Condition of the Teeth."

[The report by Dr. Dunning and the paper by Dr. Gies, together with the discussion, will be published in a later issue of the COSMOS.]

The President then introduced Dr. HOMER C. BROWN, Columbus, Ohio, president of the National Dental Association, who addressed the society on behalf of the coming meeting of the National Dental Association to be held in Rochester.

Motion was made and carried to adjourn until the evening session.

FRIDAY—*Evening Session.*

The meeting was called to order Friday evening, May 15th, at 8 o'clock, by the president, Dr. Smith.

After the report of the Executive Council,

The next order of business was the reading of a paper by Dr. J. V. CONZETT, Dubuque, Iowa, entitled "The Technique and Relative Value of Gold Fillings and Inlays."

[This paper is printed in full at page 183 of the present issue of the COSMOS.]

Discussion.

Dr. HENRY W. GILLETT, New York. It is not easy to discuss a paper which is a statement of the best practice in any specialty. Discussion of such a paper must be largely confined to commendation, and to an emphasis of the most important items presented.

I wish to refer first to the choice of gold for cast inlays. The essayist speaks of the alloying of twenty-four karat gold and of twenty-two karat gold. I have been so well pleased with the results of the use of an alloy composed of twenty-four karat gold and at least two and one-half per cent. of platinum that I wish to call your attention thereto. This alloy seems to offer just about the right degree of resistance for occlusal surfaces, and it is sufficiently ductile to permit of satisfactory burnishing for the perfection of the margins.

Dr. Conzett referred to the argument which we hear so frequently presented, namely, one of the objections which is being constantly raised by the advocates of the foil filling is that the cast inlay requires broader cutting—greater sacrifice of tooth structure. I wish to read the paragraph in question: "The preparation of a cavity is practically the same for an inlay as for a gold filling, the only possible difference being that in the preparation for a gold filling some undercut retention is permissible, while for an inlay this is of course absolutely prohibited."

The essayist has spoken of the "saving of the teeth." Dr. Johnson used the same expression several times yesterday. I feel that it is time we should outgrow that expression and employ a broader

term. Many a tooth has been "saved" with but little advantage to the patient. It is time that we as a profession realize the saving and restoring of the efficiency of teeth, nay, the efficiency of the masticating organ, as our field. I believe we focus our attention too closely on the individual tooth, and need to study more carefully the function of the masticating organ as a unit, and the relation of the individual tooth to the whole organ. One of the marked differences between the results of foil fillings and cast inlays in cavities involving occlusal surfaces is the difference in efficiency of mastication. It is comparatively easy to restore the cusps, fossæ, sulci, and marginal ridges on which that efficiency depends, when cast inlays are used. It is not feasible within the bounds of reasonable demands upon the strength of either patient or operator to restore the enumerated features of occlusal surfaces with gold foil. The much increased efficiency of such surfaces when lost portions are replaced with duplicates normal to that case is sufficient warrant for a much freer cutting than would otherwise be permissible. If conditions are such that the removal of a foot will conserve and increase the efficiency of an individual, then it is good practice to remove it. Likewise, if the removal of a part of any tooth will be more than counterbalanced by the benefit accruing to the individual, then there is need for caution in accepting the dictum that the removal of such a part is a sacrifice.

Dr. Conzett has referred to the discrediting of inlays by reason of failure to produce creditable results, and of unseating of inlays. Inlay systems have now reached a status where no dentist can have a legitimate excuse for either kind of failure. If they occur habitually in any practice, they necessarily stamp either the practitioner's standards or his methods, or both, as inexcusably faulty. They lay upon him the responsibility of reforming one or both. Our opportunity at the present time is a broad and wonderful one, but upon us is laid the responsibility of improving that opportunity. This can only be done by maintaining our standards individually as well as collectively.

Dr. A. R. Cooke, Syracuse. The subject of cavity preparation as presented by the essayist has been so extensively discussed before this society and its component district societies that I feel unable to add much of interest. It seems to me that the theory of extension may be, and in many cases is being carried to excess. The determination of the amount of extension requisite in each individual case is a matter of judgment. Endless trouble may be entailed upon an unsuspecting public during the formation of a mature judgment by young practitioners, owing to their lack of due consideration of the vital forces of the organs upon which they are operating.

It was recently my privilege to examine a large number of specimen cavities prepared by the older students of one of our prominent dental colleges. I was impressed with the beautiful work, and admired their adherence to the principles of cavity preparation as advocated by the essayist; I noted the similarity of each case to that of its neighbor, and from the mechanical standpoint was unwilling to criticize the work. We all know that the gentlemen who have preceded me have the judgment, acquired by experience, to apply these principles successfully in their daily practices, but —like a large number of others—I find myself unable to make the extensive preparation advocated in every case without often involving the pulp, or at least endangering it from thermal shock. We shall have a reaction in this practice, as we have had in other lines, and the greatest good will be accomplished by the conservative operator.

It is a common occurrence in the practical licensing examinations conducted in this state that the candidates make unnecessary pulp exposures in the preparation of these cavities, and I have seen a large number of similar errors made by otherwise careful operators.

The passing of the use of non-cohesive gold in the form of hand-rolled cylinders

is to be deplored. Many operators of the past generation were skilled in this method, and were able to produce beautiful results in a fraction of the time required by the present system. The adaptability of this particular form of gold to the cervical wall rendered its use specially desirable, and somewhat obviated the necessity for extreme extension. The preparation and insertion of a good inlay requires as much skill and often more time than the insertion of a good gold filling, and the choice of process is dependent upon the ability of the operator to produce results. The young men of the profession are inclined to use the inlay wherever possible, whereas some of the older practitioners prefer the foil filling. My experience with the five per cent. platinum-and-gold alloy for inlays has not been entirely satisfactory. It seems to have more shrinkage than pure gold, and I have been unable to burnish the edges as closely as desired.

Dr. H. E. S. Chayes, New York. I am sorry that Dr. Conzett's effort seems to have awakened so little interest, and I am going to ask your indulgence to allow me to discuss his paper.

At the outset I may say that there is hardly anything in Dr. Conzett's paper that anyone may disagree with, but there are so many points upon which he has not touched and which he has not fully emphasized that I, as one interested in this particular branch of our work, feel it necessary to raise my voice in justice to myself and to him who is responsible for the awakening of interest in that unquestionably established treatment, namely, Dr. Taggart. Inlay work is no longer an experiment. Contrary to all expressions and belief of the older practitioners that there is still a great deal of room left for malleted gold fillings, these men will find themselves in a gradually but constantly diminishing minority, and the quicker they recognize that fact and begin to master the technique of inlay work, until they have almost eliminated from their practices that long-hailed and much-worshipped material, the gold foil filling, the better it will be for their patients and themselves. Perfection means one thing and one thing only—*perfection*. The insertion of an inlay the margins of which it has not been found necessary to burnish, if the cavity has been properly prepared and every step has been followed according to the principles laid down by Taggart six or seven years ago—which it has not yet been found necessary to change in order to render them more perfect—will fill every demand of every sincere operator who works for the interest of his patients. The softening of the wax in water at from 140° to 148° F., and the force exerted in holding the wax within a cavity in order to overcome the molecular tendency of the wax toward changing when once forced into position will be sufficient to remove the bugbear so much talked about in journals, namely, the shrinkage and expansion of wax, which cause microscopical changes in the inlay. The selection of a proper investing compound, the proper temperature and quantity of water, the taking into account of the humidity of the atmosphere, the proper mixture and the careful application of a creamy mixture of investment compound to every part of the wax model, care in eliminating air-bubbles, and finally the proper drying-out and heating of the investment, the proper burning-out of the wax within the flask, and finally casting in a cold mold, as mentioned by Dr. Conzett and repeatedly referred to by Dr. Taggart, will eliminate the myriads of difficulties which some operators have made for themselves by not following a proper technique. It is a peculiarity of the human mind that the moment anything new is offered, it is immediately opposed. We should first fairly and calmly investigate the merits of an innovation, and not until we have studied its possibilities are we justified in either adopting or discarding it. It is hardly possible that when a man offers to a scientific body some thought upon which he has spent years of careful study, we shall be able in a moment to pass a verdict upon its value. As an illustration, the author of the paper preceding the one under discussion pointed out the close interde-

pendence and relationship between the functions of all organs in the human body. The dentist places an inanimate appliance in a vital environment with the expectation that it will take a part in the maintenance and preservation of the vital organism. He must therefore exercise extreme care in all such operations. It is impossible to judge hastily a method as being defective which has been evolved by a man who has spent a lifetime in perfecting it. Such a method must be religiously followed step by step, in order to insure perfect results.

Not so long ago, railroad tracks were laid in short sections, bolted together in such a manner as to leave room for the shrinkage and expansion of the metal. This method has been abandoned, because it was found that, if the holding force is sufficiently strong, the tendency to linear change in the rails can be overcome. In other words, there is no force that cannot be overcome by a greater force. Thus we can overcome the shrinkage of gold by applying sufficient pressure to overcome it; this pressure, of course, must not be so excessive as to force the investment apart, but just enough to overcome the tendency of the gold to shrink. The addition of two and one-half per cent. platinum to pure gold is a good suggestion. Platinum can be combined with gold up to ten per cent. of platinum, if the work is done carefully and impurities are kept out.

Dr. W. A. Price, Cleveland, Ohio. I rather fear to discuss this question, because I know my weakness when I get to speaking on a physical problem like the one under discussion. I am reminded of an incident which happened in Washington a few years ago, when the famous Dr. Murray, who corrected the atomic weight of hydrogen, was working in the department of Weights and Measures. Someone inquired if he could furnish from that department a ruler that would be absolutely straight; that he wanted it as soon as possible, and asked what the cost would be, etc. Dr. Murray replied that a ruler could be made accurate to one-tenth of a millimeter for the distance of one-fourth of a meter, that the expense would be practically eleven hundred dollars, and it would require about two years to make it. The man wrote back that he wanted just a good straight ruler. This simply showed that the man had no conception of what the word "perfect" means. Speaking of relative exactness, we have a number of men in our part of the country who have the confidence that they do things to the absolute gage, and they use the words "absolute" and "exact," etc., with great confidence and freedom. It has been not unusual to hear men make the statement that they could cast a crown base that would absolutely fit. I have had the privilege of working out the physical determinations of wax and gold, and found that absolutely accurate reproductions could not be made. As a result of these findings, a series of tests were made by different members of the profession, and a prize of one hundred and fifty dollars was offered by me for any member of the profession who would produce a cast restoration which would go to place within one-fiftieth of an inch. The form that was provided consisted of a taper column one-fourth of an inch in diameter, the taper of the sides to be one per cent. per inch with respect to a perpendicular. This form was expected to reproduce, approximately, the conditions that obtained when casting a gold base for a molar porcelain crown where the gold extended over the bevel of the porcelain as well as over a bevel on the roots. This condition provided for the reproduction of both an inside and outside dimension at the same time. The outside dimension, represented by the periphery of the root and the base of the porcelain, was represented by the taper column, the inside dimensions being the pulp chamber and post-hole in the porcelain. A number of restorations were made for this form by operators living in different parts of the country. The conditions for securing the prize required that the ring go to place over the outside dimensions and in the inside dimensions of this form to within one-fiftieth of an inch; but the competitors' attempts failed. What was the reason? It soon

became evident that defects due to human error appeared in the restoration, and the men who used a cold investment and obtained by that means abnormal contraction of the wax, had their inlay stand that much higher than the form for which it was made, and we could every time, by adding the contraction of gold, viz, 2.2 per cent. to the manipulation of a given wax, tell what procedure had been used, and it always added up accurately mathematically. A definite amount of contraction always occurs in the cooling of gold, viz, about twelve per cent. of its volume from the molten state to room temperature, but about five per cent. of this contraction occurs at a certain point in the change of temperature by less than one degree. The larger part, therefore of the contraction of gold from its crystallizing point to normal temperature amounts to about seven per cent. of its volume, or 2.2 per cent. linear. It is this large fixed error, due to the contraction of the gold after it leaves the molten state, which presents the greatest difficulty for which we have been seeking to find a solution. Since the contraction of gold is a constant factor and of a definite amount, we may systematically introduce an error which will precisely compensate for the contraction of the gold, and this can be done by the manipulation of the wax pattern. By certain manipulation enough expansion can be produced in almost any wax on the market to compensate for the contraction of the gold. By warming the wax its elasticity is released, and an error in expansion is created sufficient to overcome the contraction of the gold.

A little experiment will show very clearly the effect which the elasticity of the wax may have on the finished inlay. Two pieces of inlay wax are placed in warm water and heated to their low working range. One of the pieces is removed, stretched and plunged into cold water to chill, thereby retaining its elasticity. The other piece is condensed by pushing it together endwise and chilled. While it is cold, a section one inch long is cut from each of the pieces and attached to a sprue; then investment is mixed with water of the temperature of the high-working range for the wax used, and the piece is invested. The warm investment releases the elasticity of the two wax pieces like the thawing of a frozen stretched rubber band. Each relaxes to its normal molecular state of rest, the elongated one shortening, and the shortened one elongating. This change in the wax after it is invested is prevented by releasing that elasticity while the wax is in the form, the procedure being as follows: When we make a mesio-occlusal-distal pattern and chill it in the cavity, the wax contracts, and, being held, takes on a condition of elastic strain. If this pattern is removed from the form or tooth, after being chilled, and we undertake to introduce an expansion sufficient to overcome the contraction of the gold, the warming of the pattern releases this elasticity and produces a distortion. If, however, we remove the wax while it is warm and place it in cold water, producing a contraction without strain, it does not take on an elastic stress. It would, however, be too small to go back into position in the form or tooth. If now we break it across the occlusal surface while keeping it chilled, and replace it in the form, we will have quite a wide crack between the broken surfaces. We then take a wedge of new wax and force it into this opening, after softening the edges with a warm instrument. This will introduce enough new wax in that particular part which has to do with our outside dimensions, so that, when the pattern is removed and invested in a warm investment, the temperature of which is dependent upon the formula of the pattern material, we produce sufficient expansion of the mass of wax so that it will readily go over the outside dimensions.

Another suitable method consists, instead of breaking the pattern, in cutting it across the occlusal surface with a sharp knife in one or two places before chilling it in the tooth, thereby allowing the contraction to express itself at the point of separation; after producing the contraction, we insert additional wax as before. This will introduce an expansion correc-

tion in the wax which will be more than sufficient to compensate for the fixed contraction of the gold.

Another method consists in putting into the occlusal portion of the wax pattern a metal that has a low coefficient of expansion, viz, one-quarter of that of gold.

These are some of the methods by which we can control a large part of the error observed in mesio-occluso-distal fillings due to the expansion and contraction of the wax and gold. It is therefore very necessary to know exactly the expansion and contraction at various temperatures of the particular wax used, and to manipulate it so as to introduce just the proper amount of expansion to overcome the contraction of the gold.

Dr. CONZETT (closing the discussion). I wish to thank you for the very kind reception accorded to my paper, which is confessedly incomplete, as it was absolutely impossible in the time at my disposal to cover the subject. That is the reason why I have not gone into detail in regard to some of the points mentioned by Dr. Chayes, and which must be carried in mind in any inlay technique and cavity preparation. I was glad that Dr. Gillett emphasized the restoration of the function of the tooth. A filling or an inlay which reproduces lost tooth tissue and does not perfectly reproduce the function of that tooth is a failure. I have frequently removed fillings that seemed perfect except that they did not restore the mesio-distal diameter of the tooth, hence did not restore the function of the tooth, and in order to correct such defects I have removed fillings apparently perfect in every respect, inasmuch as they prevented recurrent caries. The restoration of sulci and cusps is more easily made in an inlay than in a gold filling. In regard to the question of extension for prevention, operators who are cutting teeth all to pieces are not following Dr. Black, and the operator who exposes a pulp in making an extension is lacking in skill. The extension is not made toward the pulp of the tooth, but in the surface of the tooth.

I do not wish to go into the question of the expansion of wax, but, as Dr. Price says, the factors of expansion and contraction can be controlled largely. I wish to join Dr. Chayes in his tribute to the genius who brought out the cast inlay. It is almost impossible for us to appreciate the tremendous amount of work which Dr. Taggart has done in this field. He made magnificent inlays when the method was first brought out, and those practitioners who are carefully following his technique are making magnificent inlays today. So many are casting in hot molds, using an investment material which is disintegrated, and instead of controlling the expansion and contraction get a breaking-up of the investment material and a distortion of the inlay. If the wax is properly introduced into the cavity, as Dr. Price has said, and if the inlay is cast in the mold at the proper temperature, there will be a shrinkage in the gold that we cannot get away from, but which we can overcome. I have demonstrated that for one and the same model, we can make with the same wax one inlay that will rattle, and another inlay that cannot be forced into the cavity because of the expansion of the gold, the difference being due simply to the different temperatures of the flasks in the casting.

The next order of business was the Report of the Correspondent, Dr. E. B. PRENTISS—viz, "Nitrous Oxid Analgesia in General Dental Practice"—which was read by Dr. Hasbrouck.

[This paper is printed in full at page 156 of the present issue of the COSMOS.]

Discussion.

Dr. JAMES F. HASBROUCK, New York, N. Y. I have read the report of our Correspondent with a great deal of interest. There is unquestionably, at the present time, a feeling of uncertainty as to the practical value of nitrous oxid and oxygen as used by the general practitioner for producing analgesia during dental operations. I am not prepared to commend its use as an analgesic pure

and simple—my own experience, comprising a rather long series of cases, being that whenever any part of the operation would really produce actual pain, the only method of eliminating shock is the induction of anesthesia. Analgesia may be excellent in selected cases; we are perfectly willing to accept the statements of those who report this, but I should like to know whether or not, at critical moments during their operations, anesthesia is not induced. Should nitrous oxid and oxygen form part of every dentist's equipment? This is a different question. Offhand, one would be tempted to answer Yes, but we must make so many qualifications that my answer would be No—excepting that I believe Dr. Hartzell is entirely correct in his statement that the equipment should be in the office of every man who is capable of using it and who has work demanding its use.

Observing the data at hand, there seems to be a unanimity of opinion regarding the qualifications of the administrator of nitrous oxid and oxygen. I am quite in accord with this opinion, and believe that one should receive special instruction from one qualified to teach, and by this I mean to imply that I do not consider a demonstration or two by the exploiters of an apparatus sufficient for this purpose. A trained and experienced assistant should always be present. I know that many will think that all of this preliminary preparation is unnecessary, but as one acquires experience in the administration of these gases, I think he will agree with Dr. Connell's statement that nitrous oxid and oxygen in unskilled hands is more dangerous than either ether or chloroform. It is not the easy cases that we are here to discuss—they will take care of themselves; anyone can handle an easy case. But the difficult cases are exasperating, and we seldom know beforehand when complications will arise. It is the emergency which we must provide for; therefore I should strongly advise against adopting the use of this method either without proper instruction or without having a trained assistant.

Patients do experience unpleasant effects at times from the use of nitrous oxid and oxygen; headache, general weakness, and nausea many times, in longer operations particularly. In all operations which are to consume more than a few minutes of time, I should advise preparation of the patient as for a major anesthesia, and by so doing much embarrassment may be saved to all concerned. I have prepared a clinical statement based upon 1200 consecutive administrations of nitrous oxid and oxygen, as follows:

Total cases—nasal method, 1200.

Estimated average duration of anesthesia, 10 minutes, the duration of the anesthesia in individual cases being from 3 to 50 minutes.

Ages of patients, from 3 to 85 years.

Nausea during or after anesthesia, 20 per cent.

Hysteria after anesthesia, 4 per cent.

Patients difficult to control under the anesthetic, due either to non-susceptibility to nitrous oxid or extreme susceptibility to both gases, 7 per cent.

Bad breathers, 4 per cent.

Heart involvement during anesthesia (syncope), 3 in 1200 cases.

Spasm of glottis, 1 in 1200 cases.

Dr. Hertz seems to have dealt with the problem most satisfactorily. His answer to question No. 2, concerning the perfection of equipment, does not altogether agree with my experience, since up to the present time I have been unable to find a fixed point for any patient at which either analgesia or anesthesia may be evenly maintained; in other words, that point will not *stay* fixed. We may have an approximate point, but owing to variable outside influences this point will vary, and only by constant care and attention can this variation be followed so that the patient's condition will remain even.

Much is still to be desired in the way of perfection of apparatus, although the machines are being improved from year to year. The perfect machine should be capable of delivering the gases under the most accurate adjustment as to volume and pressure, and the mechan-

ism necessary to accomplish this result should be of the simplest description.

It is apparent that, in order to obtain the best result, a fine adjustment of the mixture is necessary, also very close observation of the patient during the operation. The important point to be considered is that in all mouth operations, whenever the gases are administered nasally, a variable factor is introduced, namely, the amount of air entering the lungs through the mouth, which may or may not be excluded, depending upon one's technique. There is always more or less manipulation of the cheeks, tongue, and fauces, but in many cases the admission of air is reduced to the minimum, in anesthesia, by packing the pharynx with gauze; in analgesia, however, this packing might not be tolerated, and the varying pressure at the mouth must be met by changing the proportion of the mixture and readjusting the pressure, which cannot easily be done by the operator unless a skilled assistant be present.

One's success with this method is going to vary considerably, depending upon several factors, the most important of which are the condition of the patient, both mental and physical, control of the patient by the operator—and here we might mention his psychic or suggestive influence—and finally, perfection of one's technique in administering the anesthetic.

Dr. W. D. Tracy, New York. In these times of transition and rapid development a report such as the one submitted by our Correspondent is of inestimable value.

The subject with which it deals seems to be paramount in the dental mind throughout the country, and the facts concerning the use and advantage of analgesia, coupled with a statement of the disadvantages and dangers connected with the administration of nitrous oxid and oxygen, will be of great help to many who are endeavoring to decide in their own minds the true status of analgesia in its present stage of development.

The numbered questions propounded by the Correspondent have been so splendidly answered by so many men of high scientific achievement that I will not attempt to discuss them further. The word of caution as found in the letter over the signature of Dr. Gillett is worthy of emphasis, and I trust that the warning will not be unheeded by those who are tempted to jump into a field of work for which so few general practitioners are qualified by experience or education.

Dr. Prentiss has asked me to say something from the viewpoint of the general practitioner concerning the danger of too deep cutting or possible injury to the dental pulp during cavity preparation under analgesia. It is my opinion that before analgesia is begun, a careful diagnosis of the general condition of the individual tooth and those adjacent to it should be made. If there is any element of doubt concerning the condition of the pulp or of the pericemental membrane, the usual methods of reaching a definite conclusion should be used prior to the administration of the nitrous oxid. From my own experience and observation there seems to be no more danger of unintentional exposure of a dental pulp under analgesia than there is without it, when the work is being done by the hand of a careful operator who understands dental anatomy and pays heed to his knowledge of that important factor. It is my belief that dentin is even more sensitive where it joins the enamel than it is oftentimes in the deeper portion of a cavity, and with the present-day apparatus of the best type, which secures and maintains a definite mixture of the gases used, there is no need for undue haste in removing deep-seated carious portions of dentin. If the removal of carious dentin leads to actual exposure of the pulp, as it must in many instances, no matter whether analgesia is used or not, the patient who is in an analgesic state is in an excellent condition for the application of pressure anesthesia. As soon as the application of novocain under pressure has been completed, the inhaler is removed and the work is thus effected

with a minimum of discomfort to the patient. If, in certain cases, the patient's sensation of pain is desired by the operator as a help in diagnosing conditions during the progress of his work, a slight analgesia will permit him to have the intelligent co-operation of his patient, and at the same time will securely protect the patient from that kind of pain which is declared by some to be "simply unbearable;" but such conditions do not often prevail in my own work.

While we cannot work under any fixed rule, it seems to me the general principle under which we proceed in preparing cavities is simply to lay our cavity margins in areas of immunity, gaining proper resistance from an adequate retentive form and the necessary removal of carious dentin. I do not see why the use of analgesia should in any sense interfere with an intelligent diagnosis of all these requirements, and in many instances analgesia is of great assistance in permitting the operator to proceed, not in the direction of least resistance, which would lead to an improperly prepared cavity because of his desire to spare the patient, but analgesia enables him to make a perfect operation.

I wish to revert a moment to Dr. Gillett's comment that "The present interest in the practice is largely commercial." This we acknowledge to be true, but it is true only because the dental profession has made it possible. Dentists for years have threaded their way through a maze of obtundents seeking to find some panacea for sensitive dentin, and now we are lost in the labyrinth of analgesia, anesthesia, conductive anesthesia, etc. There is an insistent demand on the part of the public, and a persistent desire on the part of the dental profession, that the pain necessarily incident to the performance of dental operations be reduced to a minimum, and if possible altogether eliminated. Analgesia has been a step in this direction, but admittedly falls far short of the desideratum, for the many reasons mentioned in this report. But until something better is presented, many operators will continue to find help from its use. There is, however, some light on the horizon; it may be that local and conductive anesthesia, produced by the injection of novocain, will be the next step in advance, though no man can come forward to say that this method is not beset with great drawbacks and grave dangers.

As far as the outlay of money for new and untried appliances and the building-up of a junk-heap is concerned, I freely charge such money to the cost of my education and advancement, and have just ordered a complete outfit of local anesthesia instruments and accessories. We must try the new ideas that are presented to us in order to prove or disprove the merits that are claimed for them.

Dr. Henry W. Gillett, New York. I would like to say a word or two in addition to what was said in the report. After I had sent my letter to Dr. Prentiss, as read by Dr. Hasbrouck, I had a talk with Dr. Thomas Bennett of New York, who is, if not the leading, one of the leading specialists in anesthesia in New York City. Following this conversation, I sent him a copy of the letter Dr. Hasbrouck read to you, and later called him up and asked for his opinion concerning it. He indorsed the letter with enthusiasm, saying that he felt it was an excellent statement of the situation. In talking with him I gained some further impressions of his own viewpoint, as, for instance, that he considers nitrous oxid and oxygen one of the most dangerous anesthetics in use. After an observation of four hundred cases, he has limited his use of it to a small and carefully selected class of cases.

In the May 1914 issue of the Dental Cosmos there appeared in the Review of Current Literature, on page 628, a review of an article by Dr. A. H. Miller on "Gas-Oxygen Anesthesia," in which the writer calls attention to a number of contra-indications to nitrous oxid and

oxygen. There is also included in this article a list of deaths ascribed by the compilers of the list to nitrous oxid and oxygen anesthesia, as follows: Teter, 21; Crile, 2; Lydston, 3; Allen, 29; Gatch, 15; Olow, 6; Boys, 7; Miller, 8; Flagg, 9; Salzer, 11; Collins, 12; Buchanan, 13. I think that is sufficient comment concerning the safety of nitrous oxid and oxygen anesthesia and analgesia apparatus.

The next order of business was the installation of the newly elected president, Dr. A. M. Wright, Troy, N. Y.

Dr. A. P. Burkhart moved that a rising vote of thanks be extended to Dr. Smith, the retiring president.

The motion was unanimously carried, and the society extended a rising vote of thanks to Dr. Smith.

(To be continued.)

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held October 27, 1914.

The regular monthly meeting of the Academy of Stomatology was called to order Tuesday evening, October 27, 1914, at eight o'clock, by the president, Dr. J. V. Mershon.

The essayist of the evening, Dr. Hermann Prinz, Philadelphia, was introduced by the president, and read a paper entitled "Radio-active Substances and Their Therapeutic Application in Dentistry."

[This paper is printed in full at page 150 of the present issue of the Cosmos.]

Discussion.

W. S. Newcomet, M.D., Philadelphia. When Dr. Guilford asked me to discuss this paper, his invitation was accepted with the idea of my not missing any paper on radium, for the reason that I am particularly interested in this subject. After consenting, I began to reflect that my knowledge of dentistry was limited to the experience of pulling teeth while an interne in the hospital; so, to bridge over this difficulty, I concluded that the exhibition of some borderline cases between dentistry and medicine might be profitable.

For instance, leukoplakia is a disease which concerns you as much as it does medical men, and the dentist is really more likely to apply caustics than his brother in the medical profession. Dr. Hartzell, at one of our meetings, said that the medical man who cauterizes leukoplakia should be put in the penitentiary; I will leave it to you, gentlemen, to say what should be done to the dentist who does so.

Those of us who have been working with the X ray and radium for a number of years have observed many changes; some have been able to produce results, while others have failed. You may recall that when X rays were first employed in medicine it was not unusual for many surgeons to assign the operating of these machines to inexperienced nurses. This procedure was continued until many severe burns gave timely warning that the X rays should be handled by men who are specialists in their application.

When radium was first discovered, many surgeons implanted it in various tumors and experimented with it along divers lines; it shortly fell into disuse, however, for want of satisfactory results, regaining favor only when one of our eminent surgeons in the United States

took up the question of radium, and gave it sufficient time and study to establish it as a determining issue. While his work has been opposed, it has been of great scientific value. Few persons seem to realize the actual worth of radium, and with that fact in view, these cases are presented for consideration.

(Dr. Newcomet then presented several patients, among them (1) a case of leukoplakia, (2) one of carcinoma of the palate, (3) carcinoma of the buccal mucous membrane perforating the cheek, (4) osteosarcoma of the jaw, (5) lupus of the palate, and (6) sarcoma of the tonsil.)

There is no doubt that this subject is of more interest to those handling radium than to the observer. When one has been studying these cases for two or three years, some pride must be felt in their recovery, and a pleasure in making some reference to them.

I quite agree with the essayist in regard to the newer methods being recommended, and commend him for his remarks upon the use of radium in rheumatism and gout, for you all know the long list of short-lived remedies for this trouble. It is possible that radium in the treatment of pyorrhea may be consigned to the same position.

Some exception must be taken to the essayist's comparison of radium and thorium. Beginning with uranium, we have an element which disintegrates into uranium I, II, and uranium X, and has a life of about eight billion years. Ordinary uranium dissolved in water to which is added a small quantity of iron chlorid, then precipitated with ammonia, will separate the uranium X, which has a life of about thirty-five days, and gives off the alpha with weak beta and gamma rays. After the uranium series follows another disintegration, and we have ionium, with a life of two hundred thousand years. Ionium disintegrates into the substance now well known, radium, which has a natural life of about two thousand years. While everyone knows of radium, it is not the useful therapeutic agent it is generally supposed to be. Radium, in itself, is absolutely useless in therapeutics, but it gives off a small alpha and possibly beta ray. The emanation is the next product, and has an active life of four and one-half days; this is a gas, and it is confusing to speak of the emanations from radium in connection with the alpha, beta, and gamma rays. This gas has been named *niton* by Dr. Rutherford. It has an active life of about four days, disintegrating into radium A, B, C, and it is here where we find a useful activity from a therapeutic standpoint. Radium C is divided into C′ and C″, disintegrates rapidly, and from it are obtained the powerful gamma rays. Following this series of rapid disintegration, we have the first of the series of slow disintegration, which is radium D, or radio-lead. This explains the activity of the average lead, which must be kept years before it can be used to make the electroscope of which the essayist spoke. After radium D, we have radium E, and radium F, which is polonium, and then possibly the series ends in lead.

In considering thorium, we have an irregular grouping, as follows: Thorium, life three million years; mesothorium, 5.5 years; mesothorium II, about six hours; radio-thorium, two years; thorium X, 3.6 days; thorium emanation, 50 seconds; we then have thorium A, B, C, D. The essayist calls attention to the fact that we cannot use thorium, at least when it comes to the use of its emanation. The reason for this is that thorium emanation disintegrates in a few seconds.

The emanation of radium in water—radio-active waters—has a life of about four days, and explains why we may have radio-active waters from radium, but not from thorium, the latter requiring continuous preparation. In London and Boston there are hospitals making use of this process and giving the preference to the emanation rather than to radium as radium, the reason assigned being the tremendous amount of energy capable of being confined in a small amount of space.

If one desires the emanation in natural mineral waters for use in the mouth,

as the essayist mentions, in the form of mouth-washes, and advocates such performances as described, I would relate to him a story which was recounted a few days ago: A woman said she had purchased a large bottle of hydrogen peroxid at a department store for fifteen cents, whereas her daughter had previously paid twenty-five cents for a small bottle at the drug store. No doubt both obtained peroxid of hydrogen. The same is true of radium emanation. There are very few waters that do not contain radium emanation. But is it of medical value? Furthermore, as a solution, radium emanation is very unstable. It has been calculated that, in being poured from one vessel to another, the water will lose from ten to thirty per cent. of its emanation. If the loss is so great from such a slight manipulation, it is reasonable to believe that a much greater loss would occur from rinsing or washing the mouth.

The emanation of radium has been introduced into wax and other substances for filling teeth, but the fact that we are dealing with the most fickle substance known precludes the idea of retaining its radio-activity. It should be remembered that some of the elements change in the fraction of a second, and yet they are recommended for use in the filling of teeth!

Dr. R. H. Riethmüller, Philadelphia. In these days, when some of us think that the Germans are not receiving their full dues, I wish to report that in 1900, one full year before Curie started to manufacture or even make experiments with radium, a dentist—and I think we as dentists should be proud of this fact—Professor Walkhoff of Munich, in co-operation with Prof. Dr. Giesel of Braunschweig, manufactured the first appreciable quantity of radium from pitchblende and published their results.* I think this should be marked in history, because a great many other discoveries have been appropriated by individuals of piratical tendencies. I only have to mention the wireless telegraph, which was by no means invented by the men who were shrewd enough to exploit it commercially. A great many other inventions and discoveries have been made without the originator receiving the credit due for his work.

I have been interested, during the last few years, in reading a great many articles on radium therapy in dentistry, and the names which Dr. Prinz has mentioned have become familiar to the zealous reader. In fourteen or fifteen articles reviewed in the Dental Cosmos, the results of radium therapy in dentistry which Dr. Prinz has so ably reported to us tonight have been verified, that is to say, radium is by no means the panacea which it was hailed to be by its first advocates.

It was interesting to me to note the cases presented by Dr. Newcomet which have been under successful treatment by radium emanation. In the case of the woman who was being treated for leukoplakia, I think every dentist would first extract that second molar root in that suspicious area which has not yielded to radium treatment, and which will probably not yield until that diseased root, which must be causing a great deal of irritation, shall have been removed.

Dr. P. B. McCullough, Philadelphia. Dr. Newcomet, in closing, may explain why the physiological effects of radium application were so bad in the early period when this agent was not so well known. Dr. Newcomet will probably recall the case of a superintendent of a hospital who was afterward operated upon for carcinoma of the lower jaw after having been previously treated with radium. The report which I received stated that his death was not due to kidney failure, heart failure, shock of the operation, or anything that occurred immediately before or as a consequence of the operation that could be directly held responsible for his death. He died of what the surgeon characterized as dissolution similar to another disease the etiology of which is not known; disso-

* See Dental Cosmos, November 1913, p. 1192, review of seven papers on "Radium in Dentistry."

lution of the entire system, under which he declined very rapidly, and the customary treatments which were resorted to at that time had no effect. I hope that I make my point clear. It was assumed that too long application of radium had produced an entire change in the animal cell, affecting the entire constitution, and precipitating a death that might have been avoided if the operation had been performed without radium treatment.

Dr. Newcomet. In regard to cases of brain tumors, several cases have come under observation, but in only one was the result favorable. This young man [presenting a patient] was presented before a medical society about a year ago, and he is still in good health. From this little group of favorable cases presented tonight the impression must not be gained that such results occur in all persons treated with radium. You must be reminded that in these instances the condition is desperate, and usually terminates fatally. Possibly only five or ten per cent. of these cases are restored to health, and it can be safely said that, so far, no cure for cancer has been found.

Dr. McCullough's reference to a certain case is sufficient proof of the above assertion. While the application of radium failed to check the disease in that case, it can hardly be said to have produced any influence which hastened the end. Under certain conditions, however, radium may be the cause of a violent reaction which may lead to trouble. One such instance occurred in a case of cancer of the tongue. This patient had been treated in Germany as well as in this country. He would not submit to a radical operation, and finally radium was applied. After a few treatments his tongue became swollen; this was followed by a cellulitis of the neck, and finally a septic pneumonia was too much for his greatly burdened system. These are a few of the unfortunate cases which come under observation. Other cases could be mentioned that have received treatment here and elsewhere. The disease has but one issue, and when we save *one* from its natural course, a just pride can be taken in the recovery of such a case.

It was most curious to see how cellulitis follows the reaction from radium in some cases. This is not observed as a reaction to the X ray. On the other hand, the usual burns from radium are as a rule trifling, while the burns from the X ray are a serious matter. One of the cases presented tonight showed a well-marked burn upon the tongue, but it can be safely stated that this will heal within a few weeks. Such burns are to be regarded as accidents, and indicate clearly the result of inexperience and the necessity for skill in handling not only the X ray but radium as well; they undoubtedly should both be administered by a specialist.

In speaking of the physiological effects of radium treatment, we must divide the subject into two heads—(1) the effects, both local and general, from local applications, and (2) the effects, both local and general, from internal administration. This is an enormous subject. When we consider that, if radium is applied locally only nine per cent. or less of the energy is used, and, if it is employed internally, the total amount of energy is distributed over the whole body, the vastness of the subject can be easily seen, and it would be impossible to do it justice in a short space of time.

Dr. Prinz (closing the discussion). I wish to thank you heartily for the kind reception you have given me, and thank Dr. Newcomet and Dr. Riethmüller for their discussions. There would be a great deal more to say about the physics or the chemistry of radium, but in a short hour's talk this subject could hardly be treated with justice. Nevertheless, I presume we have possibly gotten some sort of impression that will help us to judge whether or not it is advisable to use radium.

Motion was made and carried to adjourn.

PHILADELPHIA, FEBRUARY 1915.

EDITORIAL DEPARTMENT.

THE PASSING OF THE FATHERS.

On the 27th of February, 1904, a "golden jubilee" banquet was given by the dental profession to Drs. James Truman, Louis Jack, C. Newlin Peirce, W. Storer How, and Eri W. Haines (whose portraits we publish as a group illustration in the current issue), the then surviving members of the class of 1854 of the Philadelphia College of Dental Surgery, in commemoration of the fiftieth anniversary of their graduation. An obituary notice of Dr. Louis Jack, the last surviving member of this group, also appears in the current issue. During the something more than ten years that have since elapsed all of those who were honored upon that occasion have died.

In his own way, each of these men was a notable figure in the history of dentistry. Each had contributed largely and variously to the common store of dental knowledge; each had exerted a definite influence in shaping the standards and ideals of our professional life and activities, not only in a national but to a

large degree in an international sense. At the time of their graduation dentistry as an organized profession was but fifteen years old, and but little more than the foundations of a professional organization had been laid; the superstructure was yet to be reared. The new profession, in the nature of the case, had no established precedents by which to direct its course. It was an untried thing, and because of its novelty was regarded with suspicion and distrust, especially by members of the medical profession, who were inclined at times to resent the aspirations of this new fledgling in the science and art of healing as those of an impertinent usurper. The close relationships of the art and craft of dentistry to that of the skilled artizan obscured for the time being the larger possibilities of dentistry as related to the science and art of healing, and tended to develop a spirit of commercialism which permeated in greater or less degree, with minor exceptions, the entire dental professional body. In the more than half-century which has elapsed, dentistry has developed from its humbler beginnings to the full stature of a recognized profession, and the change has been wrought out by the recognition and general acceptance of the ideals which those men of the class of 1854 of the old Philadelphia College of Dental Surgery and other seers and pioneers of the same period in that early formative stage of dentistry realized and adopted as their professional standards.

On the occasion when these men received their degrees, the honorary degree of Doctor of Dental Surgery was conferred upon John Tomes, later Sir John Tomes, of England; upon Chapin A. Harris of Baltimore, and Thomas W. Evans of Paris. It was not an empty honor that was thus conferred, nor was it intended to add luster to the reputations of the eminent recipients thereof. It signalized the appreciation which those master pioneer minds felt for the ideals and attainments of men of their own intellectual caliber, and was more particularly the mark of an effort to band together in a common brotherhood all of the leading men in the dental profession, regardless of nationality, who were representative of that faith in the future of dentistry which would, by reason of an appreciation of its greater possibilities, ultimately win for it the status which it has later achieved.

It is regrettable that while the personal influence of the lives of such men continues indefinitely to contribute to our advance-

ment, we are prone to overlook and forget in the busy activities of life the part which each has played and the debt of gratitude which we owe to them individually for the service which they have rendered. We accept the legacy, and forget the benefactor. When the real history of the growth and development of the dental profession is finally written, when the analysis is made of the factors which have contributed most largely to the growth of dentistry as a professional calling, the names most conspicuous will not be those who have perfected inventions that have facilitated operations which in their turn have made the emoluments of our calling larger, but the honor roll will be bright with the names of those fathers of our profession to whom was given the vision not only of the larger possibilities of service of which dentistry is capable, but who through their years of self-sacrifice and of devotion to professional advancement gave of the best that was in them of effort, of intelligence, and of service in promulgating the gospel of professionalism as the dental ideal, and who demonstrated the soundness of their faith in that ideal by the broad measure of success which they themselves attained;—success as teachers, success as practitioners, and above all, success as measured by the admiration, respect, and love of their colleagues.

BIBLIOGRAPHICAL.

LOCAL ANESTHESIA, ITS SCIENTIFIC BASIS AND PRACTICAL USE. By PROF. DR. HEINRICH BRAUN, Obermedizinalrat and Director of the Kgl. Hospital at Zwickau, Germany. Translated and Edited by PERCY SHIELDS, M.D., A.C.S., Cincinnati, Ohio, from the Third Revised German Edition. With 215 Illustrations in black and colors; 385 pages and Index. Philadelphia and New York: Lea & Febiger. 1914.

The editor of the first English edition of Professor Braun's work on local anesthesia says in his preface, "The writer of this work, Professor Braun, has justly been called the Father of local anesthesia." Considering the variety and extent of work done by the investigators and students of the subject of local anesthesia, one might at first be inclined to question the justice of the appellation as applied to the author of the work under consideration; but when it is realized that through the elaborate, painstaking, and scientific investigations of Professor Braun the principles and technique involved in the introduc-

tion of local anesthesia have been made safely applicable to the production of anesthesia for not only minor but capital surgical procedures—that is to say, a system of local anesthesia which has "no mortality" in its record, running into many thousands of cases, one must admit the justice as well as the propriety of regarding its author as the father, at least, of *successful* local anesthesia. Moreover, his studies on the osmatic tension of watery solutions, his determinations of the relative toxicity of cocain and its numerous substitutes, his advocacy of novocain, and his pioneer work in the admixture of the active principle of the suprarenal gland to the anesthetic solution, so essential for the phenomenal progress of local anesthesia, fully justify this honorable appellation.

Besides these studies, which eliminated the factor of mortality from local anesthesia, it is to Professor Braun that we owe the introduction of conduction anesthesia in general and major surgery, whereby the extent of the anesthetized area is greatly enlarged through the anesthetization of the main sensory nerve trunk, thus inducing anesthesia of the territory covered by its terminal distribution. But conduction anesthesia has made possible not only the enlargement of the anesthetic area with a minimum dose of the anesthetic drug; it has also practically eliminated the factor of autoinfection, a danger always present in the older methods, in which the anesthetic agent was oftentimes injected directly into an infected area.

The work of Professor Braun is a classic on the subject of which it treats. A comprehensive historical *résumé* of local anesthesia serves as an introduction to an elaborate presentation of what is now scientifically known about local anesthesia and the drugs capable of producing it; after which follows a minute and comprehensive exposition of the technique employed in the production of local anesthesia for the entire range of surgical operations.

It is surprising indeed to see the extent and character of major surgical operations that may be successfully performed under local anesthesia with the consciousness of the patient quite undisturbed.

The section related to surgical procedures involving the mouth and jaws, including as well the extraction of teeth, is extensive, and has been the fruitful stimulus to a number of notable works by dental surgeons whose supplemental labors can but reflect additional merit to this monumental work by Professor Braun. While the interest of dental practitioners and practitioners of oral surgery would be necessarily limited to the group of surgical procedures within their special field, yet no surgeon, whatever his specialty, could fail to be benefited by the comprehensive view of the whole subject which is presented in Professor Braun's work.

The English translation has been excellently done, and the text is readable and intensely interesting throughout. The typography, presswork, and other mechanical features of the American edition are fully up to the standard of the well-known publishers. It is a book which should be in the library of every progressive dental practitioner.

Review of Current Dental Literature.

Conducted by RICHARD H. RIETHMÜLLER, Ph.D., D.D.S.

[*Deutsche Zahnaerztliche Wochenschrift*, Berlin, 1914, No. 17.]

THE EMPLOYMENT OF ALUMINUM DENTURES AND THE ATTACHMENT OF ARTIFICIAL TEETH AND GUM TO CAST PLATES. By Dr. Eugen Wünsche, Berlin.

When aluminum was used for casting purposes, as early as 1888, the metal was not as pure as it can be obtained today, and Carroll, who reported his system of casting aluminum under compressed air in the *Dental Register*, added platinum, silver, and copper to overcome the considerable contraction of the impure metal at his command. Owing to the low specific gravity of aluminum, which when cast is 2.64, when rolled 2.68, when drawn 2.70, it is necessary to exert a continuous pressure when casting in order to obtain perfect adaptation to the model.

Wünsche briefly reviews the history and metallurgy of aluminum, which today is obtained 99¾ per cent. pure. In casting, the contraction, in his opinion, is best overcome by the use of Wood's centrifugal casting apparatus, in which the pressure is uniformly maintained during the transition of the metal from the molten to the solid state, thereby insuring a close adaptation of the plate and avoiding porosity. The slight expansion of the plaster impression and the cast is counteracted by the slight contraction of the aluminum in casting. In taking the impression of the mouth, all hard portions must be carefully noted and relieved, in order to avoid pressure or rocking in the finished plate. The cast is poured in investment compound, and the plate, as well as the channels connecting it with the three sprue holes in the casting flask, is modeled in wax, which is coated with thickly mixed investment compound, and invested while on the model. After slow, gradual drying, the wax is carefully burned out, making sure that no wax vapor remains in the flask. After the molten metal has been poured into the flask, the centrifugal machine is kept in steady motion for three minutes. Wünsche employs continuous-gum work on his cast aluminum plates, building up the gum in wax on a model of investment compound, and pouring counter-dies of plaster, to be used in pressing the porcelain body after the wax has been burned out. Instead of investment compound and plaster, synthetic stone may be advantageously used for making this die and counter-dies. The porcelain body is baked to a bisque and covered with pink enamel of a lower fusing-point. The continuous-gum work is either cemented or vulcanized to the cast aluminum plate. In lower plates a lug of porcelain on either side buccally will greatly aid in retention in cases of advanced absorption of the alveolar ridge.

Wünsche claims great hygienic as well as anatomic advantages for this method. He warns against the use of hydrogen dioxid in mouth-washes, etc., in connection with aluminum prostheses. Excessive smokers sometimes complain of an insipid taste, which they attribute to the aluminum, but which may usually be ascribed to negligence in cleaning the plate.

[*New Orleans Medical and Surgical Journal*, New Orleans, November 1914.]

THE CAUSE AND CURE OF PYORRHEA ALVEOLARIS. By Dr. C. C. Bass and Dr. F. M. Johns.

[*American Journal of Clinical Medicine*, Chicago, December 1914.]

EMETIN—A "DOUBLE-BARRELED" SPECIFIC. Editorial.

In the January 1915 issue of the Dental Cosmos we have briefly noted the work of Bass and Johns, who have corroborated the

discovery of Barrett and Smith in regard to the endamœba buccalis and emetin as a specific in pyorrhea alveolaris. In the article under review the joint authors report having examined material from pyorrheal lesions in 87 cases, and having found the endamœba buccalis in 85 of them. One of the negative reports was based upon a single slide prepared at a distance from the laboratory; the other negative case was that of a thirteen-year-old child with acute gingivitis, involving all the gums, of about eight days' duration. In addition to these 86 cases in which the disease was either diagnosed by dentists or was so advanced that no mistake could be made, they have made more than a hundred examinations from apparently normal gums and teeth, either in the mouths of patients who had the disease involving other teeth, or in people who appeared to have normal gum margins. They have not been able to find amœbæ in a single such instance. They have, however, found them on several occasions in instances where the gum margin appeared inflamed, indicating an early stage of the disease. In several instances, amœbæ were found in similarly mildly inflamed and easily bleeding gum margins of one or more teeth in patients who had well-advanced pyorrhea around other teeth. Thus amœbæ have been demonstrated in all stages of the disease, from the early beginnings described to entire looseness of the teeth and total denudation of gingival tissue and alveolar process.

The writers' technique for examining the amœbæ consists in collecting material from the bottom of the lesion with a suitable instrument or toothpick, and transferring it on a slide after dilution with a little salt solution, saliva, or water. A cover glass is immediately placed on the diluted material, which is promptly examined with the high dry lens of the ordinary microscope. The amœbæ—whether there is more than one species the writers are not as yet prepared to say—show the characteristic amœboid motion, and vary in size from a leucocyte to about three or four times that size. No contractile vacuole is recognized, but nutritive particles, more refractile and prominent in appearance, are observed. The ectosarc is quite clear, and is well differentiated from the endosarc. For staining, a thin spread of scrapings and pus from the bottom of the lesion is made on a slide, allowed to dry in the air, fixed with heat, and stained with carbol-fuchsin about one-fourth minute, washed, stained with Loeffler's methylene blue about one-half minute, washed, dried, and examined. The amœbæ are well stained by this method and show their inclusions or tissue or cell remains, indicating pathogenicity. The writers have been unable to demonstrate that these amœbæ take up bacteria, though they sometimes seem to do so.

After discussing the destructive influence of the active principle of ipecac, *i.e.* emetin, which was first demonstrated by Vedder and Rogers in amœbic dysentery, the writers describe their method of applying emetin, which they do not inject into the gum and pus pockets, like Barrett and Smith, because it does not seem reasonably probable to them that all the diseased tissues can be reached in this way. They have had 68 cases under observation and treatment for from two days to two weeks, using hypodermic doses of from one-half to one grain. Only one dose was given in a day. Several cases have been given a dose daily for several days. Others were given one or more doses until the amœbæ disappeared, after which an interval was allowed to determine how long it would be before they would return, or what other results could be observed. In several instances no amœbæ could be found the next day after the first dose was given. In a few, however, they were found the next day after emetin had been given on two successive days. In no case have amœbæ been found the next day after emetin has been given on three successive days.

The studies regarding the duration of the absence of demonstrable amœbæ following three or less doses of emetin are not as yet final. In several instances, no amœbæ could be found after seven days or longer intermission of treatment. On account of the wide distribution of this amœba in nature and the character of the lesions of the disease, the writers do not think it likely that advanced cases of pyorrhea alveolaris will be permanently disinfected by a few doses of emetin given during a few days. The chances of reinfection are so great, and the damaged gum, alveolar, and tooth structure offer such favorable soil that it must surely be necessary to continue the specific treatment until nature has had time fully to heal the dis-

ease, the length of time necessary for this depending upon many factors. If the gum only is involved, the length of time probably necessary for it to heal will not exceed a week. The writers have observed great changes in forty-eight hours, and gums that bleed easily often become perfectly normal in this regard in from forty-eight to seventy-two hours. The results are so striking as to be evident both to the doctor and the patient.

The writers are certain that rapid and favorable results may be expected to follow the administration of ½ grain of emetin hydrochlorid hypodermatically in any part of the body daily for three or four days, to be repeated during one or more days after an interval of three to ten days, except in mild cases. In very bad cases, it may be found necessary to repeat treatment several times before complete recovery. Adjuvant treatment, consisting in removal of tartar, scaling, and other local dental treatment, also injection of ½ per cent. emetin into the pockets as recommended by Barrett, will favor the success of the hypodermatic treatment with emetin.

The *American Journal of Clinical Medicine*, in an enthusiastic editorial, hails the "double-barreled" specific action of emetin in tropical dysentery and in pyorrhea alveolaris, and reports that a number of cures of pyorrhea following the administration of emetin in cases which had not responded to other methods of treatment have come to their attention. In one case treated by a New York dentist virtually all the teeth were affected, the gums were spongy, the gingival pockets were exuding pus in large quantities, the teeth were loosening, and the patient's general health was very poor. After a few days' treatment with emetin, the clinical picture was changed for the better "in a manner and degree which were simply marvelous." The journal also points out that in curing pyorrhea the dentist or physician giving this treatment is undoubtedly preventing other more or less remote but crippling diseases, since it is believed that a large percentage of the chronic arthritides, arthritis deformans, for instance, are caused by pyorrhea.

[The fulness of this report appears justified by the importance of the subject no less than by some derogatory criticisms which have emanated from operators who had made but casual clinical trials, without going to the trouble of assuring their diagnosis by previous bacteriological examination or securing proper application, with certainty of correct dosage and consistence, of the emetin hydrochlorid used.]

[*British Dental Journal*, London, December 15, 1914.]

THE ACTION OF OIL OF CLOVES AND OTHER OILS ON GUTTA-PERCHA POINTS. By H. Humphry, Dartmouth.

The writer has experimented with several essential oils to determine their action upon gutta-percha, which was found to be as follows: Oil of eucalyptus and creasote dissolved the gutta-percha, oil of cinnamon and oil of cajuput caused no change, while oil of cloves caused a large increase in size in all directions. Both creasote and eucalyptus dissolved gutta-percha points in about one month, the dissolving action of the eucalyptus being quicker. Cinnamon and cajuput oils exerted no appreciable action upon the gutta-percha points after four months' immersion. In the experiments, both round and square gutta-percha points of the same size were used, controls being carefully kept aside for comparison. Each point was fitted to the cork of a bottle containing the oil, and the bottle was then inverted. Within about one month the square point of pink gutta-percha immersed in oil of cloves had doubled in size in every direction. It altered very little during the second month. Its shape had become very tortuous, while a round point of white gutta-percha showed a little greater expansion, but no loss of shape. Both points became hard and brittle. A point immersed in a very thin paste of zinc oxid, thymol, and oil of cloves showed no alteration in size within about one month; the paste however, soon set very hard.

From these experiments, the writer draws the conclusion that oil of cloves and gutta-percha form an ideal root-canal filling, if the canal is well saturated with the oil and a point of suitable size is selected. He suggests leaving a fiber of cotton saturated with oil of cloves for one day after successful pulp extirpation and root-canal treatment,

and inserting a gutta-percha point well saturated with the oil on the following day.

[While interesting, the writer's experiment is by no means conclusive, as the quantities of oil of cloves in the bottle as employed in the experiment and in the tooth respectively are not comparable, hence also the action of the oil upon the gutta-percha point.]

[*Correspondenz-Blatt für Zahnaerzte*, Berlin, 1914, No. 2.]

POTASSIUM PERMANGANATE AND ALCOHOL IN MOUTH-WASHES. By Dr. R. Klein.

As the growing appreciation of oral hygiene leads more persons to employ mouth-washes, it must not be overlooked that the process of rinsing the mouth is performed hundreds of times during the year, and the chemical reactions produced thereby, no matter how weak, may exert untoward influences by their frequent repetition. The writer describes the case of an artist who had been using "weak" potassium permanganate solutions in his dental toilet for eighteen months, with the result that his teeth showed a grayish brown discoloration, and being denuded of gingival tissue at the cervical portion of the alveolar processes, had become loose, seeming to have lost all enamel. The potassium permanganate had attacked not only the food débris, micro-organisms, etc., but also the oxidizable constituents of the teeth and the very delicate mucous membrane. Klein asserts that all alkalis in time render a tooth soft and frail; potassium permanganate is decomposed into potassium sulfate, hydrated manganese dioxid, and oxygen. Microscopically small fragments of the drug remain in the dental interstices, exerting their caustic action for days, and manganese dioxid becomes deposited upon the teeth. All efforts at removing the stains by acids are made at the expense of the matrix, the manganese dioxid, moreover, under the influence of sodium chlorid, no matter in how small quantities, giving off chlorin.

Alcohol, owing to its affinity for water, also produces deleterious influences in the mouth, as shown in acute form in arthritic alcoholics, whose teeth are denuded of gingival tissue. The alveoli and teeth lose their elasticity, are of gray color, and break easily owing to loss of lime. The topical application of strong alcohol to aching teeth by patients who hesitate to seek the dentist's services is, according to the writer's contention, responsible for the brittleness of these teeth, which frequently break in attempts at extraction. Such applications, moreover, are very deleterious to the approximating teeth.

RÉSUMÉS OF PAPERS PRESENTED AT THE SIXTH INTERNATIONAL DENTAL CONGRESS,

London, Eng., August 3, 1914.

Section I.—*Dental Anatomy, Histology, and Physiology.*

THE AMYLOLYTIC ACTIVITY OF SALIVA. By C. Lovatt Evans, D.Sc., Institute of Physiology, University College, London.

The amylolytic activity of the mixed saliva has been studied by the author (*Journ. of Physiol.*, xliv. 191, 1912) by a method which gives accurate comparative results, and it has been shown that the action very closely resembles that of malt amylase, both as regards the products formed—maltose and stable dextrin, and afterward traces of glucose—and as regards the dynamics of the reaction. The method used has been shown to give better results than two of the commonly used methods do (*Ib.* xliv. 220, 1912). The influence of food on the amylase content has also been studied (*Biochem. Zeitschrift*, Bd. xlviii. 432, 1913); an increase in amylase has been observed after carbohydrate food, but not after protein and fat meals. The increase lasts for some hours, and the influence of psychic factors was excluded by sham meals of carbohydrate, which were without effect. The cause of the increase was shown to be an increased activity of the parotid secretion. Parotid saliva is about four times as active as the other mixed secretions of the mouth taken together. The importance of these facts in the physiology of digestion is discussed in the original paper. The author cannot agree with Pickerill that the only use

of the saliva is to remove traces of starch from the mouth and thus prevent caries ("The Prevention of Dental Caries and Oral Sepsis," 1912, p. 160). Unpublished experiments made in conjunction with Mr. A. W. Wellings failed to show any relation between amylase content and dental caries. Moreover, the saliva of many animals not liable to dental caries is free from amylase.

Section III.—*Dental Surgery and Therapeutics.*

THE TREATMENT OF SENSITIVE CAVITIES. By C. Every Brown, Dundee.

The fear of dentistry and the need of more gentle and painless methods of treating sensitive cavities have brought about new methods of doing so. Analgesia by N_2O and O is neither convenient nor necessary. The ethyl chlorid spray is very useful when immediate treatment is required.

Hypodermic injections are also very useful in certain cases.

The use of formaldehyd gas given off by paraform has the useful properties of hardening gelatin, rendering it insoluble and inflammable; it works very quickly in the teeth of young people and on carious dentin; it is very irritating if used near the pulp, therefore a good deal of judgment is required. The use of para-mono-chloro-phenol, a preparation of carbolic acid and chlorin, is non-irritating and strongly antiseptic and anodyne; it is used in cases where the caries has penetrated near the pulp. If a tooth has given sufficient pain to keep the patient awake at night it should be devitalized. The para-mono-chloro-phenol has a modifying effect on the arsenic, greatly lessening pain. The dentin of young people is much more porous than that of old dentinal tubes obliterated in old subjects.

Section IV.—*Dental Anatomy, Histology, and Physiology.*

X-RAY OBSERVATIONS ON ABSCESSES, CYSTS, AND ROOT RESECTIONS. By Conrad A. Achner, Ph.D., L.D.S.Eng.

The writer desires to emphasize the following points:

1. The great importance of X-raying every mouth in order to ascertain the condition of the alveolus and hidden abscesses.

2. The darkness of the shadow on the skiagram indicating an abscess cavity depends entirely on the depth of the bone lesion and the amount of bone still intervening between it and the film.

3. One can diagnose a cyst from a granuloma on a skiagram by the shadow being of greater density, more defined regular outline, and the tendency sometimes of displacing the neighboring teeth.

4. The great importance of removing the entire root in extractions, the scraping out of abscess cavities, or removal of granuloma in order to prevent suppuration, formation of sinuses or cysts.

5. The presence of a shadow around the root apex and the history of a sinus is sufficient to denote the presence of a granuloma.

6. The correct way of reading skiagrams enables one to determine the extent of the bone lesion, and thus prevent waste of time by treating with drugs where a radical cure ought to be performed.

7. A tooth causing an abscess cavity or a dental cyst, if otherwise in good condition, can be saved by means of apical resection.

Section V.—*Dental Prosthesis.*

REMOVABLE BRIDGE WORK AND SADDLE BRIDGES. By Dr. A. C. S. Angel, Copenhagen.

The root-canals must be easy of access, and the root as little weakened as possible. The bridges must be made so that they will fasten well and yet be easy to remove. When the bridge pillars are molars and premolars, they are cut down a little below half height, and the sides are made cylindrical—with a transverse section like that of the root. A cylindrical ring of platinum-iridium or platinum-silver, with a cover of the same material, is made to cover these and soldered to it. Over this another cylindrical platinum-iridium or platinum-silver ring is adjusted. To the exterior of the latter, on the visible side, is soldered a thin gold plate twenty-four karats fine. On the exterior ring the crown cover is cast with a buttonlike stop down to the capsule directly placed over the root. If a greater contour of the exterior capsule is required mesially or distally, a little of the upper edge is removed at this place, and the contour is restored by casting in gold on the ring together with the crown cover. When the bridge pillars are incisors and canines, a thinner platinum-iridium or platinum-silver

cap with tube fastened to it—which must not be too substantial—is used. Outside this is adjusted a platinum-iridium or platinum-silver ring a little thicker than the former. On this is soldered a cover and a pin fitting into the tube. A steel facing is now ground on in such a manner that the foremost part of the exterior cap is removed. The tooth is now standing upon the foremost edge of the interior cap, and is soldered to the exterior cap. The remainder of the foremost half-part of the ring of the exterior cap is then removed. The foremost visible part of the ring of the interior cap is covered with gold twenty-four karats fine.

These appliances were used in—I, Bridges; II, Saddle Bridges; III, In connection with Prosthesis.

EXAMPLES OF I.

(*a*) In the upper jaw, second molar and first premolar remaining in right side; and in the left side, second premolar and first molar. These are prepared with double capsules; upon this is placed a complete removable upper denture without palate.

(*b*) On the root of two canines and on two molars a complete upper denture without palate is fastened by using the different preparations of the different bridge pillars.

EXAMPLES OF II.

(*a*) Molars wanting in the upper or lower half jaw of one side. To the premolars in the same half of the jaw double capsules are adjusted. Such exterior capsules are soldered together and connected with the gold or rubber which is to replace the molars.

(*b*) In the upper jaw the two premolars and the first molar are wanting, second and third molar are prepared in same way as explained in (*a*) preceding, and connected with the gold or rubber which is to replace the teeth.

(*c*) Lower jaw. In one side molars and premolars are wanting. First premolar of the other side is shortened and covered with inside capsule. The similar outside capsule is with a bar connected with a double capsule with tube and pin of the canine on the other side, and this again connected with the denture replacing the wanting teeth.

EXAMPLES OF III.

(*a*) Lower jaw. Only two second molars, one on each side, are left. All the rest of the teeth are wanting. Double capsules. The exterior ones are connected with the denture.

(*b*) In the upper jaw are only left two incisors or canines. Double capsules with tubes and pins, the exterior ones of which are connected with an upper denture.

CASE OF ABSCESS IN THE NECK, OF DENTAL ORIGIN, CURED BY THE ANTI-STAPHYLOCOCCIC VACCINE. By Dr. B. Landete.

The case described is that of a man of thirty years, of feeble constitution, and presenting an abscess in the left side of the neck arising from periodontitis in connection with a molar. After eight or ten days of fruitless treatment by warm antiseptic bath, extraction of the tooth, and disinfection of the wound and the mouth, treatment by vaccine was proposed to him, and this gave very good results.

Four injections were applied with intervals of five days, the first injection being of half a cubic centimeter, and the last one of two cubic centimeters.

The patient felt after the first injection a great *local* and *general* reaction, as when twenty-four hours had elapsed he had an attack of fever. At the second injection he only suffered a very slight febrile attack, and this was six hours after application; during the following injections and notwithstanding the increased proportions, the patient was not in the least disturbed.

Improvement took place immediately after the second injection.

The writer is convinced that vaccines will afford excellent results in this affection.

Section VII.—*Oral Surgery and Surgical Prosthesis.*

TOOTHACHE IN THE TOOTHLESS. By Dr. Med. Max Melchior, Chief Physician, Docent of Surgery at the School of Dentistry, Copenhagen.

It is well known that a patient may feel pain in an amputated limb, and that pain caused by a blow on the ulnar nerve is felt at the finger tips: but less is known of the toothache which is felt by the toothless, although its occurrence is not rare, and the pain is severe. The causes of trigeminal neuralgia are numerous; they may be central or peripheral, and the familiar causes of neu-

ritis, such as alcohol and syphilis, may be responsible, or the condition may be due to constipation alone, as pointed out already by Charles Bell. The condition to which the writer draws attention was described by Gross of Philadelphia in 1870, and has since been scarcely noticed. The pain is severe and obstinate, being neuralgic in character, and occurring in elderly, toothless subjects. It is situated in the remainder of the alveolar margin, or in the overlying gum, whence it radiates to the face and neck. The upper jaw is most often affected, and the area involved is usually very small. The soft tissues are less affected than in most forms of neuralgia of the jaws and face, and they may even escape entirely. When affected they are firm and adherent to the underlying bone and are cut with difficulty. The bone at the point is abnormally hard and ivory-like, and its inclusion of nerve-endings causes the pain. Excision of this bone is therefore necessary.

SECTION VIII.—*Anesthesia (General and Local).*

WHAT MEANS SHOULD BE TAKEN TO PREVENT THE OCCURRENCE OF ANESTHETIC ACCIDENTS. By J. STEWART ROSS, M.B., F.R.C.S.E., Anesthetist Edinburgh Dental Hospital, etc.

The object of this paper is to provoke a discussion upon what is certainly a matter of real public importance.

While fatalities in dental practice are not common, they do occur, and are probably nearly all preventable. So far as England and Scotland are concerned, however, the returns of the registrars-general give little help in estimating the absolute frequency, and none in fixing the percentage rate. We are therefore driven back upon general considerations.

The preventive means to which we must look appear to the writer to fall into the following groups: (*a*) legislation; (*b*) education of the dental and medical professions; (*c*) advances in scientific knowledge; (*d*) the immediate provision of some simple, safe method which can be relied upon to yield fairly uniform results in the hands of careful but not specially skilled men; (*e*) education of the public; (*f*) the evolution of specialism.

Of these, (*a*) has been unsuccessfully attempted in England, but seems to the writer to hold out no very great promise of improvement; (*c*) may of course prove of the greatest help, but cannot affect the general situation without (*b*), and perhaps the pressure of public opinion evolved by (*e*). As regards (*d*), there will no doubt be conflict of opinion as to what methods will satisfy the definition; (*f*) is always desirable, even though (*d*) were accomplished, but financial considerations will always prevent more than a small minority of patients availing themselves of the services of the specialist.

PERISCOPE.

Making Casts of Dental Pulps.—The casts produced after the methods of Preiswerk and Fischer in celluloid or low-fusing metal did not always give ideal results, as some of the canal contents were not fully reproduced. Albrecht's root-canal filling material (see "Review," DENTAL COSMOS, October 1914, p. 1192), opened the possibility of noting the relationship of the pulp to the tooth without destroying the latter. The Spalteholz method of rendering teeth transparent (see DENTAL COSMOS, April 1913, p. 374) enabled the observer to see even those spaces which had not been completely filled with the filling material, as air-filled hollow spaces of silvery luster. Moral's new method consists in introducing India ink as deeply as possible into the root-canals by means of a hypodermic syringe, the ink by its own gravity penetrating the pulpal spaces. The teeth are kept standing upright in a moist medium, then decalcified, and rendered transparent by carbolic acid, thus giving ideal pictures of the distribution of the branches of a pulp.—H. MORAL, *Deutsche Monatsschrift für Zahnheilkunde*, per *Zahnärztliche Rundschau.*

Sawing Thin Sheet Metal.—To saw thin sheet metal "sweetly" with a hack saw the metal is clamped firmly between boards and both are sawed through. A special saw with fine teeth is best for this purpose; it is not essential, however, if the metal is clamped between substantial boards.—*Dental Brief.*

Aluminum Paint as an Adjunct in the Dental Laboratory.—Aluminum paint is a most useful adjunct, since with it an old vulcanizer, gas ring, or kerosene heater may be made to look like new. It is easily and quickly applied, and will stand heat well.—G. H. Fetherston, *Australian Journ. of Dentistry.*

Sterilizing Fluid for Small Instruments.—A very good sterilizing fluid for small instruments can be prepared by adding to a 10 per cent. solution of formaldehyd as much borax as will dissolve. The borax prevents any action of the formaldehyd on the instruments themselves, while not interfering with its sterilizing efficacy.—*Edwards' Dental Quarterly.*

Cleaning the Cervices of Teeth Before Applying the Rubber Dam.—The rubber dam should never be applied to a tooth before its cervix has been cleaned and disinfected. If this precaution is omitted, infectious material is forced by the rubber and the ligatures under the gum margin, where it may remain for hours. The interruption in the circulation of the blood favors infection of the weakened tissue. For disinfection, hydrogen dioxid followed by thymol-alcohol is recommended.—H. Pichler, *Oesterreichische Zeitschrift für Stomatologie.*

A Quick Method of Making Impression Trays for Difficult Cases by Means of a Vulcanite Press.—The method suggested for obtaining an accurate impression, if isolated or elongated teeth remain in the mouth, is as follows: An impression is taken in modeling compound; around the teeth the compound is scraped off to a depth of 2 mm., and a cast is poured with low-fusing metal of lead 5, tin 4, bismuth 9 parts. A sheet of soft metal is roughly swaged to the cast, which is then invested in a flask and pressed once or twice in the vulcanite press.—Dr. Barra, *Deutsche Monatsschrift für Zahnheilkunde.*

Protecting a Lancet Blade.—It has been recommended for a long time to protect that part of a lancet blade not needed in lancing the gums, in adults and especially in children, by wrapping it with gauze, leaving only the end of the blade exposed. Any sudden movement of the patient would not then endanger the soft parts. Protecting gauze thus applied, however, is difficult to keep in place, and unless tied with thread may loosen and be a source of annoyance. A much better plan is to cut a Johnson cotton roll slightly shorter than the blade and press the blade through the center of it, exposing only what is required at the end. The roll holds tightly on the blade, and can be safely pressed against the lips or cheeks to hold them away while the point reaches the desired spot.—*Dominion Dental Journal.*

The Water Syringe as a Tongue Depressor, Cheek Retractor, and Light-Reflector.—In grinding roots or teeth in preparation for crown and bridge work, water is most important. With an office assistant, this problem is only partly solved. Most practitioners are without an office assistant, and find it difficult in most cases, especially in posterior teeth, to feed water to the stone, to retract the patient's cheek, or depress the tongue and reflect light at the same time. The stem of a water or air syringe is cut down to a length of 1½ inches, and to it is riveted a piece of aluminum plate slightly bent. With this, the cheek can be retracted so as to protect it from burns or lacerations, and the tongue depressed for grinding the lingual surfaces of teeth. If the aluminum shield is kept polished, it will reflect light very brightly.—F. F. Schwartz, *Dental Review.*

The Teeth and Life Insurance.—That dental and oral conditions have an influence on the health of individuals is being recognized by life insurance companies. In 1914, one of the large companies, the Metropolitan, issued a pamphlet—"Teeth, Tonsils and Adenoids"—in which is stated that it is "Printed and distributed by the Metropolitan Life Insurance Co. for the use of its policyholders." The issuing of a pamphlet of this character is commendable and shows a progressive spirit on the part of this insurance company. While some portions of the text would have been more exact had it been written by a dentist, it is an acceptable publication as it is, and will undoubtedly prove of value as an educational medium along these lines.

People are awakening to the fact that diseased conditions of the teeth and mouth are more detrimental to health than they formerly supposed, and one of these days general dental and oral conditions will be taken into account when examining applicants for life insurance.—*Dental Summary.*

Contra-indications to the Use of the Rubber Dam in Amalgam Filling Operations.—The use of the rubber dam in amalgam operations is rarely indicated, provided the cotton rolls and saliva ejector are intelligently used, and all things arranged for a careful but expeditious operation. Washing the cavity and margins with warm alcohol precludes contamination from the saliva, and thoroughly dries the field of operation. Many good cavity preparations extending beneath the gum would be extremely difficult cases for the use of the rubber dam, and a rubber clamp would interfere with the use of a matrix. One of the principal indications against the use of the rubber dam is the necessity of *immediate* closure of the jaw for the purpose of noting the occlusion, and particularly the movements of the mandible. This must be done at once, and before the filling material begins to crystallize, at which time there is great danger of crushing and breaking down a carefully contoured filling. This danger is *nil* before the filling has commenced to set. The saliva does no damage to the filling material after it is in place.—W. R. Pond, *Items of Interest.*

Collecting Blood for the Wassermann Test of Syphilis.—In view of the fact that whole volumes have been devoted to the Wassermann reaction, any attempt to describe it briefly would be useless, particularly as the actual performance of the test consumes too much time to bring it within the province of the busy practitioner. It consists in the detection in the patient's blood of certain substances produced by the action of the syphilitic virus. It is of more practical importance to the dentist to know how to collect the blood for the test, and the interpretation of the results obtained. To obtain the blood, the patient's middle finger is first wiped off with alcohol, and the pulp of the distal end of the finger toward the ulnar side is given a deep puncture with a sharp-pointed lancet. This as a rule causes little or no inconvenience. About two cubic centimeters of blood should be collected in a small sterile test tube, and can usually be obtained in a minute or two by having the patient's arm hanging down and squeezing the finger after the manner of milking a cow. When the blood is obtained, the tube should be sealed with a cork, not with cotton, and put in a cool place, preferably on ice, until the test is made. Ordinarily the blood will keep in good condition for three or four days.—R. H. Ivy, *Dental Review.*

The Quality and Quantity of Gold to be Used in Casting Gold Inlays.—The inlay should be cast of 24-karat gold for ordinary cases. Whenever the stress of occlusion demands a metal of greater strength, or attrition requires a metal with the property of hardness in a degree not possessed by pure gold, then five or ten per cent. of platinum should be alloyed with it.

The quantity of gold employed should be greatly in excess of the amount actually required, about five times as much in small cases, and at least twice the required amount in large cases. A mixture of nitrous oxid and illuminating gas used in the nitrous oxid blowpipe furnishes the most suitable means of properly melting the gold for casting. The metal should be heated until white-hot and immediately cast while it is in this extremely fluid condition.

The shrinkage of gold or the management of its shrinkage as commonly understood and applied to inlay work is not of so much importance as is the management of the property of spheroiding. This property is possessed by metals in the fluid state, as is evinced by the molten gold, which refuses to run into the mold. However, as soon as pressure is applied this property is overcome, and it is forced into the mold and so held; but on congealing, this pressure is automatically cut off and its property of spheroiding again manifests itself in its power to control the direction of the shrinkage.—A. J. Bush, *Dental Summary.*

Hints, Queries, and Comments.

FINISHING VULCANITE PLATES.

Vulcanite plates can be finished beautifully with pieces of glass in the manner customary with shoemakers. This simple method seems to be superior to the use of scrapers.

Jacob Julian Fischman.

Brooklyn, N. Y.

COLORING PLASTER IMPRESSIONS.

A few grains of carmine powder placed into the water which is used for mixing the plaster will impart to the impression a pleasing color and one which is of service in separating the plaster cast from the impression.

Wright B. Lee, D.D.S.

Eugene, Ore.

REPAIRING A BELLOWS DISK.

Often a bellows disk will break during an important soldering operation in such a way that the rent is beyond repair. In case of such accident, the piece to be soldered is kept hot over a Turner burner. At a garage, a piece of inner tube 24″ × 4″ is obtained, split lengthwise, and cut in halves so as to make two pieces, and a bevel of about 1″ is shaved or pared on one side of each piece. Rubber cement is then applied to both surfaces and allowed to dry for a couple of minutes. The surfaces are then put together and the resulting sheet of rubber is laid between two boards, placed in a vise, tightened, and left for five minutes. This emergency repair will prove valuable to the country dentist who lives miles away from a base of dental supplies or a dental repair shop.

Franklin S. Adams, D.D.S.

Waterville, Kans.

Obituary.

DR. LOUIS JACK.

Died, at his home, Moylan, Pa., December 9, 1914, in the eighty-second year of his age, Louis Jack, D.D.S.

Dr. Jack was born at Germantown, Philadelphia, March 26, 1832. His parents were Josiah and Elizabeth (Foster) Jack. His early education was obtained at the Bridgewater Academy, in Beaver county, Pa. When Louis was a young man eighteen years of age, his father went to California with the "forty-niners," leaving the family in the care of a guardian at their home in Beaver county. It was the father's desire that his son should join him in California, but he had developed an interest in the subject of dentistry, and after careful consideration he decided that he would remain in the East and take up the study of dentistry in Philadelphia.

He entered the office and laboratory of the late Dr. Wm. R. White, a brother of John DeHaven White, where he remained for a period of three months as a pupil, working interestedly in all of the procedures of the laboratory and observing as much as possible of operative work in Dr. White's office. At the end of three months he accepted a position as laboratory assistant to the late Dr. C. C. Williams of Philadelphia, with whom he remained in association until he entered the Philadelphia College of Dental Surgery

DR. LOUIS JACK.

in 1852, continuing the association throughout his college course until he graduated in 1854. During his period of studentship with Dr. Williams he read all available works upon the subject of dentistry.

At the old Philadelphia College of Dental Surgery he became intimately acquainted with Dr. Robert Arthur, then a teacher in that institution, an acquaintance that ripened into an association and friendship which continued until Dr. Arthur's death. During the winter of 1855–56 Dr. Jack had an office in Dr. Arthur's house, and by reason of his close relation with Dr. Arthur became thoroughly acquainted with his methods of work and with the character of his operations, concerning the high quality and excellence of which Dr. Jack has borne public testimony. When Dr. Arthur left Philadelphia to take up his work in Baltimore many of Dr. Arthur's former patients came under his care, and in 1904 Dr. Jack publicly stated that much of the work done by Dr. Arthur nearly fifty years ago, for those patients who had fallen under Dr. Jack's observation, was in perfect condition, much of the work having been done with cohesive gold.

Dr. Jack was, by reason of his association with Dr. Arthur, immediately concerned with the former's discovery of the practical utility of the cohesive property of pure gold foil. It had previously been known that certain makes of gold foil for dental use possessed an adhesive or sticky quality, but that quality was until its practical usefulness was demonstrated by Dr. Arthur, generally considered to be a defect—which, as a matter of fact, it was, with respect to the older methods of manipulation concerned in the production of so-called "soft gold" fillings. During the winter of 1855, however, Dr. Arthur requested Dr. Jack to make tests of the comparative density of crystal ("sponge") gold and ordinary foil. He furnished Dr. Jack with a book of foil which had for many months been left uncared-for in his cabinet. Dr. Jack on commencing to use it found that it was harsh and hard in its working quality. Dr. Arthur suggested annealing to soften it, and immediately observed with surprise the fact that it would adhere particle to particle like crystal gold. After watching the progress of the test filling made by Dr. Jack he went to his office and proceeded to make practical use of this newly discovered "adhesive" property. From that date he ceased to use any other kind of gold.

Dr. Jack has made several contributions to dental literature dealing with the use of cohesive, or as it was then called, "adhesive" gold foil, and has also definitely fixed the credit for the practical utilization thereof on an historical basis; but while Dr. Jack modestly accords to Dr. Arthur the whole credit for the discovery, the data would strongly indicate that Dr. Arthur and Dr. Jack were jointly the discoverers of the utility of this useful characteristic of our most important filling material.

While Dr. Jack was always intensely interested in everything, both scientific and practical, pertaining to the development of dentistry as a profession, he was pre-eminently the dental practitioner. He had been closely related to a relatively small group of eminent men in dentistry who achieved distinction as teachers and investigators, and whose activities were more particularly concerned with the increase and dissemination of the data upon which professional dentistry has its foundation, in all of which Dr. Jack maintained an intense and sincere interest throughout his long professional career. It was his contact with these developmental activities that quickly led him to appreciate the very great importance of dentistry in its health relations, and shaped his professional ideals upon a most exalted plane.

He entered upon the practice of dentistry at a time when it had not appreciably freed itself from the handicap of a spirit of commercialism which permeated in greater or less degree the whole professional fabric. He at once put into effective practice the principles of professionalism which were representative of his own attitude of mind toward his life-work. He was among the very first to realize that his remuneration must be based upon service and not upon the sale of things necessarily incident to that service. He consistently carried out a system of fees for service when the majority of his colleagues were charging a price for fillings and for artificial dentures based upon kind or amount of material involved in their making. Through his success in demonstrating the application

of those higher ideals to practice he became a center of professional influence which encouraged others to follow his example, for which reason it may be truthfully said of him that he did more than any other one man in his locality to raise the standards of dental practice and place it upon a professional basis.

He gave much attention to the improvement of the dental armamentarium. He was probably the first to use the matrix as an adjunct in contour filling operations. His matrices, matrix pluggers and accessories are the embodiment of the first attempt to utilize the matrix in filling operations. When the electro-magnetic mallet of Bonwill was first produced, Dr. Jack was among the first to use it, experimenting largely and with a considerable degree of success in the direction of its improvement.

He was interested in the development of the *International Dental Journal*, and was for a time president of the corporation which owned and published it. He was a member of the National Dental Association, the American Academy of Dental Science, the Odontographic Society of Pennsylvania, the Odontological Society of Pennsylvania, the Pennsylvania State Dental Society, the Academy of Stomatology, and the Philadelphia Dental Club.

Dr. Jack retired from active practice a number of years ago and devoted himself to the pleasures and comforts of a retired life, pre-eminent among which to him was the culture of roses, upon which subject he was a recognized authority.

He was the last survivor of the class of 1854 of the old Philadelphia College of Dental Surgery.

Simple-hearted, transparently honest, gentle, sympathetic, accessible and helpful to his younger colleagues, without egotism yet confident of the ultimate success of the principles for which he stood; successful in every phase of his professional work;—he was the embodiment not only of the best type of professional man, but of the citizen and Christian gentleman.

His death was due to physical complications of old age. His widow and six children survive him. His remains were incinerated and were buried in Germantown, Philadelphia, on December 12, 1914.

DR. G. BERTRAM F. MONK.

Killed in action, December 18, 1914, G. Bertram F. Monk, D.D.S., lieutenant in the Royal Warwickshire Regiment.

The son of Dr. Chas. J. Monk, late of Wiesbaden, Germany, now of 142 Harley st., London, W., Dr. G. Bertram Monk was born September 15, 1891. He was graduated at the Michigan University Dental College with the class of 1913.

At the outbreak of the war he was a member of the London Artists Rifles, and was studying at Guy's Hospital, London, for his English dental and medical degrees. Shortly afterward sent to the front, he was given a commission in November last in the Royal Warwickshire Regiment, which he had held for about five weeks, when he fell on the field of honor in France.

DR. ALEXANDER M. HOLMES.

Died, July 31, 1914, in Morrisville, N. Y., of old age, Alexander M. Holmes, D.D.S., in his eighty-eighth year.

One of the oldest and most prominent dental surgeons in the state of New York, and a distinguished citizen of Madison county, was removed in the demise of Dr. Alexander M. Holmes, who, on July 31, 1914, in his eighty-eighth year, died from infirmities incident to old age.

Although all his life was spent in a small community, Dr. Holmes attained unusual distinction within the ranks of his profession. In 1867 he was one of the charter members who drafted laws for the organization of the New York State Dental Society, in which body he was called to hold various offices, including that of president. His tenures of office, as state censor for the Sixth judicial district, as president of the Sixth District Dental Society, and as president of the Board of Dental Examiners, and his connection with the University of the State of New York and the State Board of Regents, all attest to the respect in which he was held in dental, social, and educational circles.

For many years the deceased had enjoyed a large and lucrative practice, spending his winter months in New York City in the practice of his profession. He kept even pace with the progress of dentistry, and contributed several valuable mechanical devices in its aid.

Dr. Holmes was born in Westford, Otsego county, and served as apprentice to Dr. Wiggins, a medical practitioner of McGrawville, and to Dr. Thompson of Cortland, Dr. Allen of Syracuse, and Dr. Dwinelle of Cazenovia, dental practitioners, receiving the degree of D.D.S. from the Baltimore Dental College in 1851. In 1849 he started dental practice in Morrisville, N. Y., where also he took a most active part in political and economic movements, and enjoyed such positions of honor and trust as that of county treasurer, delegate to the republican national convention at Philadelphia in 1872, member of the Madison county board of supervisors, representative of the town of Eaton in that body for thirty-two years, state senator, president of the First National Bank of Morrisville for forty years, and other high positions of distinction.

He was one of the promoters of the Madison County Home for Destitute Children at Peterboro, and for many years president of the board of trustees of that institution.

Interment was made at the Cedar Street cemetery.

Death of Dr. Chas. R. Butler.

We regret to have to record the death, suddenly, on December 15th, from neuralgia of the heart, of Dr. Chas. R. Butler of Cleveland, Ohio. An obituary notice of this distinguished practitioner will be published in the next issue of the Cosmos.

Society Notes and Announcements.

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

The Dental Faculties Association of American Universities will meet on February 24 and 25, 1915, in the Thomas W. Evans Museum and Dental Institute, at Fortieth and Spruce sts., Philadelphia, Pa.

Edward C. Kirk, *Sec'y.*

NATIONAL MOUTH HYGIENE ASSOCIATION.

A series of illustrated lectures on Mouth Hygiene has been prepared by this association for rental service. The first lecture of the series, a talk suitable for a mixed adult audience or school pupils above the age of twelve years (designated as lecture "A") is now ready. The lecture set (manuscript and 36 slides) will be furnished to members of state dental societies and others who may be considered competent to present the matter to the public, at a fee of One Dollar per use.

For further particulars and application blanks, address the Director of Extension Lectures,

Edwin M. Kent, D.M.D.,
222 Washington st., Brookline, Mass.

WASHINGTON UNIVERSITY DENTAL SCHOOL.

Alumni Association.

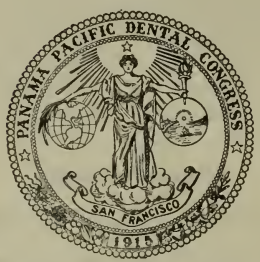
The forty-ninth annual clinic of the Alumni Association of the Washington University Dental School will be held on Monday and Tuesday, February 8 and 9, 1915, in St. Louis, Mo. Papers of interest to the progressive dentist will be read. The Executive Committee is making every effort to have this meeting one where the practical as well as scientific side of modern dentistry shall be shown. Mark off the date—come—get new inspiration. All ethical dentists cordially invited.

H. M. Fischer, *Sec'y,*
St. Louis, Mo.

Panama-Pacific Dental Congress.

San Francisco, Cal., August 30 to September 9, 1915.

THE following explanation of the meaning of the seal is given by Dr. Herbert J. Samuels, of Oakland, Cal., its designer: The female figure, representing Minerva, the Roman goddess of wisdom, and more especially the knowledge of the arts and sciences, scientific and practical truth, surmounts the universe, and standing on a bank of clouds, offers on one hand the light of learning, typified by the torch, and on the other the reward of achievement and honor, symbolized by the laurel. The two spheres represent the name of the congress and the place of meeting. On the right of the figure is the Western hemisphere with the two oceans which have been made one by the Panama Canal, and on the left is the "Golden Gate," the Bay of San Francisco, and the wonderful city on its shores. The fruits and flowers furnish a pleasing setting for the year, "1915," and signify that the country in which the congress will be held abounds in fruitful opportunities and blessings.



OPENS AUG. 30TH, 1915

THE SEAL.

THE Panama-Pacific Dental Congress is fortunate in having secured space for its meeting in the new Auditorium in San Francisco, as it is one of the finest auditoriums in the world. It covers an entire city block, and contains every modern convenience for the use of societies and conventions. Its main hall will seat 12,000 persons; 6000 in the balcony and 6000 on the floor. The latter space will be occupied by the exhibits of dental and pharmaceutical goods, and some of the general sessions of the Congress will be held in the balcony, the exhibit hall being closed to visitors during these sessions.

Besides this main hall, the Auditorium contains six halls with a seating capacity of about 1200 each, and four with a seating capacity of about 500 each. Enough of this space will be at the disposal of the Congress to accommodate the Oral Hygiene and other educational exhibits, the clinics and meetings of the various sections, and space will also be provided for the special meetings of the societies which will meet here as a part of the Dental Congress.

The Auditorium is located in the center of San Francisco, within eight blocks of all the leading hotels, and may be reached from the Exposition grounds in about ten minutes by either one of two direct car lines.

No Dental Congress ever held has had such good accommodations, and the fact must not be overlooked that all its sessions, clinics, and exhibits will be held in one great building, easily accessible from everywhere.

Hotel Reservations.

There are 1328 hotels and rooming-houses, which with 600 apartment houses represents a total of over 90,000 rooms, with accommodations for over 200,000 guests at any one time. Just finished are over 150 hotels and apartment houses giving nearly 15,000 rooms more, in addition to thousands of flats and rooms obtainable in private residences.

The San Francisco Hotel Bureau, representing more than 350 hotels, etc., will make contracts for hotel and other accommodations, and guarantees all its contracts. A San Francisco bank is its depository. These accommodations will be at rates of from $1.00 to $3.00 a day, per person, European plan, and from $3.50 and up per person, a day, American plan, for any date and any length of time desired. No charges of any kind, but a satisfactory guarantee must be given that the rooms will be used at the time stated.

The Bureau has the indorsement of and is operated in conjunction with the Panama-Pacific International Exposition, etc.

Applications for reservations should be directed to KIRK HARRIS, Manager San Francisco Hotel Bureau, Kearny and Market sts., San Francisco.

ORIGINAL COMMUNICATIONS.

TECHNIQUE FOR SOME OF THE PROBLEMS IN CASTING.

By T. P. HINMAN, D.D.S., Atlanta, Ga.,
PROFESSOR OF OPERATIVE DENTISTRY AND ORAL SURGERY, ATLANTA DENTAL COLLEGE.

(Read before the Pennsylvania State Dental Society, at its annual meeting, Philadelphia, June 30, 1914.)

BEFORE casting was announced, a great many of the steps that are now used in crown and bridge construction were very tedious and difficult in their technique, and some of them almost impossible.

When casting was first announced, it was difficult for me to become enthusiastic over this process, as I had for many years been constructing inlays and bridge attachments by other methods, with most satisfactory results. Gradually, when great possibilities seemed apparent and I became more familiar with the technique, the results obtained seemed to justify this process. Now, after a period of eight years' experience with casting, and when some of my supposed successes have returned in the shape of failures, I think it time to pause for awhile and take an inventory to find the cause of such failures.

Looking backward over the field of inlay work and some of the results obtained by skilful operators, we must admit that some of the older processes show better results than are now being obtained in casting. The permanence of some of the old burnished or swaged work which has stood the test of time should be to the observant dentist food for thought.

Difficulty in obtaining accuracy by the indirect method. On account of the difficulties encountered when we attempt to cast some of the more intricate inlays and bridge attachments—and I find when they are finished they rarely go to place—we might consider some of the older methods to see if, in part, they could be applied to our modern casting system. The use of the indirect or amalgam model method solved some of the difficulties, but still, when an attempt was made to cast the large mesio-occluso-distal inlays, following the most careful technique in impression, model, wax matrix, investment, and casting, my results were far from accurate. A great many things may enter into this

failure, due to changes in the investing material during setting and the tendency of gold to shrink toward a common center, etc. It is true that when we cast a large mesio-occluso-distal inlay by the indirect method, we are able by swaging, grinding, and burnishing to secure an appropriate fit. On account of the fact, however, that such large inlays should not be cast of pure gold, owing to the inherent weakness of this material, it has been found that large restorations should be cast of an alloy. This increases the difficulty in making them fit the amalgam model accurately.

Pure gold margins. It is so essential to my mind that the margins at least of all gold inlays should be made of pure

Fig. 1. Fig. 2. Fig. 3.

gold, so that they may be burnished after the inlay has been set and before the cement has hardened, that I have adopted the old method of swaging or burnishing 3/1000 pure gold on the model, trimming this matrix to overlap the cavity margins about 1/32 of an inch. Inlay wax is melted or pressed on the gold matrix while it is in place on the amalgam model; this wax is then carved to correct form and the whole construction invested and cast with an alloy. I prefer, as a rule, a three per cent. platinum-gold alloy for this work. (See Figs. 1, 2, 3.)

Platinum-gold alloy for body of inlay. Inlays cast by this method have the advantage of great resistance, maintaining their form during masticatory stress, at the same time retaining the advantage of the pure gold margin found so desirable for burnishing purposes. Another decided advantage is gained, because the matrix into which the alloy is cast seems to prevent, to a considerable degree, the shrinkage that is so apparent in the ordinary casting. It also leaves a perfectly smooth surface next to the tooth, free of nodules and maintaining its original form—for when gold is cast in the ordinary investment, enough of this investment is brushed away by the molten gold flowing over it to prevent the inlay from going to place, in fact making an inlay larger on the inside than the original matrix. This is especially true when a sharp angle is left at the occlusal step, or a narrow neck is made in the occlusal anchorage.

I will not consider at this time the futility of casting, directly or indirectly, against porcelain, but will simply advise strongly against any such foolhardy procedure.

The advent of interchangeable facings has been a great step forward in bridge construction, as it allows us to cast against these backings from which the porcelain has been previously removed, and to obtain results superior to any of the older methods of anatomical construction.

PORCELAIN CROWNS WITH BAND AND POST, AND CAST BACKING.

Let us consider for a moment the construction of the band-and-pin crown. Everyone has noted that when an incisor root is prepared for a band, and the band is made to fit closely as it should be, and a cap soldered on it and trimmed flush with the band, the resultant cap is so small that the porcelain facing will either overlap the cap, or, if ground to fit the circumference of the cap, the result will be a constriction of the porcelain at the neck, which is very unsightly. We can easily obviate this by changing our construction to the following method:

A band is made of 30-gage platinum which is closely adapted to the root, being soldered with 5 per cent. platinum solder (see Fig. 4); after trimming to correct length, a cap is soldered on this band of the same metal. Instead of trimming the cap flush with the band,

it is left overhanging about 1/32 of an inch. The triangle left on the outside of the band and cap is then filled with pure gold by melting. (See Fig. 5.) The resultant construction gives us a correct reproduction of the root-end. (See Fig. 6.) It will be found that the porcelain facing can be ground to fit this cap and band accurately without grinding its mesial or distal surface. An interchangeable facing and backing are then adapted to this construction, and inlay wax is melted on the lingual surface. This wax should be carved to correct contour, being sure to restore the gin-

Fig. 4. Fig. 5. Fig. 6.

gival convexity or cingulum. The facing is removed, and the cap, pin, and backing are invested and cast. By this method we are able to obtain a more perfect crown anatomically than by any other method of which I have knowledge.

Causes for recession of gums around bands. I might add, in passing, that if the labial convexity and the lingual concavo-convexity are restored in crowns of this character, the tendency of the gums to recede around the band will be corrected to a very considerable degree, as I am firmly convinced that one of the chief causes of recession around banded crowns comes from want of proper contour, for if the labial surface is left flat and the lingual surface made only concave, the food, during mastication, is driven against the gingival border of the gums, tearing them away from their attachments, thereby causing the recession so frequently seen around banded crowns.

This same method is applied to bicuspids. I might add that the iridio-platinum pin which is used in this construction should always be allowed to extend well through the cap, so as to engage the cast metal.

To those who have become expert in casting, it is possible to flow inlay wax around the triangle left by the overhanging cap, and cast this part of the appliance at the same time when the backing is cast, instead of flowing the pure gold on the platinum band, as has been previously stated.

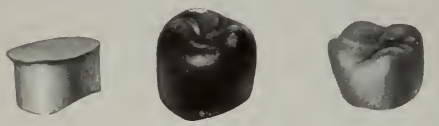
CAST GOLD CROWNS.

In the construction of all-metal crowns, I have found the following technique to give admirable results:

After the proper root preparation has been made, a band is constructed of 30-gage platinum and soldered with 5 per cent. platinum solder. This band should be made slightly convergent toward the occlusal surface. After careful adaptation, it is trimmed flush with the occlusal surface of the root, and a flat cap of the same material is soldered to it. This cap should be trimmed flush with the band. (See Fig. 7.) A wax bite is taken, and the cap and band are removed in the plaster impression. A model is run and placed in a small articulator, and the model and bite are given one coat of shellac, which has a tendency to harden their surfaces. Inlay wax is then melted and flowed to completely cover the cap and band. While the wax is soft, the impression is made in the occlusal surface of the opposite tooth. The inlay wax is carefully carved so as to restore a proper amount of lingual and buccal curvature. (See Fig 8.) The cap covered with wax is removed from the model and the mesial and distal surfaces covered with wax, this wax being carved to give the right amount of approximal contour. It may be replaced on the model to see if these are correct. All of the plaster is then removed from the inside of the band.

and the whole construction invested and cast in the usual way, thus producing a seamless, platinum-lined gold crown, which, if correctly carved, gives us a

Fig. 7. Fig. 8. Fig. 9.



more perfect reproduction of the natural tooth than any other means of which I have knowledge. (See Fig. 9.)

The wax is not allowed to go over the platinum that fits below the gum margin; about 1/64 of an inch of platinum is left exposed so that, when the crown is set, a burnisher may be run over the exposed platinum, and thus secure a perfect adaptation to the root surface.

In bicuspids, where the pulp is vital, this construction may be modified by cutting out the buccal surface of the band and soldering a piece of 36-gage

Fig. 10.

platinum over this surface. When the wax is applied to the metal band, the buccal surface is left uncovered, the result allowing for the replacement of the buccal surface with low-fusing porcelain. As it is exceedingly difficult to bake porcelain satisfactorily to a close adaptation and attachment to the buccal sides of these crowns, I have in some instances filled this buccal surface with synthetic cement, with apparently good results. Enough gold should be left on the occlusal surface to protect the porcelain replacement. (See Fig. 10.)

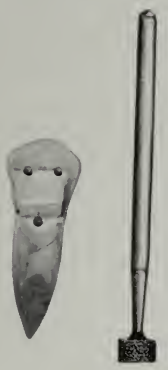
CAST HOOD ATTACHMENTS.

For many years I have been constructing attachments for vital incisors, canines, and bicuspids in such a manner as to prevent the showing of gold, and yet securing an attachment sufficiently firm to support a bridge of ordinary dimensions. After many futile attempts, for a while I abandoned casting as a method of producing these attachments, but since I have modified my technique, I have been able to cast them instead of using solder. The hood about to be described is used on canines and incisors, and is known as the three-pin two-step hood:

We will use for illustration a canine as an abutment, aiming to replace a lateral incisor. The preparation of the tooth is accomplished by cutting a step in the lingual surface of the canine about 1/16 of an inch above the gum line; another step is cut in the same surface along the line of approximal contact mesio-distally. These should be well defined and extend to the dentin sufficiently to give resistance to the finished hood. To do this, we use a No. 528 Miller carborundum stone. (See Fig. 11.) The mesio-lingual surface is then removed with the same stone, carrying the cut gingivally in line with the lingual step. This removal is necessary to prevent re-decay and give a firm attachment for the soldering. If the occlusion is very close, a portion of the lingual enamel is also removed. With a No. 3 bur, a hole is drilled in the lingual step about 1/16 of an inch deep, in line with the long axis of the tooth. Two holes are then drilled in the occlusal step in the same manner and to the same depth. These last holes should straddle the pulp. Sometimes it will be found necessary, instead of putting two holes in the occlusal step, to put one in the disto-occlusal and the other in the mesio-gingival step. The placing of these holes must be done according to the case in hand. All three holes should be

drilled consecutively without removing the drill from the mouth. (See Fig. 11.)

Fig. 11.



Pure gold 3/1000 is then adapted to the lingual and mesial surfaces, allowing a considerable overlap. An automatic mallet with a piece of orange-wood, trimmed wedge-shape with a flat end, used for a plugger will be found useful in malleting this gold on the steps; however, this may be accomplished by the

Fig. 12.

use of flat burnishers. While this backing is held in place, small holes are punched in it to correspond with the holes in the tooth. In these holes we place pins made of 20 gage iridio-platinum wire; the appliance is then removed with modeling compound which has been dry-heated. This, of course, must bring away the pins as well as the backing. The modeling compound is invested and removed, and the pins are attached to the backing with a very small quantity of 22-karat solder. (See Fig. 12.) The appliance is then returned to the mouth, reburnished, and trimmed to a slight marginal overlap.

The advantage of returning the backing and pins after soldering is that we get a re-alinement of the pins to the holes. The appliance is then removed in an impression. This may be done with modeling compound. After a model has been made, inlay wax is flowed over the backing and pins, and carved to correct contour so as to make an anatomical lingual restoration. The appliance is then removed from the model and all of the plaster cleaned away. It is then invested and cast with a gold alloy. The resultant hood gives a strong attachment, and if properly

Fig. 13. Fig. 14.

constructed, does not interfere with the vitality of the tooth. (See Figs. 13 and 14.)

Bridges have been placed in the mouth, the four incisors being restored by placing hoods on each canine. Two centrals have been restored by placing hoods on both laterals. I might add that the dummies used by me are made exclusively individual saddle, so that the speech of the patient is restored as well as the lost teeth. This hood has also been used as the anterior attachment for a bridge carrying both bicuspids, the distal attachment being preferably a gold crown. In some instances, however, I have made an inlay in the molar serve as the distal attachment. This, however, is not strongly advised, and must be used with discretion in favorable cases only.

Hoods for Bicuspids.

Where it is desirable to use a vital bicuspid as an attachment for a piece

of bridge work, the hood described in the following paragraph is found serviceable and satisfactory:

In the preparation of this tooth, the lingual cusp should be ground off completely, and enough of the occlusal surface removed to allow for sufficient restoration in gold to compensate for wear. Cavities are cut in the mesial and distal surfaces of the bicuspid, these cavities extending under the gum line. The lingual surface is then ground off so that there will be a gradual taper from the gum line to the occlusal surface. The occlusal enamel on the buccal side is gradually chamfered toward the buccal cusp: a proper tray is con-

Fig. 15. Fig. 16. Fig. 17.

structed of German silver, and the impression of this tooth is taken in Perfection modeling compound. From this impression is made an amalgam model. (See Fig. 15.) On this amalgam model is burnished 3/1000 pure gold; in some instances I use 1/1000 platinum. The matrix is trimmed to a slightly marginal overlap. On this matrix is melted or pressed inlay wax which is carved to an approximate occlusion, restoring the mesial, distal, and lingual surfaces of the tooth. (See Fig. 16.) This gold matrix and wax model may then be returned to the mouth for the purpose of correcting the occlusion, being careful not to allow the patient to bite into this hardened wax. After carving the wax away, or replacing it where it is too scant, this hood should be removed and cast with an alloy. This gives us a hood that has all the strength of a gold crown without its unsightly appearance. (See Fig. 17.)

Hoods of this description have been used by me for many years. I have inserted one such appliance in a patient's mouth, a bridge extending from the third molar to the first bicuspid, the anterior attachment being a hood of this description. It has been in the mouth for about ten years, but of course was made with solder instead of by casting.

GOSLEE TEETH.

In the construction of bridge work for the distal teeth, I have found the Goslee tooth a most excellent substitute. The technique of casting on receptacles to hold these teeth I wish to describe:

I have endeavored to cast a satisfactory receptacle directly from a wax impression, but my results have been very unsatisfactory. In a majority of instances, where these teeth are used, it is necessary to grind them in making the adjustment and occlusion, thus increasing the difficulty in casting the receptacle. If 1/1000 platinum or 3/1000 pure gold is swaged or burnished over the portion of the tooth intended to be used for attachment, and an iridio-platinum pin, 14 gage, thrust through the backing into the hole in the tooth, this pin being always soldered to the backing, it will be found that when the wax is flowed over the metal backing, and it is carved to proper contour and cast, the tooth will go to place more readily and without the necessary grinding and fitting that has to be done if no backing is used.

In this construction, it is very essential that the pin be soldered to the backing, for if this is not done, frequently investing material runs through the hole in the backing, surrounding the pin where it is attached to the wax, and thus prevents the cast gold from firmly attaching itself to the pin. The careful soldering of the pin to the backing of course prevents this, and we have a clean receptacle for the insertion of the porcelain tooth which allows it to go to place readily. It has become my practice to construct posterior work using the individual saddle in fixed bridge work. If care is used in this construction, I have found it much more

cleanly than the so-called self-cleansing bridge.

INLAYS AS BRIDGE ATTACHMENTS.

Inlays for bridge attachments have been used for many years by some operators. My experience has been that unless the inlay is well seated in the occlusal surface, and a small pin or pins placed in the gingival wall, they have invariably proved unsatisfactory. When it is desirable to use an inlay as a bridge attachment, the procedure is as follows:

After the cavity has been properly prepared, and the occlusal step and anchorage have been cut well into the crown, a hole is drilled, or in some instances, two holes are drilled in the gingival step; these should be about 1/16 of an inch deep and be made with a No. 3 bur. (See Fig. 18.) An impression is taken of the cavity in Perfection modeling compound, and a model made of amalgam. In this model is formed a matrix of 1/1000 pure gold in which are soldered pins of 20-gage iridio-platinum wire. It may then be returned to the mouth to correct the alinement of the pins. The matrix is then returned to the amalgam model, and inlay wax flowed over it and carved. This should then be cast of platinum alloy. The resultant inlay may be used as an attachment for bridge work with good results. (See Fig. 18.)

Fig. 18.

I do not, of course, cast every inlay into a gold or platinum matrix, but when an inlay involves more than two surfaces, it is my invariable custom to make my castings in this manner.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

ROOT-CANAL BROACH REMOVED FROM THE LUNG BY BRONCHOSCOPY.

By CHEVALIER JACKSON, M.D., Pittsburgh, Pa.

THE rarity of the loss of instruments from the skilful fingers of the modern dentist is evidenced by the fact that in the author's collection of nearly five hundred objects removed by bronchoscopy and esophagoscopy, the broach herein mentioned is the first dental instrument. One deciduous tooth that was aspirated after it escaped from the dental forceps, one molar that was aspirated into a bronchus after being knocked out by a fall, and three artificial dentures, constitute the only dental objects in the collection. Considering the fact that almost the entire population, at some time or other, passes through the dentist's hands, this is a wonderful tribute to dental skill. That accidents are possible, however, is shown by the following case:

A physician of thirty-nine years, while in the chair of a very skilful dentist, aspirated a root-canal broach which had slipped from the dentist's fingers during work on an upper molar. An excellent radiograph by Dr. Wm. O'Brien showed the broach in the right bronchus. Ten days later, the patient consulted Dr. H. W. Loeb of St. Louis, who referred the case to the author. Two radiographs (Figs. 1 and 2) made by Drs. Johnson and Grier showed that the

broach had worked its way downward, as small, long, pointed, metallic bodies always do, until it had reached the smallest, deepest bronchial branch it could enter. The author's positive films of the tracheo-bronchial tree when laid over the negatives showed the broach to be in a small posterior branch of a larger posterior branch of the right lower-lobe bronchus. The bronchoscope was passed under local anesthesia, and with the exact knowledge of the position

Fig. 1.

Fig. 1 is a radiograph showing a dental root-canal broach in a small posterior branch of a larger posterior branch of the inferior-lobe bronchus of a man of thirty-nine years. The foreign body is seen just above the dome of the diaphragm. It was removed bloodlessly through the mouth by bronchoscopy under local anesthesia.

of the foreign body it was promptly found and removed with bronchoscopic forceps. After removal, the patient sat on the observation stand and watched the next bronchoscopy. He left for his home in St. Louis the same evening. The time required for the operation was nine and one-half minutes for the application of the local anesthetic, and half a minute for the insertion of the bronchoscope and removal of the broach. It should be stated that bronchoscopic removal of foreign bodies from the bronchi is not always so quickly accomplished; but it is successful in over ninety-six per cent. of the cases, the bronchoscope being passed through the mouth and the foreign body thus removed bloodlessly through natural passages, with a mortality of but little over one per cent. in

Fig. 2.

Fig. 2 is a lateral radiograph taken of the same patient. The foreign body is seen to be in the part of the lung back of and below the level of the diaphragm, in this position of the patient and this stage of respiratory diaphragmatic excursion.

Fig. 3.

Fig. 3 shows the root-canal broach removed bloodlessly through the mouth by bronchoscopy, from a small broach of the right inferior-lobe bronchus.

uncomplicated cases. In children it is done without anesthesia, general or local.

Failures to remove, of which the author has had 5 in 482 cases, were all failures to find—not failures to remove when found.

A PROBLEM IN ANCHORAGE.

By LAWRENCE W. BAKER, D.M.D., Boston, Mass.

(Presented before the Eastern Association of the Graduates of the Angle School of Orthodontia, New York City, April 23, 1914.)

THIS morning I wish to present for your consideration a method of carrying the molar anchorage distally by converting the usual stationary molar anchorage into simple anchorage. This method consists in replacing the rigid buccal tubes by hinged or swivel tubes.

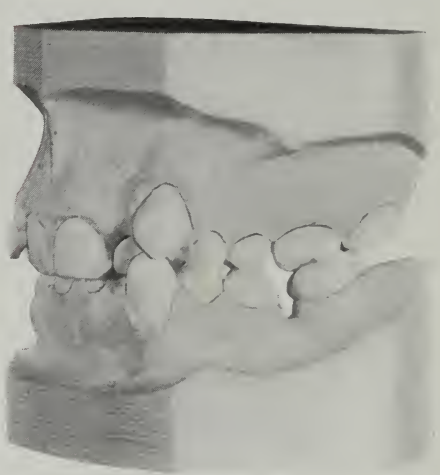
Every orthodontist present has undoubtedly met with two groups of cases in which it is necessary to gain space in the dental arches by moving the molar anchorage distally. The first group consists of cases in which room has to be gained for impacted premolars or canines. The second group is made up of mutilated cases where the remaining molars have migrated forward, and it is necessary to move one or both molar anchorages distally to gain space in order to supply the missing units of the dental arch.

All will agree that with the expansion arch and its usual form of anchorage (band and rigid buccal tube) this is a most difficult condition to bring about, for the molar anchorage is most apt to overbalance the resistance of the anterior teeth, and the space is gained at the expense of moving these anterior teeth forward instead of carrying the molar anchorage backward. The result of this mechanical disadvantage is that the osteoblasts are stimulated to activity in the wrong area, and the consequent bone growth takes place in the anterior region, and the facial lines are usually distorted according to the amount of space gained.

The case illustrated shows clearly one use of this swiveled tube and demonstrates its method of construction.

Fig. 1 shows a mutilated case of class 1. It will be observed that both the lower first permanent molars have been extracted, and that the second permanent molars have migrated forward and have partially filled the space of the missing units. In doing this these second molars have tipped forward, as

FIG. 1.



is usually the case when the first permanent molars, the foundation stones of the dental structure, are sacrificed. All modern orthodontists realize the importance of putting these second molars into their normal position and bridging the spaces of the sacrificed first permanent molars.

Realizing the difficulty of tipping and carrying back these anchor teeth with the stationary molar anchorage, it occured to me that, by substituting the

rigid buccal tube with a swivel tube, the problem would be simplified; so I proceeded to have constructed anchor bands for the lower arch with these swiveled tubes, the details of the construction of which are shown in Fig. 2.

Even with this simple anchorage and the expansion arch, I found after bringing the misplaced canines and incisors into line, that the resistance of these anterior teeth had weakened, and it was impossible to use them further for the purpose of carrying the molars backward, although this had been accomplished to a very appreciable degree. So without hesitation I employed the new Angle appliance principle, continuing, of course, with the swivel tubes. Fig. 3 clearly shows the appliance and the condition of the case at the time of employing it. It will be observed that, with this pin-and-tube principle, all the root resistance of these ten anterior teeth is utilized, and that the anchorage has been practically reversed; that is, these anterior dental units serve as stationary anchorage, while the molars with the swiveled tubes are the objects to be moved.

I have also used the same principle with the "new appliance" in several cases of impacted premolars and canines with the greatest satisfaction.

Fig. 2.

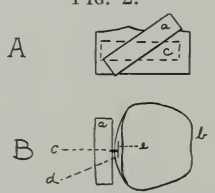


Diagram showing details of construction of swivel buccal tube. A, Side view of band and tube. *a* and *c* indicate swing of tube. B, Coronal view of A. *a*, tube; *b*, band; *c*, swivel pin, one end of which is "sweated" into a hole drilled in the wall of the tube; the other end passes through a hole drilled in the extension plate *d*, and soldered (22-k.) to washer *e*. Then each end of the extension plate is soldered (18-k.) to the anchor band.

I must add still one more important use for this swivel-tube principle, and that is in the treatment of excessive cases of infra-occlusion. It is our common experience, I believe, in treating these cases with the ordinary fixed molar anchorage to bring about a tipping of the molar anchorage; it matters little whether the case be treated with the expansion arch and rigid buccal tube or with the "new appliance" and rigid buccal tube, or with the Young lock; in each instance it is a mechanical impossibility to treat these excessive infra-occlusion cases without causing this aggravating tipping of the anchor molars. To those who have experienced this annoyance I strongly recommend this pivoted anchorage—for with it the prizing leverage on the anchorage is relieved, and the perpendicular elastics have perfect freedom of action.

I bring this method before you this morning as a contribution to the principle of anchorage in orthodontia.

Fig. 3.

TUBE TEETH AND PORCELAIN RODS: THEIR USES AND ADAPTATIONS IN PROSTHETIC DENTISTRY.

By JOHN GIRDWOOD, D.D.S.Univ.Pa., L.D.S.Edin., Edinburgh, Scotland.

(Continued from page 138.)

(XI.)

CHAPTER XIV.—Setting Crowns and Bridges.

The methods employed in attaching tube teeth, bridges, or gum tube sections to the various bases and anchorages which have been spoken of deserve more than the passing notice which they have received. With regard to the various media, those most frequently used are cement, gutta-percha, sulfur, amalgam, and vulcanite. In addition to these, screws and riveting may also be added as methods of attachment. Before proceeding to consider these, however, attention is directed to the fact that with tube crowns the attachment—generally a cap and post—can always be fixed on to the abutment before the crown is cemented to place, also in tube bridge work, the attachments being formed independently of the body of the bridge, can often be permanently fixed to the abutments before the body of the bridge is finally set. This has a more important bearing upon the choice of the cementing medium than at first appears, and favors the use of gutta-percha rather than cement in a larger number of cases than where most other forms of construction are employed. The materials and methods employed for the purpose will depend upon various factors, such as the nature and extent of the anchorage available, and the personal inclination or preference of the operator. The cementing media most commonly used are cement and gutta-percha, either singly or in combination. Cement has the advantage of affording the maximum amount of adhesion between the attachments and abutments, and so is of special value when a doubt exists with regard to the fixity obtainable by other means. It is, however, open to several objections, among which are its solubility, porosity, and difficulty of removal in case of accident or necessity. Its solubility may be lessened by attention to careful fitting, so that the junction between the root and the cap or crown is made as close as possible, as thereby the cement will obtain the maximum amount of protection. Its porosity permits it to become infected by putrefactive bacteria. This, however, can be prevented by the addition of about a tenth part by bulk of hydronaphthol to the cement powder, to which also may be added a drop of oil of cinnamon or cloves.

The advantages possessed by gutta-percha when skilfully used are the ease with which it can be removed, its insolubility, non-irritating properties, and tendency to reduce shock or stress on the abutments. The objection usually urged against it is the difficulty of manipulating it and the time thereby required to obtain the best results. The gutta-percha which is best suited for the purpose is the ordinary pink base-plate variety. The best results are usually obtained, however, by the use of a com-

bination of cement and gutta-percha employed in the following manner: The post being roughened by spurring it with a knife, in order to help the gutta-percha to adhere, post and gutta-percha should be heated, and a small quantity of the latter, barely sufficient for the purpose, molded along the post, when cap and post should be tried on to the root, forced carefully to place, and any surplus removed. It is important to avoid using too much gutta-percha, as this involves danger of spreading the band. The final cementing is to be carried out in the usual way, and the details of this process need not be entered into, as these are familiar to all. But the immediate after-effects demand more consideration than they usually receive, consequently the writer desires to draw attention to the use of hot water as a local anesthetic, after cementing the crown or bridge to place.

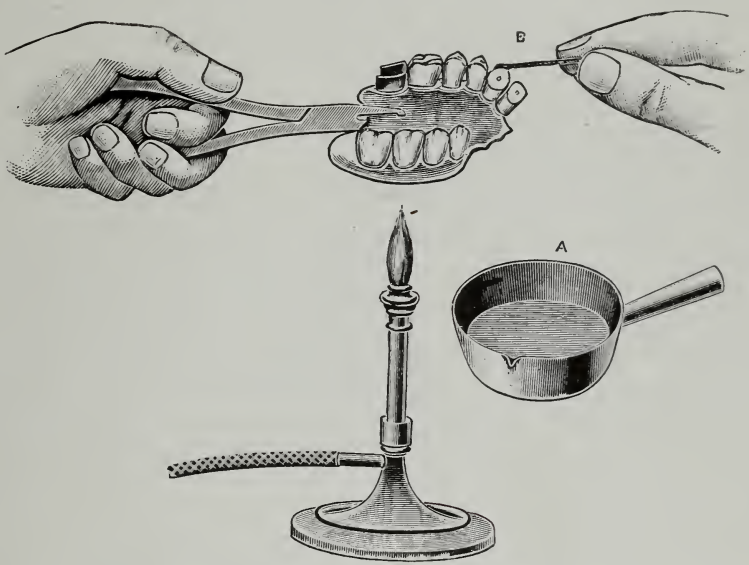
However carefully the method of cementing has been carried out, the bands fitted to the roots, and their depths proportioned to the case, the cementing-on process is always painful—slightly so, no doubt, in some cases, moderately so in most, while in others it is markedly painful. In these cases pain is doubtless due to a hyperesthetic condition of the periosteum and gum. From whatever cause it may arise, it is a form of pain which some patients are peculiarly intolerant of, and for that reason alone it is desirable to get rid of it as quickly as possible. It is surprising to find how ineffectual cocain is under these circumstances. Even a saturated solution, when applied between the gum margin and the neck of the tooth, seems to have little anesthetic effect. Of course a few drops injected will give complete anesthesia, but this is objectionable on several grounds, and is wholly unnecessary. The following plan will be found to give almost instant relief, and is unfailing in its action: Fill a fairly large syringe—say a 2-ounce one—with very hot water, as hot as can be borne without producing actual pain on the gum. The right degree of heat can be approximately judged by directing a stream on the finger before applying it. Before the cement has quite hardened, remove all pieces of lint, cotton, etc., from the mouth, and having the saliva ejector in place to remove the hot water as fast as it is applied, direct the stream of water forcibly on to the gum around the neck of the tooth, by holding the point of the syringe about two inches away from the neck of the tooth. By the time the syringe is half empty the pain will either have completely disappeared, or nearly so. All surplus cement should then be removed. Once more a *forcible* stream of hot water should be directed around the neck of the tooth and between the band and the gum, and if need be a third one, but this is rarely, if ever, called for. It is noted, therefore, that we have in water, used either hot or cold, as the circumstances of the case may demand, a simple, powerful, and easily controlled anesthetic agent (see Chap. V, July Cosmos, 1914, vol. lvi, p. 810) which is always at our command, and which is entirely free from the objectionable features which sometimes accompany the use of other anesthetics. Doubtless when the powerful anesthetic properties of hot water are fully realized, it will obtain wider recognition. When gutta-percha is used as the cementing medium, the same plan should be followed.

SETTING A BRIDGE WITH CEMENT AT ONE END AND GUTTA-PERCHA AT THE OTHER.

It is sometimes desirable to take advantage of the properties possessed by cement and gutta-percha in the above manner, and the cases in which a combination of these fulfils the desired results are fairly numerous. For example, the anchorage at one end may be ample, while at the other it may be deficient for the purpose of attachment by means of gutta-percha. In such a case the following plan will be found to yield entirely satisfactory results: The usual steps are carried out with regard to the preparation of the anchorage for cement and gutta-percha, and the latter is car-

ried to the point where final softening only is required before forcing the bridge to place. While an assistant mixes the cement, the operator should get ready the bridge for setting, and as it will have been heated throughout its whole length, the following plan should be adopted, whereby the end to be cemented is made cold, and will remain so long enough to permit the piece to be accurately forced to place, while the other end is not chilled too quickly. A stream

Fig. 175.



Shows mode of grasping plate in finally fixing teeth.

of ethyl-chlorid spray should be directed on to the end of the bridge which is to be cemented, and almost up to the middle. The cementing may then be carried out quickly in the usual way, before the cement has been affected by the heat or the gutta-percha by the cold.

The material and methods employed for attaching horizontal bars or posts into the tube of a crown or bridge afford considerable choice. As previously pointed out, the unglazed interior of the porcelain tube and roughened surface of the posts, along with a thin layer of cement, provide an enormously strong attachment—stronger, indeed, than is necessary. Generally speaking, the ends of a bridge or approximal surface of a crown are countersunk in order to permit of an inlay or inlays being formed on the posts or bars, and these provide against possible rotation, while adding greatly to the support of the porcelain and strength of the anchorage at the point where it is usually required. Unless there is a liability of the abutments spreading, the cementing medium need do little more than exclude moisture, consequently very soft gutta-percha, chloro-gutta-percha, or wax may be used, although of course cement is always to be relied upon; but no hard-and-fast rule can be laid down for all cases.

Amalgam, screws, split posts, riveting, and other devices may be employed with advantage in the manner ordinarily described in connection with their use, and the facilities afforded for doing so are probably greater in the case of tube work than in any other.

The use of vulcanite has been dealt with, and it only remains to deal with the use of sulfur.

As a cementing medium sulfur can

claim priority over the various forms of cement used at the present day, its use dating back to the eighteenth century. It is most commonly employed for fixing tube teeth to gold plates, and where it is possible to do so it is to be preferred to cement, for the reason that if circumstances arise which necessitate the removal of the teeth from the plate, this can be easily and quickly done by carefully heating the case to the melting-point of sulfur.

Sulfur can, of course, be employed in crown and bridge work also, but its special advantages are most apparent in plate work. The method of using it is as follows: The plate having been finished in the usual manner, a few shallow cuts are made in each pin with a file. The teeth having been cleaned and freed from all traces of oil—which can be done by boiling them for a few minutes in a strong solution of soda—the tubes should be dried by means of cotton wound around a broach, and, where platinum tube teeth are used, their interiors roughened by a clean tube file. The sulfur is melted in a small Berlin porcelain cup or an iron spoon until it is quite fluid. The plate should be grasped with pliers held in the left hand (Fig. 175), and plate and teeth heated carefully over a spirit or small Bunsen flame. This must be done gradually, and the flame ought not to be allowed to play on the porcelain. A wire spatula—a piece of flattened iron wire, pin-wire size—is dipped into the melted sulfur, and repeatedly conveyed to the heated plate and teeth. The sulfur runs by capillary attraction under the teeth and along the pins. When it has been ascertained that the sulfur has filled all the tubes and spaces, plate and teeth may be allowed to cool, and the excess of sulfur removed by means of a fine-pointed knife or point, after which the plate may receive the final polishing.

Various modifications in the manner of using sulfur are employed; for example, lump sulfur broken into small pieces may be placed on the end of each tube, and when plate and teeth are heated the sulfur will run through, additional pieces being used until a surplus shows.

Repeated melting of sulfur seems to improve its quality rather than to spoil it.

CHAPTER XV.—On the Use of Porcelain Enamels for Shading Artificial Teeth and Crowns.

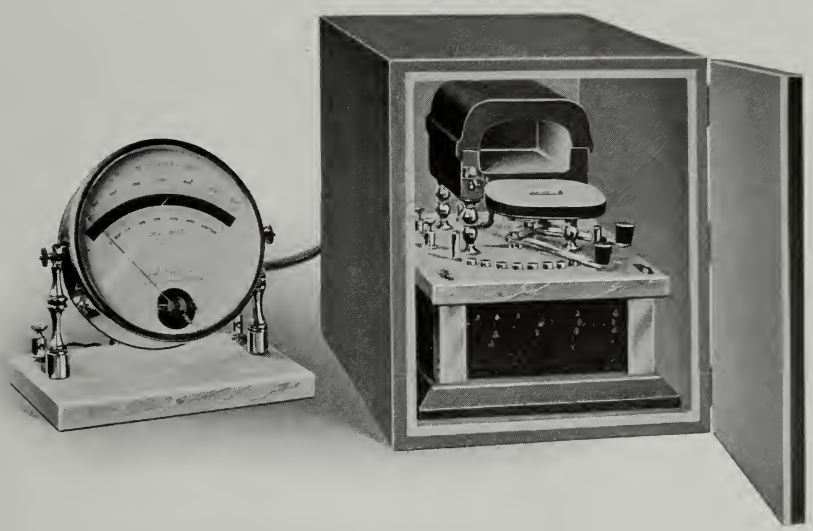
The introduction of porcelain enamels has made us much less dependent than formerly upon that wide selection of shades of teeth and crowns hitherto deemed indispensable, and the variations obtainable by their use cannot, in many cases, be got in any other way. It is unnecessary here to enter into a lengthy description of the use of these materials, as the instructions furnished by most of the well-known makers who supply them enable the least experienced to gain the end they have in view, with a little practice. The choice of high, medium, or low fusing enamels is, generally speaking, a matter of individual preference; at the same time care must be observed not to employ a very high-fusing enamel when poured teeth are used. The temperature at which the various enamels fuse to yield the best results are carefully set forth in the instructions which accompany them. It necessarily follows as the result of coloring teeth by the use of these enamels that the matter of cooling the porcelain becomes a question of importance, and while this has been already spoken of, its importance is such that no apology need be made for once more reverting to the subject, especially as most writers do not seem to have given this matter sufficient consideration. Doubtless this neglect has arisen from the fact that porcelain brought to a high temperature during soldering operations is protected by a mass of investment material, which, even when of moderate bulk, permits of the porcelain being cooled nearly uniformly throughout; whereas when porcelain is brought to a high temperature without the protective aid of investment material, such as the muffle of a furnace, a much longer time must be allowed for it to

cool down uniformly if the maximum amount of strength is to be obtained.

The period between 1840 and 1880 may be said to have marked the highest level of porcelain tooth manufacture, but even until 1890 the quality was generally excellent, although there were distinct evidences of falling off. One of the reasons given for this in a former chapter was "the stress of modern competition." Manufacturers will probably deny the truth of this, nevertheless it is true. Moreover, they have no cause to feel ashamed, as the fault lies with us as a profession, for the reason that we have followed the modern craze and sought cheapness rather than quality. Doubtless in many cases we have done so from lack of thought rather than from intention. The result, however, has been as stated. In fact, a comparison between the prices of the teeth manufactured about sixty years ago with those of the present day will go far to explain the difference in quality.*

No doubt, once the profession realizes that a high quality of porcelain is worth paying for, the manufacturers will endeavor to meet the demand; but they can only do so by following the lines of the old makers, who, in order to obtain the results which they achieved, never attempted a batch of more than a few hundred teeth at a time. These were fused at a sufficiently high temperature, and the muffle was allowed to cool slowly and evenly. This took from twenty-four hours to two or three days, the time depending upon the size of the furnace and muffle. Subsequent heating of such porcelain to a high temperature and allowing it to cool rapidly would not greatly impair its strength or toughness, but such treatment would greatly weaken present-day porcelain, particularly, as already explained, when the porcelain is not protected by investment. The treatment ordinarily considered sufficient nowadays is to allow even the smallest electric furnace to cool down without attempting to protect it from drafts or to retard the cooling in any other way.

FIG. 176.



Annealing box for electric furnace.

* Sixty years ago porcelain teeth were sold at 50 cents apiece; single gum tube teeth at 60 to 70 cents; two single gum tube teeth in one piece $1.75; three single gum tube teeth in one piece $2.00; four single gum tube teeth in one piece $2.50.

This may take from two to three hours, but is altogether insufficient. The plan which the writer has found to give best results is to stand the electric furnace in a box similar to that shown in Fig. 176. A box such as this might be made of wood or metal, but should be lined with asbestos slabs, about one-half inch thick, carefully jointed so as to make it practically airtight. After the porcelain has been fired, the door, which is also lined with asbestos in the same way, should be closed, and not opened for at least twelve hours. This will allow the porcelain to become sufficiently tempered or annealed, and so permit of its maximum strength being developed, although no treatment will make up for imperfect fusion of the porcelain in the first instance.

CHAPTER XVI. — Supplementary Suggestions.

It was the writer's intention to have concluded these papers in the last chapter, but on further consideration it appeared desirable to extend them still further in order to make them more comprehensive. At the same time the subject is far from being exhausted—and it is hoped that this may also be said for the reader's patience.

In addition to the materials mentioned in Chapter II, the following may be added:

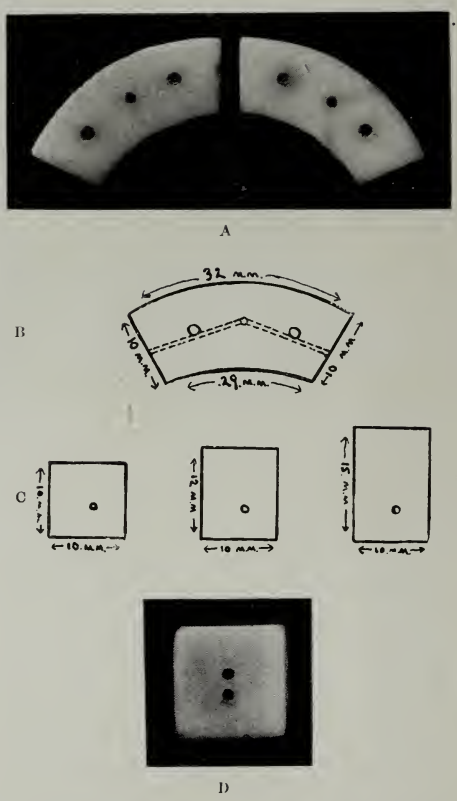
Description and Use of Curved Blocks.

Two sets of curved blocks, three in each set, known as Nos. 33, 34, 35, and Nos. 36, 37, 38; also rod, 15 mm. square on section, known as No. 39. (Fig. 178, D.) The set of three blocks Nos. 33, 34, and 35 are exactly similar in size and curve to the other set, Nos. 36, 37, and 38. The former, however, have only two vertical tubes through them (Fig. 177), each 12 mm. apart measured from their nearest points, while a detailed description of the latter set, Nos. 36, 37, and 38, is as follows: These blocks are each 32 mm. measured along the largest arc of the circle (Fig. 178), and are made in three sizes, 10 mm., 12 mm., and

Fig. 177.

Shows curved block.

Fig. 178.



A, Curved blocks Nos. 36 and 37. B, Sketch showing plan of blocks Nos. 36, 37, and 38, with vertical and horizontal tubes. C, Shows relation of horizontal tube to bottom edge of block. D, End view of rod No. 39.

15 mm. Each block has three vertical tubes through it, those at either end

being similar in size to those in the other porcelain rods and non-platinum tube teeth, while the central vertical tube has a caliber smaller than the others, about 15½ U. S. gage. The tubes at either end are 10 mm. apart, measured from their nearest points, while the center tube is situated exactly midway between these two. (Fig. 178, A.) In addition to the vertical tubes there are two tubes which extend horizontally through the blocks from either end, and

FIG. 179.

Case of edge-to-edge bite. The upper central, lateral, and canine of each side is formed from block No. 35. The lower incisors and canines are single-tube teeth crowns.

meet in the center at the point where the vertical tube intersects them, as in Fig. 178, B. These curved blocks overcome the disadvantages which sometimes arise from employing the ordinary straight single or double-tubed rods, whereby the horizontal posts are apt to project either on the labial or lingual surface, as mentioned in Chapter X and shown in Fig. 126 (see COSMOS for November 1914, page 1224). They also do away with the necessity for drilling vertical tubes in certain cases where this might be necessary. They are also useful for the purpose of shaping up plain sections of 2 or 3 teeth, gum block sections, removable facing sections, and for many other purposes. (Fig. 179.)

By the use of these sections any desired curve of arch can be obtained, while sufficient material is available to permit of any form of irregularity being reproduced. With regard to the tubes, experience has shown that the distance between the center of the canals of the canine and central incisor of either side is about 10 mm., irrespective of the width of the crowns of the teeth; but should the canals be wider apart, or closer together, the porcelain tubes may be reamed out in the direction required, or one or both posts may be resoldered to the cap, as mentioned in Chapter VII, page 940, COSMOS, August 1914.

The object of the central tube is to provide for a post in a lateral incisor where this may be necessary; but, as it is likely to be less frequently required than the other two, a smaller tube only is provided, and this can be enlarged, if need be, by means of one of the special diamond reamers.

Lastly, with regard to the horizontal tubes, these are for the purpose of providing additional strength and anchorage, as shown in Fig. 178, B, and the horizontal tubes in blocks Nos. 36, 37, and 38 are all situated 4 mm. from the bottom edge, as in Fig. 178, C; and the purpose for which this is intended is to provide for the tube's being so situated with regard to its relation to the teeth and gum portion, or to the crowns where crowns only are used, that the horizontal post need not be exposed during the shaping-up process.

Where either a vertical or horizontal tube is not required, it can readily be filled by means of a section of post cemented into it, and here it may be well to state how this may be done in the case of a bridge formed from a straight porcelain rod with single or double tubes, and the method is applicable in a similar manner to curved blocks also. Where the continuity of the tube is not broken by intersecting vertical tubes, the horizontal post or bar may be cemented to place in the manner described in Chapter XIV, but where

vertical posts entirely obstruct the passage of the horizontal one, a section of

Fig. 180.

Shows how each short length of wire is cemented in from either end.

post or bar should be cut off equal to the length of the tube between the points A and B, Fig. 180, and cemented to place.

Cutting-off Sections from Porcelain Rods.

In the chapter on grinding and shaping, the use of a thin carborundum wheel was recommended; and this serves the purpose well in many cases, but it is open to one serious drawback, namely, the liability of the wheel to "jam." When this happens, the wheel is almost certain to break. This is not to be wondered at when one notes that these wheels are thick in the center, and tapered toward the edge. It follows, then, from their shape that the deeper the cut the greater the amount of friction on the sides of the wheel, hence the greater the danger spoken of. Elastic base wheels meet this difficulty admirably, indeed for industrial purposes they are exclusively employed in work requiring thin or narrow cuts. At present similar wheels are not procurable for our purpose, although they are made for industrial purposes as thin as 1/32 inch up to 4 inches in diameter, 1/16 inch thick up to 8 inches in diameter, and they have been made as thin as 1/64 inch. An efficient substitute will be found in a brass disk 4 inches in diameter, thickness about 17 U. S. gage, and fine carborundum powder mixed with oil. The oil and carborundum powder may be used on a small piece of sponge in the same manner as water for keeping wheels wet while grinding. The use of oil is attended with one disadvantage. The fingers become soiled with the débris from the wheel, which is difficult to remove; but a solution of sugar and water,

Fig. 181.

Cut made in porcelain rod No. 25 with a brass wheel, using Columbia lathe at lowest speed with carborundum powder and sugar mixture. Time taken, 70 sec.

in place of oil, etc., while equally effective, does away with this. (Fig. 181.)*

The Use of Tube Teeth, Single or Double Tube Rods, or Porcelain Blocks, for the Purpose of Forming Removable Facings or Interchangeable Teeth.

In the chapter entitled "Superiority of the Tube Tooth," page 699, Cosmos, 1914, it was pointed out that in certain cases of abnormally close bite the whole of the porcelain covering the lingual surface of the post either of a tube crown or of a tube tooth attached to a plate, might be ground away and yet leave the porcelain facing as strong, if not stronger, than an ordinary plain tooth unprotected by a backing: because in such a case the porcelain face would be supported in the whole of its length, provided the post was not ground too far through. Figs. 41 and 42, in Chapter IV, illustrated the amount of anchorage which would thus be obtained in the case of a tube tooth or section of porcelain rod, as well as when a double tube rod or porcelain block is employed. It will also be observed that it is greater in the case of the former than the amount of anchorage provided by any of the well-known forms of removable facings, while in the case of the double-tubed rod used

* The writer hopes to deal much more fully later on with the subject of grinding materials and methods.

in like manner, the amount of anchorage obtained is greater than is afforded by any form of plain tooth, due to the fact that the anchorage tubes extend from the incisive edge—or, in the case of the back teeth, to the crown surface of the tooth or facing—to the cervical border. Moreover the disposition of the tubes one on either side of the middle third of the tooth adds greatly to its strength, for the reason that a hold is obtained over the widest possible area. Thus, these facings may be employed for any or all of the purposes for which plain teeth, interchangeable teeth, or removable facings are employed. When used for vulcanite work they require no anchorage post, although a simple form of anchorage, or anchorage and strengthener combined, can easily be formed. The tube tooth, when it has been ground away in the manner to be described, has far more of the character of a natural tooth than any of the ordinary forms of plain teeth, for which it can be so readily substituted. Moreover, all of the double-tube rods and porcelain blocks spoken of may be used to form two or more removable facings joined together in a manner similar to the illustrations already shown of tube crowns treated in this way, and the claims which have been advanced in favor of those multiple crowns where the tubes are used vertically are likewise applicable in the case of removable facings. In consequence, they permit of a much wider application of the principle than appears to have been hitherto suggested—while others will doubtless suggest themselves to the reader.

To Form a Removable Facing from a Tube Tooth or Porcelain Rod or Block.

This is a very simple matter. In the case of one of the older forms of platinum tubed teeth the platinum tube or lining may be retained or removed. If for any special reason it is decided to remove it, this may be done by means of a cross-cut bur before the tooth is ground through to the tube on its lingual surface, or afterward, when it may sometimes be dislodged without much difficulty by means of a sharp instrument; failing which, it may be removed by means of a cross-cut bur as described. The lingual surface should first be ground off by means of the large 4-inch wheel, $\frac{3}{8}$ inch or $\frac{1}{2}$ inch thick, until the

Fig. 182.

tube is nearly exposed. It should then be ground quite flat by being held against the side of the same wheel, which should run perfectly true. But, previous to being ground, a post should be temporarily cemented into the tube or tubes to act as a guide to the amount which should be ground off, and at the same

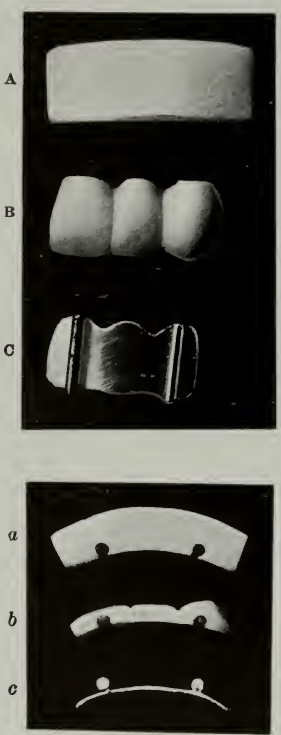
Fig. 183.

Central incisor facing formed from double-tube rod No. 27, with backing.

time to preserve the ground edges of the tube. Care should be observed merely to expose the platinum tube. If a doubt should exist about the lingual surface being perfectly flat, the tooth facing should be rubbed down or ground on a flat carborundum hone with water or oil, using a rotatory motion. When a facing is formed from a tube rod, a section

should be ground down nearly to the level of the tube, and then cut off, and the preparation of the lingual surface completed in the manner described. The facing should then be ground to the desired shape in the usual way. Fig. 182 shows the various stages. In Fig. 183 is a facing formed from a double-tube rod.

Fig. 184.



A *a*, Labial and incisive views of section of block No. 33. B *b*, Shaped up. C *c*, Labial and incisive views of backing.

In the case of two or three facings formed from a double-tube rod, the lingual surface may be ground in the same way, or, better still, it may be hollowed to conform to the arch (Fig. 184), and the facings then shaped as described in the section on "Grinding and Shaping." When three facings are formed from a double-tube rod, the lingual surface of the section of porcelain should also be hollowed out in the manner suggested, otherwise the arc of the circle representing the labial surface of the teeth can only be obtained at the expense of needless thickness of the teeth, with its attendant disadvantages.

In grinding the concave surface of the block down to the tubes, a wheel 1, 1½, or 2 inch diameter and ⅜ inch or ½ inch broad, grit 80 to 100, should be employed, and a finer one, about grit 150 and of the same size, for final grinding. Great care should be observed not to carry the grinding too far; the point where it should cease is when the tubes are only just exposed evenly along their whole length, or it may be stopped short of this by about the thickness of note-paper, when the tubes may be further exposed in the whole of their length by means of a thin S. S. W. Vulcarbo disk, No. 3, 6, or 7. In the event of interchangeable teeth or removable facings, either single or multiple, being manufactured, the tubes might with advantage in many cases be size No. 3, therefore similar in size to the tube of the platinum tube tooth, but of course not lined with platinum. This would permit of a thinner facing, an advantage which though seldom necessary, would not entail any sacrifice of strength which could not be well spared, and it would still leave these facings stronger than any others.

Fitting a Backing to a Tube Facing.

In order to form a backing for a single-tube facing, take a piece of perfectly flat backing, and scrape it lightly in order to obtain a bright clean surface which will solder readily. Then take a length of straight wire which will accurately but easily fill the tube, and lightly scrape it also along the surface which is to be soldered to the backing. Now tie the wire and backing together by means of thin binding wire, and having boraxed the surfaces which are in accurate contact, apply a very small piece of solder to the joint and flow the solder carefully but thoroughly in the Bunsen flame. If

this has been done carefully, the facing, after the backing has been pickled, should slip on easily. Success depends upon using the smallest possible amount of solder which will form a union of the parts and no trace of solder should be visible after the operation is completed. Where a double tube is employed, the procedure is similar, although the details are necessarily somewhat different. The first post may be soldered to the backing in the manner described; the second post may have its relation to the first one (on the backing) determined by using a short

Fig. 185.

Shows section of double-tube rod used as a guide for fixing position of wires to backing for soldering.

length of tube rod cut from the same porcelain rod placed temporarily on to the post at each end (Fig. 185), the post or wire tied to the backing, and the porcelain sections or guides withdrawn —leaving, of course, the second post in its proper relationship to the first—when it should be soldered to the backing in the way described. Instead of the sections of porcelain rod being employed as a templet or guide, two small permanent guides or templets made of brass may be used, one set for each of the double-tube rods. An alternative method is to solder both posts to the backing at the same time; or the backing and posts may be invested and then soldered, or a cast backing may be used, backing and posts being cast in one piece.

A Repair Facing.

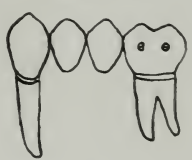
A repair facing may be formed in the manner shown in Fig. 186, and this may be done by cutting off a thin section of

Fig. 186.

Stages in the formation of a repair facing from double-tube rod No. 26.

a double-tube rod in the manner already described. Such a facing will often be found of use in replacing a molar or bicuspid facing broken off a crown or bridge, using the existing pins or anchor screws for the purpose of obtaining anchorage. (Fig. 187.) The position and size of the hole will allow of ready adjustment, and the facing may be ce-

Fig. 187.



Molar facing fixed with anchor screws.

mented to place in the usual way, or a combination of cement and amalgam, or cement and porcelain cement, may be used. Should one or both pins come away with the porcelain facing of a molar or bicuspid crown, the remaining portion of the pins which may adhere to the backing should be ground off, and two holes drilled and tapped in the backing, and a headed screw screwed into each, or two short How screws used, and the facing cemented to place.

A Further Consideration of the Question of Tubes and Posts.

For ordinary purposes the size of the tube in the non-platinum tube teeth and rods is all that could be desired, but, as previously mentioned, there are conditions which call for modification. For instance, the size of split or solid posts best suited to all cases cannot be arbitrarily fixed, neither can the size of metal tube or the thickness of its walls be dealt with in this way. In consequence, the writer begs to withdraw the suggestions of the table on page 610, May Cosmos, 1914. It is to be understood that the reader must judge for himself as to the size of the posts and tubes which will best meet the circumstances of exceptional cases. There are one or two points, however, which will serve well as a general guide: A split post should be stouter than a solid one. Where a solid post No. 13 U. S. gage is used, a split post No. 12 U. S. gage would generally be as strong. Metal tubes should be quite thin when they are surrounded by an inlay or used for lining a porcelain tube.

(To be continued.)

PRINCIPLES OF CAVITY PREPARATION.

By H. W. P. BENNETTE, M.D.S.Liv., L.D.S.Eng., Birkenhead, Eng.

(Report presented to Section III, Sixth International Dental Congress, London, 1914.)

IT does not enter into the province of this paper to discuss the advantages or disadvantages of the cast gold inlay as compared with the foil filling, nor do I intend to do so, beyond stating my belief that the cast inlay affords us a better means of restoring to full functional activity any tooth which has been attacked to any appreciable extent by caries, than does the foil filling.

It must not be understood by this that I have discarded the foil filling, but that I have limited its use to small cavities which have a box-like formation, that is to say four walls and a floor, and which do not call for a contour restoration.

For convenience of description, I will divide the types of cavities into three groups:

(*a*) Those rendered necessary, or brought into being, by imperfections in development, such as fissure cavities or pits.

(*b*) Those which occur upon smooth surfaces.

(*c*) Those which involve both of the above.

In group (*a*), I use the words "rendered necessary by imperfections in development"—wishing to imply that I do not hesitate to cut out faulty fissures or pits, even though they are not as yet seats of caries.

The reasons for treating carious teeth are two, namely, the removal of diseased tissues, and secondly, the restoration in full of these lost tissues.

Bearing this in mind, I invariably divide my operation strictly into two sections, and therefore never begin to shape up a cavity until I have completely removed all affected parts.

Technique of Cavity Preparation.

The first step in the operation is to break down all frail enamel margins by means of a freshly sharpened chisel, cutting until hard, healthy enamel is reached in every direction.

When this has been done, as much of

the carious dentin as can be removed by the use of excavators is cut away, the cutting being done from points near the center of the cavity toward the circumference in order to avoid undue pressure and consequent pain being inflicted upon the pulp.

When it becomes difficult to remove partly infected dentin by this operation, a suitable rose-head bur is used, and by this means all unhealthy dentin is removed. If at this stage any overhanging enamel margins are present, they should be removed by means of a convenient sized carborundum stone moistened and used with a light steady touch while revolving rapidly in a true-running handpiece.

I use stones in preference to burs for all trimming of enamel margins, as I consider they cut better and are less painful to the patient—to say nothing of the speed the work can be done at, and the finished surfaces they give. Small knife-edged stones used in either the straight or contra-angle handpiece are particularly useful for opening up fissures, especially where there is little or no caries present.

At this stage, and not before, should the shape of the cavity and the position of the cavity margins be finally decided upon. At this point also, pulp or root treatment, as the case may be, should be taken in hand, and generally speaking completed before passing on to the rest of the operation of preparing the cavity for the reception of the inlay.

The above description serves for every form of cavity met with.

It would be quite impossible in a paper of this length to go into the minute details in the preparation of even all the most typical cavities we have to deal with. I shall therefore attempt so to word my description as to cover the majority of them.

SHAPING OF CAVITY MARGINS.

First, let us consider a typical case in group (*a*).

Assuming that all infected tissue has been removed, and leaving out of consideration any pulp or root treatment, we must decide upon the position to be occupied by the cavity margins.

Here, as in all cases, due regard must be paid to the chance of the recurrence of decay, and the joint between healthy tooth and metallic restoration must lie in the region of comparative immunity. This on all occlusal surfaces is, practically speaking, at every point except the defective fissures, so that when these have been freely cut away the cavity margin occupies a position of safety. Sharp corners, such as lie at the junction of the fissures, should be rounded off in order to simplify the cavity as much as possible.

SHAPING OF CAVITY WALLS.

This being done, the next step is to shape up the walls of the cavity. The floor, or pulpal wall, should be made as flat as possible, and the remaining walls should be as near a right angle to this as it is convenient to make them. In practice this angle will be slightly obtuse; but it is wise to make it as little so as possible.

The best procedure in my hands for bringing this about is first to cut the floor with the face of an inverted-cone bur, taking care not to undercut the walls, then proceed with a Dall's inlay bur and finish off with either a drum-shaped stone or else with an old fissure bur covered with moistened carborundum powder. This gives a smooth surface, and insures cutting the face of the wall in its entire depth at one time. The angles made by the perpendicular walls with each other should be rounded and follow the line created by the margin of the cavity.

At this point, if I have any doubt about being able to withdraw my wax matrix, I soften some gutta-percha and force it into the previously moistened cavity, let it stiffen and then carefully remove by fixing a heated sprue, which when cold can be seized by dressing-pliers. If it leaves the cavity easily all is well, and in any case a careful examination of the plug often suggests

some slight modification or improvement in the shaping of the cavity.

PREPARATION OF THE CAVO-SURFACE ANGLE.

The last step, but a most important one, is the treatment of the cavo-surface angle, and with Dr. J. V. Conzett and others I lay particular stress upon this part of the preparation. I prefer a long bevel, taking in the whole thickness of the enamel. This requires care and a good deal of patience. In the type of cavity at present under discussion, I find a cone or drum-shaped stone of great use.

When this surface is carefully polished I consider the cavity is ready to receive the wax from which the matrix is to be made. This paper is not concerned with this part of the procedure, but it is well to examine the pattern when obtained, and to learn from it whether the cavity preparation is all that it should be, or not; if not, it can still be remedied.

Quite a common complication of this simple class of cavity is where a defective groove extends over the buccal or lingual surface of the tooth. In this case the treatment is the same. The pulpal wall is extended and becomes the floor of the groove, the walls are at right angles to it and the cavo-surface angle is beveled; obviously the occlusal end of this groove is wider than that which approaches the gingival margin, for the convenience of withdrawing the wax pattern. In the cases where this groove leads into a pit which when cut out is larger than the width of the groove, I prefer to treat it as a separate cavity rather than sacrifice too much healthy tooth substance.

The pits formed on the lingual surfaces of the upper incisors need no more description than the above, as they should be simple box cavities.

LABIAL AND BUCCAL CAVITIES.

To pass now to those cavities which occur upon smooth surfaces. Very little further description is required for this type of cavity. The most common examples are those which are situated at the gingival margin on the labial surfaces of incisors and canines, and the buccal surfaces of premolars and molars.

Here the floor or pulpal wall should be flat and the surrounding walls at right angles to it, and the cavo-surface angle beveled, except in the region where the cavity margin passes beneath the gum. Here I prefer a face joint, for the simple reason that it can be practically finished out of the cavity, and thus avoid damage to the soft tissues; it also occupies a region of immunity.

The only cavities on the mesial or distal surfaces that I treat in the above way are those which are situated in teeth which have lost their neighbors, and where the enamel and dentin on the occlusal boundary are strong and healthy. All other cavities which have their origin on these surfaces I open up to the occlusal surface and treat from there.

MESIO- OR DISTO-OCCLUSAL CAVITIES.

One description for all mesio- or disto-occlusal cavities must suffice:

All defective tissues having been removed, the cavity margins are extended to those regions which are comparatively immune from decay. The gingival margin should occupy a place just beneath the gum, and the buccal and lingual margins, which should be parallel or slightly divergent at their occlusal ends, should meet it in slightly rounded-off angles. The occlusal margin will depend upon its position on the condition of the fissures on that surface. If these are involved they must be cut out as described above and the two cavities must merge into one another. The gingival wall should be cut flat at right angles to the long axis of the tooth, and the pulpal wall should meet this at a right angle. The gingival wall may here be considered as the floor of this portion of the cavity. The remaining two walls, buccal and lingual, should meet both the gingival and pulpal at right angles.

or if there be sufficient tooth substance to allow of it without risk of weakening, these two walls may occupy a position at an angle which is slightly acute with the pulpal wall. If this is not possible or is undesirable, anchorage may be obtained in most cases by either broadening the end of the fissure or occlusal portion of the cavity which is distant from the main portion, or drilling a depression in the pulpal wall of this portion of the cavity.

When this is done nothing remains but to create the cavo-surface bevel and take a test wax pattern. The object is so to form the cavity that the wax matrix can be withdrawn from it in an occlusal direction.

If the fissures are not involved, I find the simplest form of retention is to make the bucco- and linguo-axial angles slightly acute, and if possible increase this tendency as the occlusal surface is reached. This, together with a flat gingival floor, an accurate contact-point restoration, and good occlusion, is sufficient to retain any medium-sized inlay in this position.

If the root-canals have had to be treated, additional retention can be obtained from this source by means of a post of iridio-platinum wire around which the inlay can be cast.

MESIO-OCCLUSO-DISTAL CAVITIES.

In those cases where both the mesial and distal surfaces are involved, it is necessary to make one complicated cavity. The preparation is the same with this addition: The cusps are deliberately reduced, so that they may be reproduced in gold. This is particularly necessary in the case of upper premolars. In this way the risk of splitting either half of the tooth during mastication is reduced to a minimum.

APPROXIMAL CAVITIES IN ANTERIOR TEETH.

It only remains now to give a brief description of the preparation of cavities situated in the approximal regions in the anterior teeth. Generally speaking, these cavities can be made fairly simple by quite freely opening them up from the lingual aspect. The margins are extended in every direction until the safety line is reached. If the cavity is one which does not involve the incisal edge, sufficient retention can be obtained by preparing it as follows: The gingival margin is placed beneath the interdental portion of the gum tissue, and merges into the labial margin, which extends as far as the mesio- or disto-lingual angle of the tooth. The lingual margin is brought into existence by the preparation of the pulpal or axial floor.

The gingival wall is shaped so as to be at right angles with the long axis of the tooth, and the axial wall is made at right angles to the gingival wall. This is accomplished by opening up the cavity from the lingual aspect with small stones or fissure burs held in the contra-angle handpiece, great care being taken not to remove all healthy dentin from the back of the labial wall. This operation virtually forms the labial wall, which thus makes a right angle with the axial wall. It will be seen also that this forms the lingual margin of the cavity. Sufficient retention can then be obtained by prolonging the lingual margin and the portion of the axial wall adjacent to it, both in the direction of the root and the incisal edge of the tooth—thus forming a dovetail. This portion of the margin and a small portion of the extremities of the labial and gingival margins can then be beveled and the cavity is ready for the trial wax pattern.

Those cavities which involve the incisal edge must be prepared on slightly different lines to the previous variety. Additional retention must be obtained on account of the extra strain to which the filling will be subjected during mastication. In a large number of these cases where so much restoration is called for, the pulp has been involved and we have the root-canal at our disposal by which to secure a strong anchorage. In those cases where the pulp is alive, additional hold is obtained by treating the

lingual surface of the tooth as though it were an occlusal surface, and following the same principles of retention as described for mesio-occlusal cavities in the molar region.

Much more could be written on this subject, but I think the above description to some extent covers the chief points in the principles of cavity preparation.

A NOTE ON THE TREATMENT OF HABIT SPASMS.

By V. E. SORAPURE, M.B., Ch.B., F.R.C.S.(Edin.), New York, N. Y.,
ATTENDING PHYSICIAN TO THE CENTRAL AND NEUROLOGICAL HOSPITALS, NEW YORK.

(Read before the Eastern Association of Graduates of the Angle School of Orthodontia, at its fall meeting, New York City, November 28, 1914.

AS the purpose of this paper is to deal with a particular line of treatment of habit spasms, it is not my intention to burden you with a lengthy discussion on etiology or pathology, or to attempt to classify the variety of conditions leading up to these.

SCOPE OF PAPER.

I will merely refresh your memory that these include the various tics, chronic facial spasms, spasmodic torticollis, purely mimic spasms, and organic post-paralytic tremors and spasms.

In many cases there is a natural or acquired instability of the subconscious reflex centers. In others, apparently healthy, the repetition of a certain movement or trick becomes first involuntary, then automatic, and finally exaggerated. They also depend on a well-known principle that nervous impulses have a tendency to travel more easily along a track they have traveled before.

It should always be borne in mind that there may be an organic basis for the condition; especially in the cases in which you are interested, the fifth nerve may be in operation.

The teeth, the ears, the eyes, the throat—all should be thoroughly examined. Diseases of bones through which the nerve may pass, also all the structures in relation to the nerve, should be taken into consideration.

CONSIDERATIONS IN TREATMENT.

In the treatment of habit spasms, the first consideration should be to give the fullest attention possible to the general constitutional condition of the individual, to raise this to the highest possible state of efficiency, and above all to make the most painstaking search into his environment.

There are cases which need no more than a complete removal of the circumstances which gave rise to the habit, to effect a complete cure. It should be borne in mind that in many instances the parents are unaware of the condition, and in some instances the victims themselves of the habit are entirely unconscious of the spasm, and unable to appreciate it on its occurrence. I may say here that I think it a most essential preliminary to successful treatment that the individual be taught to pay close attention to his sensations, so that he may acquire the capacity of appreciating the movement on its occurrence.

The treatment I propose to outline depends entirely on the intelligence or rational co-operation of the patient. It is therefore necessary that he should be quite capable of perceiving at all times

the slightest tendency to the movement we wish him to correct. This treatment has always been a matter of exceptional difficulty, and the result is often unsatisfactory because of the constant tendency to recurrence of the condition. The method employed in the cases which I showed you this afternoon is based more directly on clinical experience than on scientific evidence deduced from experimental work.

The precise psychological process is fully open to discussion, and I do not intend to defend any particular view in explanation of the phenomena. I propose briefly to explain to you the technique, and the inferences we have drawn from clinical observation.

TECHNIQUE OF TREATMENT.

We know that muscular contracture may be initiated in the cord or cerebral cortex, and we know also that these contractions can be controlled by psychic impulses acting on the cortical cells.

Clinical observation leads us to believe that in conditions of muscular spasms, no matter how initiated, the tendency to control this is by means of a psychic impulse through the cortical cells which control a muscle group of muscles of *opposing* action.

Observation also leads to the conclusion that in cases where there are *unopposed* muscle groups, as in the case of some sphincters, the constant overaction of the lower center seems to predominate, and an effort on the part of the higher centers in making active efforts to overcome it directs attention to the pathological spasm, and results not only in failure to control it, but often serves to accentuate the stimulation and increase the spasmodic state.

It is well recognized that in sleep, though no conscious effort can be made to control habit spasms, they are usually entirely absent. Beginning with this observation, our endeavor should be to teach our patients to assume a state of muscle tone similar to that which obtains during sleep, and this is what we try to accomplish. In order to do this, they are first taught how to acquire control over emotional states.

Next, we employ a method by which they may improve their capacity to concentrate their attention on the exercise which will lead to muscle control; and finally they are taught, step by step, not only the exercises, but their application in daily life, by which means they will acquire a capacity to control the spasmodic conditions, and develop a habit of poise and of repose—a condition the opposite of that which is responsible for the spasms from which they have suffered.

The first step in controlling the emotional state is based on the much-disputed theory of James and Lange, in which it is contended that the emotional state is always consequent on the physical state, and that the physical state is the immediate source and precursor of the emotion.

According to this theory, when we receive a mental shock, our heart beats quickly; all our breathing comes in short and hurried gasps, or our peripheral arteries undergo changes of contraction or dilatation, and the resultant is a physical sensation which leads to the psychic emotion we term fear. Fear, without visceral change, cannot occur; absence of visceral change implies absence of emotion. This theory, though not universally accepted, finds ample confirmation in clinical observations. It is our constant experience that patients who are excitable, despondent, or worried, or fearful of their ability to walk through crowded streets, or to speak in public, may readily, by controlling visceral change, subdue the rising emotion, and accomplish their purpose entirely free from the state of fear which otherwise had overwhelmed them.

DEEP BREATHING.

It is now an accepted fact, that deep breathing reduces the rate of the heart's action; it necessarily also diminishes the rate of respiration; it increases the influx of blood from the abdominal to the thoracic viscera, and that of air into

the lungs, and so promotes better oxidation of a greater volume of blood in a given time.

Deep breathing is therefore the first means we have adopted for controlling the emotional state. In order to make this as efficient as possible, we aim from the outset of our exercises to increase the muscular development, the forcibility of contraction, and the willed control of the action of the diaphragm.

We insist on voluntary control of this muscle throughout the initial exercise because of the undisputed fact that intentional movements exercise a much greater trophic influence on muscle fiber than uncontrolled movements, and for the further reason that it is a simple and efficient manner of beginning to teach the dicipline of close attention to the exercise.

ROUTINE OF EXERCISES.

In the first lesson the patient lies on his back, with the waist line entirely loose. The hand of the operator is laid on the abdomen, with a moderate degree of pressure, and the patient is taught to lift the weighted abdomen by inspiratory effort only.

The pressure is gradually increased, and the duration of inspiration, of expiration, and the period of pause varied at the will of the operator—a metronome being used to measure accurately the time devoted to each phase. Inspiration, expiration, and the pause between each act is timed, and the movements persisted in until the patient is capable of controlling the depression and elevation of the diaphragm. He is taught to breathe entirely abdominally.

Advantage of abdominal over thoracic breathing. It may be well to lay some stress here on the advantage of abdominal breathing as opposed to thoracic.

We know that the lungs are cone-shaped, the upper apical portion being therefore much smaller than the basal parts.

No matter how vigorous a thoracic breath is taken, and how great the consequent chest expansion, there is a tendency to hold the bases of both lungs tightly compressed against the vaulted diaphragm; to lift the shoulder girdle, and so diminish the air pressure in the upper third of the thoracic cavity, into which the air rushes, and where practically all the aeration that takes place is carried on. In this manner we use far less than half of our available lung tissue. In abdominal breathing, on the other hand, with practically no muscular effort, the diaphragm is depressed, and there follows in consequence a considerable degree of negative pressure in the lower two-thirds of both lungs, and the air literally drops in, aeration being favored in about two-thirds of the available lung tissue.

This is readily appreciated by anyone who will take a deep thoracic inspiration, and note in his own person the amount of muscular work done, and the relatively small amount of air which enters the lungs, while, on the other hand, if an abdominal inspiration be taken by simply depressing the diaphragm, one will not fail to note the striking contrast—the small amount of effort entailed, and the greater volume of air which rushes in.

Having accomplished the technique of deep breathing, the patient is able to practice at home or at work; sitting, walking, lying, or standing, and so acquire immediately the benefits of a diminished tendency to emotional states, and a better aerated blood.

Vigorous deep breathing, however, if persisted in for long, leads to a dyspneic state, but we have found that from twelve to twenty deep inspirations taken consecutively may be considered a safe and sufficient exercise at any one sitting, and is never likely to lead to any discomfort.

As soon as the patient masters the mechanism of abdominal breathing, the guiding hand of the instructor should be replaced by a sandbag weighing about from two to four pounds.

CONCENTRATION AND CONTROL OF IMPULSES.

With the now improved control of the diaphragm, the next step is to acquire

during waking hours the slow, satisfying rhythm of sleep. This is characterized by a deep inspiration, a rather rapid, uncontrolled expiration, and a relatively prolonged pause between the second and first act. This method of breathing is quite characteristic of one sitting or lying in a state of complete tranquillity who is unembarrassed by tight clothing around the waist.

The patient's capacity for concentration is now further developed by teaching him to give his undivided attention to the sensation of air as it streams over the mucous surfaces of nose and throat and distends the abdomen in passing in and out of the body. By thus riveting his attention on this rhythmic sensation, he learns readily to exclude all the distractions and imagination and memory, and gradually, with each succeeding lesson, his capacity for concentration improves.

Having now improved his ability to focus his attention, he is taught to relax his muscles. This is attained by repeated passive movements, the object of which is to increase the acuity of his perception of the impulses of joint sense and of muscle sense. It is upon the adequate development of this sense that efficient control of muscular movement rests—whether physiological or pathological. The patient must be taught to rest in a state of perfect muscular relaxation, and the control of his impulses must be such that any group of muscles may be moved in any direction by the operator, while he lies absolutely inert, not aiding and not resisting in any degree.

The operator, by constant practice, readily detects the slightest muscle change in the limb which he is manipulating, and by a word warns the patient of the fault, and the movement is persisted in until it is quite evident that the limb throughout the movement has been entirely passive.

It will be seen that this is a definite and rational endeavor to teach the patient to use his own will-power to control the tendency to abnormal muscular contraction by showing him how to acquire complete mastery of normal muscular movement.

DIFFERENCE FROM HYPNOSIS.

Some efforts have been made to liken this method of an hypnotic state, but I am unable to see anything in common with hypnosis.

The hypnotic state, it is well known, is a fatigue phenomenon, dependent on complete exhaustion of the higher centers, depriving an individual of his will-power and leaving him in a state so receptive to the will of the operator that he has no choice but to obey. In this condition, by the constant exercise of attention and by the effort of will required for the performance of this monotonous exercise, the higher centers are brought more definitely under immediate psychic control, and are maintained in a state of quiescence by a purely voluntary act.

In strong contrast to the hypnotic state, we find that the more intelligent the patient, the quicker and more satisfactory the result, and the more clearly the patient is able to understand what is required of him, the more complete is his mastery of the technique throughout the exercise. He must be as watchful and as alert as in the exercises of boxing or fencing.

INDICATIONS FOR THE METHOD AND AN OBSTACLE TO THE TREATMENT.

This method of treatment has been found beneficial in a variety of conditions. In collaboration with Dr. W. J. Maloney, I have already published notes on the treatment of high vascular tension, organic conditions such as paralysis agitans, hemiplegia, and tabes dorsalis.

It is also found highly beneficial in the treatment of inco-ordinate speech—stammering—but it is particularly in these purely habit spasms that one may look for quick results, and hope for their maintenance.

A disadvantage of the method of treatment is that it takes a great deal

of time. The sitting should be conducted in a quiet room, well shaded, and preferably with no third party present, the last being a source of distraction which the average patient finds very great difficulty in setting aside. One often has practical experience of this in demonstrating the method to doctors, particularly in cardio-vascular cases when the object is the reduction of high blood pressure. Not infrequently, when being demonstrated on a patient in the presence of his doctor, the pressure may fail to fall, or may even rise, yet when after a lesson or two, the doctor conducts the sitting himself, alone with the patient, he is able to obtain the desired result.

As an offset to this disadvantage, however, the treatment is so simple that an intelligent parent or nurse is quite capable of mastering the technique.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

SYMMETRY IN DENTAL CARIES.

By I. S. WECHSLER, M.D., D.D.S., New York, N. Y.

MANY dentists have no doubt observed the symmetric occurrence of caries in various teeth. Recent work in the mouths of children served to call the writer's attention to the extreme prevalence of symmetry in decay. In fact, the symmetric condition seems to be so extensive that the vast majority of all cases are actually characterized thereby. Although sufficient data in adults were not at hand with which to compare those obtained from deciduous teeth, it seems that the latter show a greater tendency toward symmetry than do the permanent ones. Also, of all teeth, the first permanent lower molars are perhaps most often symmetrically affected. So far, indeed, does the likeness in the corresponding teeth go, that one almost feels as if the decay has been induced with a purpose.

OBSERVATIONS OF SYMMETRY.

Aside from the fact that the decay is symmetric, it is also synchronous, *i.e.* it is so when the case presents itself to the dentist. Observation, however, seems to show that one tooth is usually first affected, and after some time—the period varying, of course, in different cases, depending as it does on various causes—the corresponding tooth begins to give way. This point may have some importance, as we shall explain later.

Generally the symmetry refers to the corresponding quadrants of the jaw, *i.e.* right to left lower, right to left upper. But we may also consider opposing teeth, *i.e.* right upper to right lower. The latter condition would really not come under the caption of this article, but as it, too, seems to be prevalent, it may be that there is some connection between the two conditions. The symmetry exhibited in the cases under consideration, figures of which are given below, seems to be the result of various underlying causes; for not alone do we find points of caries in corresponding teeth in positions where similar anatomical peculiarities would account for them, but we also find them where no structural condition alone will explain them. Thus, for instance, caries in the mesial surface of a right second bicuspid ought, by proximity, to affect the distal surface of the right first bicuspid, but this is very often not so. Instead, the mesial surface of the left second bicuspid is found to be involved. And so we find caries apparently crop up in corresponding teeth, situated in different segments of the

jaws; whereas, according to our accepted notions that caries develops best where bacteria have an opportunity to lodge, the decay ought to attack the tooth touching the one already affected. But while this happens often, the condition to which attention is here called occurs just as often, if not more so.

CLINICAL OBSERVATIONS.

In the following a few figures are presented: In 88 cases of children we found the corresponding upper teeth to be involved in the same mouth 42 times, in crossed and opposed teeth 36 times, and in both upper and lower, right and left —that is perfect symmetry—in 7 cases. Only 8 cases of the whole number were so irregularly affected that no symmetry was discerned.

Now it may be that the figures just quoted are not really characteristic, if for no other reason than that the cases are too few; but they were obtained at random and as a matter of routine, therefore it is quite likely that other cases would show similar conditions. However, these data seem to be so striking that one cannot ignore the fact that caries in one tooth is apt to occur symmetrically in its fellow on the opposite segment of the same jaw, or even of the opposing jaw.

PROBABLE ETIOLOGY.

What is the explanation? No doubt anatomical peculiarities, which, for embryonic reasons, are apt to develop in corresponding teeth, would be accountable in some cases. But these fissures or pits or faults do not account for all of them; it seems, therefore, that a deeper and more general cause underlies the symmetric decay. This, it seems to me, is a trophic one. The nerves supplying the teeth are at the bottom of this condition. Whether it is through the trigeminal nerves, or, as is more likely, through the trophic filaments, it is of course difficult to determine, but I believe the condition to be entirely attributable to the trophic centers. It would seem that when caries attacks a tooth, the trophic nerves are irritated, impulses are carried up to the center, and through sympathetic channels the carious process attacks the other tooth. This condition is not at all unlikely, as we have similar pathological changes in other parts of the body. It is but necessary to mention optic neuritis, where disease of one eyeball is soon followed by disease in the other, to show that it is very probable that an analogous condition may exist in the teeth.

If symmetry of caries is a real condition which confronts the dentist, and if the trophic nerves account for it, then we may derive therefrom a few interesting lessons in regard to prophylaxis. Whenever caries is detected in a tooth, aside from other various reasons, the carious portions ought to be removed as quickly as possible, not only to save the affected tooth but to prevent extension by sympathy to the corresponding tooth on the other side; also, if the tooth is badly decayed, it is a question whether it is worth while saving it, because we may run the risk of sympathetic affection on the other side, and it would often seem advisable to sacrifice an already badly decayed tooth. Even if the corresponding tooth is involved, but to a lesser degree, the same consideration would hold, inasmuch as the extraction of the tooth primarily affected might prevent rapid extension of the carious process in the tooth which was, as it were, secondarily involved, and preserve its life.

It is difficult to say, from the few cases cited, how much significance we can assign to symmetry as a factor in the phenomenon of dental caries. Surely more cases are needed that we may draw a positive conclusion, but the few instances cited appear so striking that the writer was tempted to explain the condition.

One thing, however, seems certain, namely, that the corresponding teeth are more often involved than anatomical defects would account for. At any rate, it is worth while noting the condition to which I have called attention, and determining the exact significance of symmetry in dental caries.

ORAL SEPSIS AS THE CAUSE OF GENERAL OR SYSTEMIC INFECTION, AND THE DENTIST'S RESPONSIBILITY.

By ANDREW J. SAWYER, D.D.S., Manchester, N. H.

(Read before the New Hampshire Dental Society, at its annual meeting, at Weirs, N. H., June 18, 1914.)

THERE are many causes of oral sepsis, and yet most of them may well be included in the one great cause, which is lack of proper cleanliness.

Oral diseases are so prevalent that it may almost be said that no one escapes.

John Sayre Marshall, M.D., Sc.D., who was formerly examining and supervising dental surgeon in the United States army and president of the examining board, says that during a practice of more than forty years, both civil and military, in which he had examined many thousands of mouths, he never met with but four persons of adult age who were free from any form of dental or oral disease. I wish here to acknowledge my indebtedness to this same authority for much that is contained in this paper.

THE MULTIPLICATION OF MICRO-ORGANISMS IN THE MOUTH.

There have been found more than one hundred different varieties of micro-organisms in the human mouth, and of these more than thirty are pathogenic or disease-producing germs. Miller made the estimate that in a very unclean mouth there were no less than 1,140,000,000 micro-organisms. Another investigator observed that segmentation in the coccus was complete in twenty minutes; but allowing that it takes an hour to complete this process and for the new cell to attain the size of the parent cell, one coccus, multiplying by this process, would produce 16,000,000 progeny in a single day, and at the end of two days 281,000,000,000, while at the end of the third day it would have reached the enormous number of 46,000,000,000,000.

Fortunately, there are conditions which inhibit or prevent this frightful multiplication from continuing indefinitely. One of the chief of these is their own delicate susceptibility to change of environment—the slightest difference in soil, amount of oxygen, temperature, or moisture being sufficient, in many instances, to arrest their growth or completely destroy them.

Remembering, then, that these micro-organisms are ever with us, that they do not originate spontaneously but are always produced by other similar germs, that they may be in the air we breathe, the water we drink, or the food we eat, and that the great danger lies not in the fact of their presence in the mouth, but rather in the possibility that they may suddenly increase in great numbers, giving off their toxins and breaking down the barriers to infection which kind nature has placed all along the way.

IMPORTANCE OF ORAL PROPHYLAXIS.

Under other favorable conditions, their numbers are limited only by the amount of pabulum or food supply; this being true, the preventive treatment which naturally suggests itself consists in limiting that food supply, and this means oral hygiene—extreme cleanliness of the mouth. Dr. Osler, in a recent address delivered before the students of the Royal Dental Hospital of London, said, "You have just one gospel to preach, and you have got to preach it

early and you have got to preach it late, in season and out of season. It is the gospel of cleanliness of the mouth, cleanliness of the teeth, cleanliness of the throat. These three things must be your text through life."

Dr. D. D. Smith, in a paper read befor the New York Institute of Stomatology in 1901, upon "Oral Prophylaxis," said, "It may seem presumptuous to intimate that in the subject of oral prophylaxis, when fully comprehended, are matters of a magnitude to radically modify the present thought and conception of dentistry, and to greatly change the present methods of practice. To advance a step farther and suggest that there are hidden away under the débris of the oral cavity secrets of greater importance to the comfort and welfare of civilization than the great discovery of vaccination by Jenner in 1796 will doubtless seem as a magnification verging upon absurdity—and yet we venture to predict that the future of dentistry will disclose this as a truism." How swiftly has this prophecy come true!

THE MOUTH AS A FOCUS OF SEPSIS.

Sepsis, from the medical or surgical standpoint, is the effect or resultant of the decomposition of dead or necrosed animal tissue, either in molecular form or *en masse,* by a process induced by the action of certain non-pathogenic germs or saprophytic germs, and the formation of ptomains or animal poisons and their absorption by the general system. It also includes infection with pathogenic or disease-producing germs such as the pyogenic or pus-producing, the Koch or cholera bacillus, the bacterium typhosus or typhoid fever germ, the bacillus tuberculosis, and many others.

The human mouth in a diseased condition contains virulent septic micro-organisms, especially those associated with carious teeth containing dead or gangrenous pulps.

Suppurative or septic conditions of the mouth are exceedingly common, and are in a large majority of cases associated with the teeth. Indeed, the fact is recognized that dental disorders are the most common of all diseases that afflict the human race, and that many obscure diseases affecting the general system—such as chronic dyspepsia, gastritis, gastro-enteritis, certain nervous affections, tonsillar diseases, pharyngitis, bronchial and pulmonary affections, certain diseases of the eye and ear, and general conditions such as septicemia and pyemia—may be traced to infection from a septic oral cavity.

A septic mouth is generally, if not always, the result of neglectful habits, due usually to ignorance of the dangers to health and life that result from such conditions. Neglected artificial dentures, improperly constructed crowns and bridges, faulty fillings and inlays, deposits of food débris, salivary calculus, dental decay, gangrenous dental pulps, alveolar abscesses, pyorrhea alveolaris, gingivitis, and stomatitis are all active factors in producing a septic mouth.

Leading dental surgeons have for years been trying to impress these facts upon their profession, their patients, and the medical profession as well, but their plea has too often fallen upon indifferent or deaf ears. But during the last decade much interest has been manifested in this subject, not only by the dental and medical professions but by boards of health, and even by the lay public. And yet there are many professional men who do not seem to realize the importance of controlling or eradicating from our midst the evils of an unhygienic, unsanitary, septic mouth.

The spread of such infectious diseases as diphtheria, tonsillitis, pharyngitis, influenza, bronchitis, pneumonia, and pulmonary tuberculosis among school children is undoubtedly greatly augmented by the unsanitary condition of the mouth in a great majority of the children. The fight that is being waged against the spread of tuberculosis meets with many physical barriers that are difficult to overcome, but with oral sepsis the only obstacles in the way of complete revolution are indifference, prejudice, and ignorance.

THE AVENUES OF INFECTION OF MOUTH BACTERIA.

The avenues of infection of mouth bacteria are arranged by Dr. Miller under six heads, according to their points of entrance:

(1) Infection caused by a break in the continuity of the mucous membrane brought about by mechanical injuries; these may lead to either local or general disturbances. (2) Infection through the medium of gangrenous tooth pulps, which lead to the formation of abscesses at the point of infection, but may also lead to secondary septicemia and pyemia with fatal termination. (3) Disturbances conditioned by the resorption of poisonous waste products formed by bacteria. (4) Pulmonary diseases caused by inspiration of mucus, small pieces of tartar, etc., containing bacteria. (5) Excessive fermentative processes, and other complaints of the digestive tract caused by the continual swallowing of microbes and their poisonous products. (6) Infection of the intact soft tissues of the oral and pharyngeal cavities whose power of resistance has been impaired by debilitating diseases, mechanical irritation, etc.

The most common avenue of infection by pyogenic bacteria within the mouth is through some break in the continuity of the mucous membrane. A slight abrasion or a minute wound such as might be made by a toothpick, a fishbone, or too vigorous use of the floss silk, or an extracted tooth—any of these would furnish a sufficient entrance or point of attack, and might prove exceedingly dangerous in a particularly unclean mouth.

That the presence of pathogenic bacteria in the mouth does not always result in the production of disease is due, in a large measure, to a remarkable resistant power possessed by the mucosa of the mouth, to the power of the blood through the white cells of leucocytes to destroy the bacteria that may enter the system, and to the number that may gain an entrance at any one time.

The process is like a desperate battle waged between two opposing armies; the leucocyte upon the one side and the invading bacteria on the other; and here, as in all other contests, the strongest and most numerous force will conquer.

SOME RESULTS OF ORAL SEPSIS.

The common results of a violent, acute, alveolar abscess are periosteitis, osteitis, osteomyelitis, abscess of the accessory sinuses, and necrosis or death of bone. Such conditions may be productive of very grave results, as they furnish, through the constant discharge of a very virulent pus, one of the most serious sources of auto-infection, both local and general, that are to be found in the oral cavity.

The absorption of ptomains and the entrance of the micro-organisms into the blood and lymph channels are productive of many serious affections in remote parts of the body, dependent upon pyogenic infection and saprophytic or septic intoxication.

Dr. Grieves of Baltimore tells us that in an investigation of some four hundred cases of septic arthritis which he and Dr. Bear of Johns Hopkins University made, it was found that in every case the portal of entry for the infecting germs were blind alveolar abscesses. He also says that in most of these cases bad root-canal work had been done or attempted by dentists.

It is undoubtedly usually true that when pus and pathogenic bacteria are swallowed and pass into the stomach, they are there acted upon by the acid juices and so destroyed; but we must remember that there are considerable periods when the stomach is empty, and that the swallowing of water or saliva does not excite the flow of these digestive juices. It is at such times that these bacteria, as has been shown by Miller, may pass through the stomach and into the intestines, and there, unless they are destroyed by other competing germs, may set up foci of infection or be absorbed by the lymphatics, and thus reach the circulation and find lodgment in any of the vital organs.

THE DENTIST'S RESPONSIBILITY.

We frequently hear it remarked in dental circles that physicians are very ignorant on purely dental subjects. If this be true, it seems to me that in this side-stepping of the human mouth by the physicians, thus leaving to us the care of this most important part of the human anatomy, they are paying us a very great compliment in so recognizing the worth, the ability, and the integrity of our profession.

Are we, as a profession, living up to this great responsibility? And if not, wherein have we failed? These are questions which we may each well ask ourselves.

From great physicians and surgeons we hear more than mutterings of discontent and dissatisfaction with the way the dental profession, as a whole, has met these great obligations and responsibilities. Dr. Osler has pointed out the right direction, but we must do more than preach and teach oral hygiene and oral prophylaxis. We must practice it as well; and we must insist that our patients do their part, for it is only by the honest, faithful co-operation of patient and dentist that anything like success along these lines can be attained. Oral prophylaxis means something more than merely cleaning the teeth and treating the soft tissues surrounding them. It, indeed, includes every dental operation, and our responsibility does not end even with doing each operation skilfully and well. When we have accepted an individual as a regular patient, we have by no means acquitted ourselves of our responsibility to that patient when we have carefully cleaned his teeth, filled the few cavities, and treated the few putrescent root-canals that require our attention. There still remain other and exceedingly important responsibilities. It goes without saying that decaying roots which cannot be made healthy and useful should be removed, and in any case where it is impossible to make an alveolar abscess heal, the root should be amputated or the tooth extracted—always.

A careful examination of the whole mouth should be made to ascertain whether there be manifested therein the clinical picture of any constitutional disturbance which requires treatment, and, if so, the patient should be made acquainted with the conditions and also should be directed to the specialist for treatment.

There are many constitutional disturbances which are often indicated by mouth conditions long before the patient is aware that he is sick or in need of a physician; and to look for and recognize these conditions and direct the patient in the way of health is the duty, the obligation, and the responsibility of the dentist.

What gigantic strides dentistry has made in the last twenty-five years! It is destined to stand at the very pinnacle of all the professions if it lives up to the great opportunities which it possesses; for here we stand at the very gateway, the very door of health. And can there be anything greater or more worth while than the preservation of joyous health in the coming generations?

In the past we have been so intent upon the purely mechanical, and often, I regret to say, the commercial side of dentistry, that we have failed to see or realize these higher duties and responsibilities. As mechanics, we have been more or less content with the wages of mechanics; as professional men we have a right to expect—and some of us have received—compensation such as professional men receive; and as we ascend to the summit toward which we are aiming, we may expect to receive the rewards suited to our higher endeavor, but, best of all, the confident assurance that the world is better morally, mentally, and physically because we have kept clean this "vestibule of human life."

STUDIES OF INTERNAL SECRETIONS IN THEIR RELATION TO THE DEVELOPMENT AND CONDITION OF THE TEETH.[1]

1. Effects of Thyro-parathyroidectomy and Thymectomy.

By WILLIAM J. GIES, Ph.D., Sc.D., New York, N. Y.,[2]
PROFESSOR OF BIOLOGICAL CHEMISTRY, COLUMBIA UNIVERSITY,

WITH THE COLLABORATION OF

SERGIUS MORGULIS, Ph.D., AND WILLIAM A. PERLZWEIG, A.M.,
INSTRUCTOR IN BIOLOGICAL CHEMISTRY, COLUMBIA UNIVERSITY, ASSISTANT IN BIOLOGICAL CHEMISTRY, COLUMBIA UNIVERSITY.

(Read before the Dental Society of the State of New York, at its annual meeting, Albany, May 15, 1914.)

I. Introduction.

Mr. President, members of the Society, ladies and gentlemen:

FOR about three years we have been studying, under your auspices, the possible relation of salivary sulfocyanate to dental caries. Dr. Dunning gave you, a few minutes ago, a program of research in this connection that I believe could be followed to advantage if you cared to go farther along that line of investigation. I should be glad to cooperate with you in a continuance of the proposed sulfocyanate inquiry, although, as I suggested last May, "our results have taken sulfocyanate research out of the laboratory, so to speak, and put it into the dentist's chair." I am not competent to undertake the clinical study I have suggested (an outline of which Dr. Dunning has just read to you),[3] because I know too little of the clinical aspects of dentistry. For this reason I suggested here, last May, that I could be of more service to you in a study of the relation of internal secretions to dental pathology. I am here, today, to present some phases of the latter subject for your attention.

When I was first invited, about five years ago, to inaugurate research on dental caries under the auspices of the New York Institute of Stomatology, it

[1] To the substance of the senior author's address before the Dental Society of the State of New York (May 15, 1914), as given in the official stenographic report of it, there have been added various details which were suggested in only a general way by the speaker and promised for this published account of the research. Certain quotations from the writings of various authors, which were included in the oral report, have been omitted here, for the sake of brevity.

The experimental work was done in the Biochemical Laboratory of Columbia University at the College of Physicians and Surgeons, under the auspices of the Research Committee of the Dental Society of the State of New York, Dr. Wm. B. Dunning, chairman. The experiments on thymectomy, by our colleague, Dr. Pappenheimer, to which free reference is made, were conducted in the Pathological Laboratory of Columbia University, at the College of Physicians and Surgeons.

[2] The previous reports in this series, by Gies and collaborators, were published in the DENTAL COSMOS: (*1*) 1910, lii, p. 1141; (*2*) 1911, liii, p. 1324; (*3*) 1913, lv, p. 40; (*4*) 1914, lvi, p. 175.

[3] Dunning: DENTAL COSMOS, this issue—see report of *discussion*, page 316 ff.

was suggested that problems pertaining to the saliva were probably the most important. I knew so little of the subject at that time that I readily accepted this opinion and formulated our research plans accordingly. As we proceeded with our work, however, study of the literature and reflection upon experimental facts and biological probabilities led me to suggest informally, before the end of the year (1909), that general nutritional relationships and conditions are probably important factors, directly and indirectly, in resistance and susceptibility to dental caries.

This opinion was almost unanimously opposed, however, by the dentists who were consulted, on the ground that enamel once formed is wholly excluded from nutritional influences and that it can be affected, after its formation, only by external influences, such as those exerted from the oral environment. Although I realized only too well my complete ignorance of dental matters, and that I could not oppose with confidence my mere belief against the opinions of those who were better informed than I was, nevertheless I felt impelled to say, in our *first report* (1910):

> That the *systemic condition* of the individual is an important factor in susceptibility to dental caries is a conviction that we cannot dismiss (p. 283). I presume it would be hard to show that enamel once deposited is modified directly by systemic conditions that prevail afterward, yet more astonishing things than that have been demonstrated. I feel that this possibility should not be dismissed. It should be investigated further (p. 288).[4]

The dissent from my expressed conviction that the internal secretory factors, which are so important in the calcification processes in general, are involved in particular in the development and condition of the teeth, including enamel, reminds me of the discouragement against which McCrudden proceeded when he undertook his important and fruitful studies of bone metabolism. Discussing, recently, the general lack of appreciation of the possibilities in bone metabolism, McCrudden said:

> This subject of bone growth is a very important one, to which very little attention has been given. When we remember that in all the various chronic rheumatisms, osteomalacia, rickets, osteitis deformans, osteoporosis, fractures, dwarfism, and faulty development, bone growth is involved, we see the importance of knowing the normal. And yet almost no one seems to have made an experimental investigation of the question of normal bone growth. Bone is generally considered a dead tissue, not undergoing metabolism once it is laid down. Only Cohnheim and Adami definitely face the question and express the opinion that bone does undergo a continuous process of absorption and resorption, and even with these two pathologists it is merely an opinion and not based on any definite experimental studies. Several years ago, while making chemical studies in various bone diseases, I began to study osteomalacia, and my findings threw some light on this whole question.[5]

Dr. McCrudden was altogether too modest in that concluding sentence—his results have thrown a *flood* of "light on this whole question." That dentin and enamel are similar to osseous tissue, from the standpoint of metabolic changeableness, is a very strong physiological probability.

In several succeeding reports to the New York Institute of Stomatology and the First District Dental Society of the State of New York, we referred, in one way or another, to the conviction that enamel may be subject, destructively at least, to systemic influences, although the reports were devoted primarily to other subjects. Thus, two years ago, (February 1912), again referring to this subject, I said: "The more I reflect on the available facts regarding dental caries, the more I believe in the *possible influences of systemic conditions* as factors in its onset and in its progress."[6]

[4] Lothrop and Gies: *Journal of the Allied Dental Societies*, 1910, v, pp. 283 and 288.

[5] McCrudden: *Transactions of the Fifteenth International Congress on Hygiene and Demography*, 1913, ii, p. 424.

[6] Gies: *Journal of the Allied Dental Societies*, 1912, vii, p. 214.

I then mentioned with intended emphasis, in justification of this old conviction, the interesting observations by Erdheim, on the dental effects of parathyroidectomy (to which we shall refer again today)—observations which had been described in detail a few months before, in one of the German journals of pathology.

In spite of preoccupation with other phases of dental research, under the auspices of your society and of the First District Dental Society of the State of New York, my conviction that general nutritional conditions are important factors in determining the resistance or susceptibility of teeth to caries grew steadily stronger as it fed upon the many pertinent biochemical data in the literature of nutrition, especially of the facts pertaining to the functions of the ductless glands. Accordingly, a year ago (1913) I had the honor here to suggest that you authorize us to undertake, under your auspices, an investigation of dental caries from the nutritional standpoint. With the approval of your Research Committee we have been proceeding, during the past year, with an *introductory chapter,* so to speak, to such research—with a study of the influence of internal secretions on the development and condition of the teeth.

That the members of this society may be inclined to feel skeptical about the desirability or fertility of such investigation is suggested by the following quotation from a paper by Bunting, in a recent issue of the DENTAL COSMOS (March 1913, lvi, p. 286). Speaking with apparent conviction and authority on the present status of knowledge of dental caries, Bunting said:

> It is pretty well considered that although it may be possible for the structure of the tooth to enter into the question to a certain extent, it is not looked upon as being responsible for the sudden and obscure changes in susceptibility, except by those few believers in the mutability of the tooth in response to general physiological change. So that investigation today is being focused upon the environment of the tooth, the saliva, ingested food, etc., seeking in them the changeable element which determines caries.

We happen to be among the "few believers in the mutability of the tooth in response to general physiological change," *i.e.* to systemic nutritional influences, especially destructive ones. We believe, also, that research in this field is as desirable and as fruitful as study in any other in dental science.

Before proceeding with a description and discussion of our experiments, I shall attempt to show you, through the medium of a long but co-ordinated series of quotations from the research literature on internal secretions, that the type of dental investigation we have begun appears to be promising in high degree.

[At this point the speaker quoted extensively from various sections of the research literature on internal secretions, in order to show the probable value of such research, having been under the impression, from the attitude of Bunting and others, that dentists as a body doubted the bearing of this important phase of nutrition on dental physiology and pathology. The discussion of this report (pages 319–328) suggested so strongly, however, that apology for such work in dental biology is unnecessary, that the numerous citations for that purpose (some of which are referred to in the discussion) have been eliminated from this revised report. Since the date of the oral presentation of the original report (May 15, 1914), interesting reviews on this subject have been published in the DENTAL COSMOS by Grieves (August 1914, lvi, p. 954) and Pond (October 1914, lvi, p. 1155.)[7] The gist of much that was stated in our oral report appears in these two valuable reviews.]

As the sub-title of this report indicates, our experiments relate to effects of thyro-parathyroidectomy and thymectomy. The animals selected for the operations were rats, rabbits, and guinea-

[7] The senior author is preparing for presentation in a future report, or in a separate publication, the essentials of the data in the research literature on internal secretions that pertain to the development and condition of the teeth.

pigs. In collateral experiments on 16 puppies we aimed to determine some of the dental effects of artificial acidosis; also of under-nutrition with respect to calcium and phosphorus. The experiments on the dogs were in progress when the oral report was presented. The results in this particular connection will accordingly be considered in the next report.

II. Effects of Thyro-parathyroidectomy.

That the parathyroid glands are intimately involved in the co-ordination of some of the mineral matters in teeth has been indicated by the findings of Erdheim, Toyofuku, Fleischmann, Weichselbaum, Hohlbaum, and others. Results obtained by these investigators suggested that a study of the effects of parathyroidectomy might prove to be the most promising point of departure in our own inquiry.

The leading dental observations, by the investigators named above, were made in experiments on rats. The incisor teeth of rodents in general, by reason of the relatively large size, rapid development, and continuous growth of these teeth, are particularly well adapted to physiological investigation. Rodents grow rapidly to maturity. They breed early, often, and generously. With such animals it is possible to study dental physiology through many generations in a comparatively short time. It is obvious that the younger the animals in such a study at the beginning of an experiment, all other things being equal, the greater the range of opportunity for the observation of effects on the development of the teeth.

Our experiments on thyro-parathyroidectomy were conducted on about 100 albino rats, 20 rabbits, and 15 guinea-pigs, most of which were very young when subjected to operation. Our main attention was given to the rats, the experiments on the rabbits and guinea-pigs having been supplementary.

It had been our original purpose to study the effects of *parathyroid*ectomy, but the successful removal of these tiny glands from young rats was much more difficult than we anticipated. The mere location of these almost imperceptible glandules in young rats is a perplexing matter, and their excision or destruction is attended by unusual surgical difficulty. The most valuable published data on the anatomy of the parathyroid glands in rodents that we have been able to find thus far were those given by Ivanoff[8] relative to a field mouse (*Mus sylvaticus*) and two guinea-pigs. The parathyroids in the former (adult) were 0.3–0.6 millimeter in length, and in the latter they were 0.275 millimeter (young) and 0.63 millimeter (adult) long. The exceptional difficulties in the way of complete excision of organs so minute, or their total destruction by cauterization, induced us to postpone our intended parathyroidectomy operations and to substitute preliminary experiments on *thyro*-parathyroidectomy. We believed, also, that extended experience in this direction would give us special preparation for the more difficult work involving parathyroidectomy.

Our *thyro*-parathyroidectomy operations were conducted under general ether anesthesia and with ordinary aseptic precautions. After making a median skin incision, the muscle exposed over the larynx was divided longitudinally with forceps, the lips of the wound retracted, and the underlying thyroids and accompanying parathyroids carefully freed, with delicate forceps, from their connective tissue attachments. The glands on both sides were then gently pulled out of place with one forceps, while the connecting blood-vessels were compressed and held with another. Hemorrhage under these conditions was usually slight, and could almost always be stopped immediately by pressure with a small wad of absorbent cotton. The skin and muscle were sutured with silk. The wounds, after the insertion of a few stitches, healed promptly in the survivors. The oper-

[8] Ivanoff: Contribution à l'étude des glandules parathyroïdes chez les rongeurs (cobaye et mulot); Thèse, Geneva, 1905.

ation, from the time of initiation of anesthesia to the insertion of the last stitch, was usually completed in 20 minutes, often in 15 minutes, sometimes in less than 15 minutes.

Operations were performed on selected members of groups or litters, some or all of the remaining members of such groups serving as unoperated controls kept under the same dietary conditions and in the same environments.

Both before and after the operations the animals were kept in clean, comfortable, and commodious cages, which were stationed in a working-room in the laboratory where the temperature was moderate, chemical fumes were absent, and the animals could be promptly and repeatedly inspected. The diet was "mixed" in character and abundant in quantity, consisting of cereals, greens, meat, cheese, or bread, or several of these at one time, with water. Control animals grew rapidly and apparently to normal maturity on this diet.

1. *Experiments on Rats.*

Removal of the parathyroids from rats is usually followed promptly by death. A comparatively large number of animals must be subjected to this operation, therefore, in order to obtain a sufficient number of survivors for effective study of post-operative effects on the teeth—a fact involving great regret for those who aim to do such work with the least possible distress to the animals affected.

The following protocol from our notebook, in its original free-and-easy phraseology, illustrates the course of events following *promptly fatal* double thyro-parathyroidectomy in rats:

RAT 55. Young, normal, well nourished, active. Double thyro-parathyroidectomy at 4.25 P.M., April 16, 1914. Weight: 45 grams.

4/16—10.20	P.M.	O. K. up to now. Tremor beginning.
11.00	"	Respiration rapid.
12.00	M.	Ditto. Sitting up, but tends to lean back and topple over.
4/17—12.30	A.M.	Same.
—.50	"	General convulsion.
—.52	"	General prostration at conclusion of convulsion.
—.54	"	Unable to get up, though endeavors to do so.
—.55	"	Hind legs completely paralyzed.
1.00	"	Gradually resumed sitting posture; one hind leg stretched out behind—unable to pull it in and under.
—.05	"	Now on all fours, but wabbling — unable to walk.
—.10	"	Prostrate. Another violent spasm.
—.15	"	Up again. Weak.
—.25	"	Prostrate again—continuous convulsion, very violent.
—.30	"	Prostrate. Breathing very rapidly. Struggles vainly to get up.
—.40	"	Prostrate, with convulsions, since 1.25.
—.45	"	Prostrate since 1.40. Now struggles hard to get up. Finally able to raise only head and tail. Respiration continues rapid.
—.50	"	Same. Marked tremor in fore legs—nowhere else.
—.55	"	Same. Raising head and tail again, apparently in an effort to get up.
2.10	"	Same continuously since 1.55.
—.11	"	Violent convulsive jumps, as if trying to get up and run.
—.12	"	Turns on back. All limbs extended and involved in general convulsion — rapidly intermittent.
—.20	"	Prostrate. Limp. Weak general tremor.
—.21	"	Another strenuous effort to arise, same as at 2.11.
—.22	"	Ditto, several times. Violent tremor in fore legs.
—.50	"	Complete prostration with intermittent convulsions since 2.22.
—.51	"	Died in violent general-extension spasm. Weight: 39.2 grams.

The following protocol from the same note-book illustrates the course of events soon after *non-fatal* double thyro-parathyroidectomy:

RAT 37. Mature, normal, well nourished, active. Double thyro-parathyroidectomy at 3 P.M., April 7, 1914. Weight: 241 grams.

4/8 —	1.30 A.M.	Nothing so far, except labored breathing.
	12.30 P.M.	Ditto, but breathing is less labored.
4/9 —	4.30 "	Respiration more labored again.
	7.15 "	Ditto, increasing.
	10.30 "	Gentle general tremor. Breathing very hard.
4/10—	1.30 A.M.	About same.
	4.00 P.M.	Tremor disappeared slowly during day. Some respiratory distress still evident.
	11.00 "	Gentle general tremor. Breathing continues labored.
4/11—	11.00 "	O. K. all day.
7/11—	10.00 A.M.	Nothing noteworthy since 4/11, except evidence of gradual deterioration of teeth. One lower incisor has been broken off at gum line; the second, broken off half way from gum to tip. Upper incisors abnormally long. Chalky spots here and there on the teeth.
7/18—	6.00 P.M.	Gentle general tremor all day.

[*Sept. 1:* This rat (37) is alive at this date. General tremor was noted again on August 13th, 18th, 24th and 25th. Further reference will be made to this rat in the next report.]

Before the beginning of each experiment, the general condition of the animal, including its teeth, was carefully noted. Observations of this kind were made repeatedly on the survivors, during the progress of each experiment. After the death of an animal, a careful autopsy was made, and the findings noted.

After the conclusion of each autopsy, we took all the teeth and also the femurs and tibias from the animal. The teeth individually were carefully pulled out of place after the grip of the bones and membranes that held them had been broken by suitable paring and excision. Each tooth was cleaned with filter paper. Adherent muscle was cut from the leg bones, which were then gently scraped clean with a scalpel.

After free exposure to the air, for prompt superficial desiccation at room temperature, the teeth and bones were separately crushed and pulverized in a deep porcelain mortar. When, for any reason, we were unable to obtain all the teeth with both the femurs and the tibias from an animal, we used these materials from one side only, and proceeded on a 50 per cent. basis, in this way preventing any analytic irregularities that might have resulted from the use of masses that were not anatomically equivalent in kind and proportion.

After the pulverized material had been uniformly mixed and dried to constant weight at 100° to 110° C., an accurately weighed portion of it (practically all the material in each case) was decomposed in a large Kjeldahl flask, of Jena glass, with a mixture of equal parts of concentrated sulfuric and nitric acids (Neumann's method).[9] The clear, colorless, concentrated acid solution, freed from most of the mechanical excess of residual sulfuric acid, was then diluted to 500 cc., or one liter, and kept in tightly stoppered bottles. Calcium was determined, in duplicate, by McCrudden's method[10] in 100 cc. portions of each solution prepared in this way.

Our analytic data in this connection are summarized in Table 1. Additional data, pertaining to rats that survived after May 15, 1914 (the date of this report), will be given in our next communication.

The analytic data in Table 1 suggest the chemical conclusions, on the effects

TABLE 1.

DATA PERTAINING TO ALBINO RATS SUBJECTED TO THYRO-PARATHYROIDECTOMY, WITH CORRESPONDING "CONTROL" DATA.[1]

Rat. No.[2]	Control (C), or operated (O).	Weight.[3] Beginning. Grams.	Weight.[3] End. Grams.	Period of survival: Days.[4]	Percentage of calcium, as Ca (*not* CaO). Teeth.	Percentage of calcium, as Ca (*not* CaO). Bones.[5]	Remarks on symptoms, condition, cause of death, etc.[6]
I. 7	O	85	. .	19	27.71	. . .	No tremor or convulsions observed.
8	O	106	126	57	26.83	24.30	Etherized.[7] No observed effects of surgical operation.
10	C	121	137	57	28.02	24.97	Etherized.
II. 13	O	45	36	63	28.08	16.15	Partial paralysis of legs and occasional convulsions. Bones "soft."
15	C	44	72	64	27.90	17.60	Etherized.
III. 26	O	32	25	22	24.71	16.23	Severe tetany and paralysis.[8] Bones "soft."
29	O	44	40	12	28.08	. . .	Severe tetany.
30	O	34	. .	5	24.06	. . .	Severe tetany occasionally.
34	C	56	76	22	26.72	20.60	Etherized.
36	O	89	. .	2	27.05	20.61	Severe tetany. One violent convulsion.
IV. 38	O	240	208	2	27.33	. . .	General tremor. Convulsive jerks.
40	O	127	102	27	27.35	23.78	Slight tremor occasionally.
42	O	229	200	28	28.34	25.41	No symptoms.
44	O	131	72	11	28.38	25.28	Severe tetany.
45	C	122	101	12	27.73	24.55	Etherized. Open tumor on right hind leg.

V.	50[9]	O	50	47	1	22.31	17.91	Violent convulsions. Dead in seven hours.
	51	O	58	37	17	27.49	21.08	Severe tetany with marked paralytic effects.
	52	C	44	30	14	26.67	. . .	Natural death.

[1] Additional data pertaining to these rats, such as the condition of the teeth, will be given in the next annual report, with the results of work that could not be completed before the date of the meeting at which these experiments were described. (At autopsy it was found that all the thyroidal and parathyroidal tissues at the laryngeal sites of these glands had been extirpated or practically so. The possible occurrence and functionation of accessory parathyroid tissue was considered but not investigated. In the proposed histological extension of our work, this phase of the subject will receive experimental attention.)

[2] The missing numerals (to 100) pertain to rats that died within twenty-four hours after operation, or survived after the date of the meeting at which this report was presented. It was assumed for some time that rats which succumbed within twenty-four hours after the operation died before any appreciable chemical changes could occur in the teeth. The data for rat 50 suggest that possibly this assumption was unwarranted. (See table footnote 9.) Further attention will be paid to this particular point.

[3] Blanks in the series of data for body weights are due to oversights. "Nearest" whole numbers for body weight are recorded.

[4] In the case of the "control" animals, the numerals in this column indicate numbers of days from the day of operation on the first animal of the group to the day when the "control" animal was put to death by ether anesthesia. "Nearest" whole numbers for these days are recorded.

[5] Blanks in this column indicate either that the values will not be available or will be supplied with the supplementary data in the next annual report.

[6] Only the most significant facts are suggested in the "remarks." The details will be amplified in the next report.

[7] "Etherized" is used conveniently for the phrase "killed with ether by inhalation."

[8] Unless otherwise qualified, the designation in this column of a symptom implies its frequent or prolonged occurrence.

[9] This rat (50) was originally a "control," but as 52 appeared to be a normal survivor in this group, and most of its operated associates succumbed, we changed rat 50 to the "operated" subdivision. During the week prior to the day of operation, the weight of this rat increased 2 grams.

Summary.

I—A. Lower degree of calcification of both teeth and bones:
  a. Rat 8 compared with rat 10—1.19% and 0.67% respectively.
  b. " 26 " " " 34—2.01% " 4.37% "
  c. " 40 " " " 45—0.38% " 0.77% "

B. Lower degree of calcification of teeth (no comparable data on bones).
  a. Rat 7 compared with rat 10—0.31%.
  b. " 30 " " " 34—2.66%.
  c. " 38 " " " 45—0.40%.
  d. " 50 " " " 52—4.36%.

C. Lower degree of calcification of bones, but not of teeth.
  a. Rat 13 compared with rat 15—1.45%.

II—D. Greater degree of calcification of both teeth and bones.
  a. Rat 42 compared with rat 45—0.61% and 0.86% respectively.
  b. " 44 " " " 45—0.65% " 0.73% "

E. Greater degree of calcification of teeth, but lower degree of calcification of bones:
  a. Rat 13 compared with rat 15—0.18%. (This difference is too slight for any emphasis, however.) (See I, C.)

F. Greater degree of calcification of teeth (no comparable data on bones).
  a. Rat 29 compared with rat 34—1.36%.
  b. Rat 51 " " " 52—0.82%.

G. Greater degree of calcification of teeth, but no effect on bones.
  a. Rat 36 compared with rat 34—0.33%.

of our double thyro-parathyroidectomies, that are indicated by the above summary, from which we see at a glance that the teeth of *seven* operated rats contained less calcium than the teeth of the corresponding control rats; but the teeth of *six* operated rats contained more calcium than the teeth of the corresponding control rats. The average difference for the former was −1.62%; for the latter, +0.66%.

The bones of *four* operated rats contained less calcium than the bones of the corresponding control rats; but the bones of *two* operated rats contained more calcium than the bones of the corresponding control rats. The average difference for the former was −1.82%; for the latter, +0.80%.

Further summarization of the above average percentage data shows these differences more conveniently below:

The *general average* data for percentage calcium contents in the teeth and bones are the following:

	Teeth.	Bones.
Control rats	27.41%	21.93%
Operated rats	26.75%	21.19%
Difference	0.66%	0.74%

If we were seeking to verify, from the biochemical standpoint, the results obtained by Erdheim and others from the histological point of view, we might be expected to assume, with bias in that direction, that these percentage differences support Erdheim's conclusions. But we have attempted neither to verify Erdheim's findings nor to prove them incorrect—we have sought simply the facts in the case. Our data require, we think, the frank conclusion: *Nothing proved one way or the other!* With such openmindedness we shall extend

Operated Rats compared with Control Rats.

Degree of calcification.	Teeth.		Bones.	
	No.	Percentage of Ca (av. difference).	No.	Percentage of Ca (av. difference).
Lower degree of calcification	7	−1.62	4	−1.82
Greater degree of calcification	6	+0.66	2	+0.80

these particular experiments and report further, a year hence, the data that additional experience and further work may afford.

The nature of the foregoing general inference, and the purpose based thereon, make it useless to discuss the chemical data in Table 1. But before proceeding with the rest of our report, we wish to allude to the fact that our control animals were not as numerous as our cumulative experience has shown they should have been, so far as determinations of calcium content in teeth and bones are concerned. The loss of weight in two of the control rats (45 and 52) suggests that, in spite of the abundance of food available to them, they were poorly nourished for one reason or another, and probably, therefore, were not suitable "control" animals. The tumor in rat 45 (which had not been observed when the animal was selected), and the disease that caused the premature death of rat 52, may explain the obvious malnutrition in each. These disorders emphasize, nevertheless, the possible unreliability of these rats for "control" purposes in our calcium work.

The loss of weight in practically all the operated animals is a matter that requires, and will receive, special attention in our future experiments in this particular connection, involving, as it may, tissue deficiency in calcium (and other constituents) *from loss of appetite,* with consequent diminished consumption and absorption of food (calcium), rather than from inability to assimilate, into the bones and teeth, the calcium that may be available in the alimentary tract and in the blood. Such animals, both operated and control, should evidently be studied from quantitative nutritional standpoints with foods *known* to be particularly rich in *assimilable* calcium and also with diets very deficient in such calcium. The animals received a diet that is ordinarily very nourishing, and we relied in a general way on a normal outcome in this respect. Our results require the skepticism on this point, however, that we are indicating.

We are also doubtful, *now,* of the adequacy of our chemical procedure. We took *all* the teeth in each instance. Probably the incisor teeth alone would show results more strikingly. We used *whole teeth* and *whole bones,* after pulverization and *desiccation* to constant weight; but differences in the composition of dental pulp and bone marrow may have influenced irregularly our percentage data for calcium. A "water-free basis" may not be uniform enough to show certain comparative differences in calcification. Probably preliminary removal of substances soluble in water or in ether, or in both, would afford more definite and uniform bases for estimations of comparative degrees of calcification. We may find it necessary to rely solely, in this connection, on analyses of *ash* from the teeth and bones.

It is probable, also, that careful note must be made of sex differences, and that "control" rats must be of the same sex as those with which they are experimentally compared. Close relationship in a given litter, freedom from disease, identical states of nutrition, equal weights, similarity in activity, and close general resemblances are important experimental considerations, but not sufficiently inclusive. "*Segregation* of the sexes" may likewise be required in all such experiments, especially in view of the probable interference with calcification of the teeth in growing pregnant animals.

These considerations, and others of equal importance, might now be ignored, as they were by us at the beginning, if our results had been striking enough to warrant the belief that biochemical differences due to thyro-parathyroidectomy "covered" the differences due (probably) to such physiological variations and disparities as are suggested above. But it is plain that the biochemical variables to which we have just referred, and others like them, must be *experimentally* considered in detail, and controlled before further progress in exact knowledge can be made in studies of this kind. All our doubts in these and similar relations will be resolved, we

hope, by the chemical and histological experiments now in progress with that end in view.

We have not overlooked the possible counteracting influence of thyroidectomy when it accompanies parathyroidectomy. This phase of the matter will also be given due attention at an early date. Our views on this phase of the subject were intimated in one of the opening paragraphs of this section of our report.

[Certain additional facts bearing on reasons for uncertainty regarding interpretation of the data pertaining to these experiments on rats are mentioned on page 294.]

2. Experiments on Rabbits and Guinea-pigs.

Our data for rabbits and guinea-pigs add nothing of significance to the results for the rats. Accordingly, our results for these animals will be withheld for communication with the findings in additional experiments on such animals.

III. Effects of Thymectomy.

During the progress of our experiments on the effects of thyro-parathyroidectomy, we learned that Dr. Alwin M. Pappenheimer, associate in pathology at the Columbia Medical School, was studying, in the pathological laboratory, the effects of thymectomy on bones and teeth in albino rats. He was engaged in this work with special reference to the validity of the positive conclusions in this connection that were recently published by Klose—conclusions which were at variance with negative deductions previously stated on this subject by Dr. Pappenheimer. It was our good fortune to be able to co-operate with Dr. Pappenheimer in this work, from the standpoint of chemical analysis of some of the bones and teeth of a number of his most valuable rats; and to profit greatly, besides, in all our work on internal secretions in their relation to ossification and dentition, from association with Dr. Pappenheimer in this particular research, which he inaugurated independently.

[Most of the analytic figures in Table 2, and the collateral data, were available last May, and were stated in our oral report. The recent publication by Dr. Pappenheimer,[11] and by the senior author in association with Dr. Morgulis,[12] of the details of this work on thymectomy, enables us to add to this revised report much that was learned in this relation since last May, and which was detailed in the two papers mentioned above. Accordingly, with Dr. Pappenheimer's consent, we make free use, below, of the phraseology of sections of the papers by him, and by Morgulis and Gies. We are greatly indebted to Dr. Simon Flexner, editor of the *Journal of Experimental Medicine,* for permission to use the accompanying plates, which were originally published in that journal as a part of Dr. Pappenheimer's paper.]

Dr. Pappenheimer introduced his paper with the following comment:

> In a previous paper[13] dealing with the effects of extirpation of the thymus of white rats, the writer reached the conclusion that total removal of the gland at an early age was not necessarily followed by modifications of the normal development, nor by characteristic changes in the skeletal system.
>
> While that article was in press, there appeared a short paper by Klose embodying results at variance with these observations. Klose described briefly the results of thymus extirpations in pigs, goats, rats, and chickens. The rats were operated upon on the fourteenth day after birth. Some of the animals showed no results from the operation, and this failure is ascribed by Klose to the presence of accessory tissue within the thyroid gland. In rats without such accessory thymus tissue, death followed after eight to ten weeks, with symptoms of cachexia thymopriva. The bones in these rats showed severe rhachitic changes. Most striking were the changes in the ribs, in which there was found

[11] Pappenheimer: *Journ. of Exper. Medicine*, 1914, xx, p. 477 (November).

[12] Morgulis and Gies: *Ibid.*, p. 499 (November).

[13] Pappenheimer: *Ibid.*, 1914, xix, p. 319 (April).

a typical rosary, such as is seen in human rickets. Microscopically there was an extreme widening of the zone of growing cartilage, failure of calcification in the preparatory zone, great irregularity and distortion of the cartilage columns, and their penetration by bloodvessels. Klose pictures further a dense spongiosa composed in the region of the costochondral junction almost wholly of osteoid, and an accompanying transformation of the marrow into "Fasermark." Similar but less striking changes were found also in the femora.

These conflicting observations induced Dr. Pappenheimer to present the additional data in his second paper on this subject.

It has been suggested [he wrote] that[14] negative results might be due to unrecognized lobules of accessory thymic tissue which had undergone delymphoidization or other involutional change, making their identification difficult. While it is hard to refute this criticism absolutely, it may be said that in those cases in which accessory tissue has been present, there has been no difficulty in recognizing it as such and in differentiating it from lymphoid tissue. Further, the failure of such minute thymic rests to undergo hyperplasia, in itself suggests that they are of no great functional significance.

Dr. Pappenheimer's operative technique, as "fully described in the previous study," was conducted as follows:

The removal of the thymus was performed upon young rats, ranging in weight from 10–25 grams. When possible the age was accurately determined, but in some litters it had to be estimated. Probably none of the operated animals were over twenty-one days old when the gland was removed. Two or more rats from each litter were reserved as controls, and kept in the same cage as the operated rats.

The operation was performed aseptically under ether anesthesia. A median incision was made in the lower part of the neck and continued over the upper half of the thorax. The sternum was then split as nearly as possible in the median line as far as the fourth or fifth intercostal space, and the edges were retracted. The triangularis sterni muscle was separated, exposing the thymus, which was carefully dislodged from below upward with fine blunt forceps, and removed, when possible, without laceration or separation of the two lobes. The friability of the gland made this the most difficult part of the operation. The sternum and skin were sutured with silk. Healing in almost all cases took place rapidly and without suppuration. It was found advantageous to use a simple positive pressure apparatus, to prevent collapse of the lung when the pleura was accidentally injured, and to institute artificial respiration when necessary.

In the earlier experiments the control rats were also subjected to etherization and the sternum was incised without removal of the thymus. It was found later that the operation had practically no immediate effects, and this precaution was therefore considered unnecessary.

After the end of the nursing period, the rats were fed principally on bread, sunflower seed, and greens. Meat was not given, and the feeding of milk was given up, since it seemed to favor the spread of infection. The operated rats together with the controls were kept under observation for varying periods up to six months, and were then killed. They were weighed weekly.

At autopsy the organs of the neck and thorax were removed together. After fixation the lungs and lower half of the heart were dissected off, and the rest of the tissue was embedded in paraffin and cut in series of 10 micra in thickness. In the earlier litters each section was mounted, but later only every tenth section was examined.

The completeness of the operation and the possible presence of accessory thymic tissue in the thymectomized rats was controlled in each case by an examination of serial sections of the entire neck organs, including the thyroid, and the upper half of the thoracic organs. The teeth and bones were decalcified in 5 per cent. nitric acid. The staining methods included Morpurgo's modification of Schmorl's thionin-picric acid method, which differentiates even in completely decalcified specimens between osteoid and completely calcified bone.

The following abbreviated protocols and comment are quoted from Dr. Pappenheimer's last paper (page 479 *et seq.*):

1. *Animals in which complete thymectomy was not followed by alterations in growth, nutrition, or skeletal system.*

Litter U. This litter consisted of seven rats, four of which were thymectomized on

[14] Personal communication from Prof. J. Salkind.

July 28, 1913. During the following weeks mother and young received protective inoculations of a *B. enteritidis* vaccine, since fatal infections with this organism were prevalent at that time.

Rats U_1, U_3, U_5 and U_6 (see Table 2) were kept under observation until January 28 and 29, 1914, when they were killed with ether. The bones and teeth were reserved for chemical examination and were not studied histologically. There were no gross changes. (See Table 2, page 292.)

Litter O. This litter consisted of six rats, upon four of which thymectomy was performed on July 17, 1913. During the following weeks all the animals received prophylactic injections of a vaccine of *B. enteritidis*. With the exception of one rat, O_4, which developed bloody diarrhea and died after four weeks, all the rats of this litter gained steadily in weight and remained healthy. Rats O_1, O_2, and one of the controls, O_5, were killed on Nov. 15, 1913, 120 days after the operation. Rat O_3 and the remaining control, O_6, were killed eleven days later. In none of the operated rats were there found rests of thymic tissue or accessory glands. *A careful microscopic examination of the bones and teeth showed no abnormal conditions.* The *calcification of the dentin of the incisors* is shown *for comparison with that in rhachitic rats*, in Figs. 1a and 1b, Plate 1, page 298.

2. Litters in which both operated animals and controls showed lesions of the teeth and bones.

Litter X. This litter consisted of six rats, four of which were operated on Oct. 24, 1913, the remaining two being kept as controls. The estimated age at the time of operation was sixteen days. Data pertaining to four of these rats follow:

Rat X_2. On Nov. 12th a small fragment of thymus from rat X_6 was implanted beneath the skin of the abdominal wall. The small nodule disappeared after a few days, and no remains of it were found at autopsy. There were no convulsive symptoms or other evidence of illness following the implantation. The rat remained well, but was behind the remaining animals of the litter in size and weight. It was allowed to live 151 days after thymectomy, and was then killed together with control rat X_5.

Autopsy: Poorly nourished, eyegrounds pale, slight exophthalmos. Internal organs normal. In the thymic region there were five or six lymph nodes and fat; no gross remains of thymus.

The *ribs* show fairly marked deformity. The zone of growing cartilage is broad and translucent, and there is distinct nodular swelling at the junction of cartilage and bone. There are also several opaque, fusiform, whitish swellings along the shafts of the ribs. The *femur* is 5 mm. shorter than that of X_5, the control, and thicker, but not noticeably deformed. *The teeth show no gross changes, aside from a notching of the cutting surface of the upper incisors.*

Microscopic examination: In the *ribs* the zone of proliferating cartilage cells is about 0.4 mm. in width (normal width about 0.1 mm.). By actual measurement with the projection apparatus, it is found to be about six times as broad as that of a normal control. It is composed of fourteen to sixteen swollen cells. The margin is uneven and irregular columns and groups of cartilage cells in which the ground substance stains like osteoid are found amongst the trabeculæ of the spongiosa. These are wide, irregular in their arrangement, and composed in the neighborhood of the epiphysis almost wholly of a homogeneous osteoid. Only the central portions take a bluish stain and show typical bone structure. The marrow spaces are narrow, and the marrow is fibrous. The osteoblasts are very high and conspicuous. The cortex is broad, and the marrow cavity of the shaft correspondingly reduced. The nodular swellings seen in the gross correspond to localized thickenings of the compact bone. The epiphyseal cartilage of the femur is very convoluted, and there are masses of swollen cells projecting among the trabeculæ of the spongiosa. The width of the proliferating zone varies. It is from six to twelve cells deep. The spongy bone is dense, the marrow spaces reduced in width.

The *incisor teeth* show pronounced changes in the calcification of the dentin, both in the upper and lower incisors. The essential feature is a defective and irregular calcification, with ingrowth of bloodvessels into the calcium-free dentin. On the concave side of the upper incisor there are alternating striæ of calcified and calcium-free dentin. No lesions are found in the enamel epithelium. The *changes in the teeth* are illustrated in Figs. 2a, 2b, 2c, and 2d, Plate 1.

Rat X_5. Control, male. Killed with ether at the same time as X_2.

Autopsy: Well nourished, apparently healthy rat. No gross lesions of internal organs, ribs, femora, or teeth. Testes small, undescended.

Microscopic examination: Two *ribs* were examined. One shows much more pronounced changes than the other. The lesions in the more severely affected rib are identical with those described in the rib of X_2. The width of the growing cartilage is increased, and the disarrangement of the cartilage cells is extreme. There is an excessive amount of spongy bone in the region of the epiphysis, the trabeculæ having a wide osteoid margin. The marrow is fibrous in character. The *femur* also shows similar changes.

The *incisors* show a marked defect in the calcification of the dentin, with ingrowth of cells and bloodvessels from the odontoblast layer, as shown in Figs. 3a, 3b, 3c, and 3d, Plate 2. The enamel epithelium of the upper incisors is interrupted at one point and folded in upon itself. The enamel in this region has fallen out.

The remaining rats of the litter, X_3 and X_4, and the control, X_6, were killed 156 days after the operation.

Rat X_3. Large, well-nourished male. Nothing abnormal noted in viscera, bones, or teeth. Many large lymph nodes in substernal region, but no gross remains of thymus.

Microscopic examination: In the *upper incisors* the calcification of the dentin is *practically complete* on the convex surface throughout the whole length. Near the base of the tooth the border of the calcified portion is slightly wavy, and there are a few ingrowing bloodvessels. The concave edge also shows good calcification of the dentin, although in the middle portion there are a few calcium-free streaks, and in places the calcium is deposited in globular form. The odontoblast layer is well formed through the entire extent of the pulp cavity on both sides. The enamel is wanting in the sections, but the ameloblasts are normal.

Normal chondrocostal junctions in several *ribs* examined. There are four to eight growing cartilage cells, regularly disposed. The osteoblasts are well formed. There is no excess of osteoid tissue.

Rat X_4. Thymectomy.

Autopsy: Fairly well-nourished female. No changes in internal viscera. No macroscopic remains of thymus. Definite lesions are seen in the *ribs*, similar to those described in X_2. The chondrocostal junctions are swollen, and there is sharp angulation of the lower ribs. The zone of growing cartilage is broad, and the adjacent part of the shaft for a distance of about 2 mm. is grayish white and soft. Four of the ribs show on the pleural surface, about 1 cm. from the junction with the cartilage, pearly, cartilaginous swellings. *Teeth and femora show no gross changes.*

Microscopic examination: The upper *incisors* show changes similar to those described in rats X_2 and X_5, but somewhat less marked. The defective calcification of the dentin, on the convex surface, near the base of the tooth, is marked, about one-third of the entire width being entirely calcium-free. In the middle portion, about two-fifths of the dentin is uncalcified. Here, and also towards the tip, the calcium is deposited in laminæ. There is an abundant ingrowth of capillaries from the odontoblast layer. On the concave side, near the base, half the dentin is calcium-free. Toward the middle and distal portion the calcification is still more incomplete, and in the form of alternating calcium-free and calcium-containing layers. The lower incisors show similar changes, especially marked on the concave surface.

The growing cartilage of the *ribs* presents an even convex surface towards the shaft. The rows of cartilage cells are six to ten cells deep. The spongiosa is composed of very broad trabeculæ with wide osteoid zones, and high osteoblasts. The pearly swellings observed in the gross correspond to localized thickenings of the compact bone.

The zone of growing cartilage of the *femur* at the lower epiphysis is convoluted and slightly increased in breadth, but not markedly irregular. The spongiosa is formed of coarse trabeculæ with a relatively broad osteoid zone and distinct osteoblasts.

Rat X_6. Control.

Autopsy: Large, well-nourished rat, showing no changes in the internal organs. There is slight beading of the ribs, with a broad grayish zone adjacent to the cartilage. The femora and teeth appear normal.

Microscopic examination: In the upper *incisors* the odontoblasts are well formed, extending through the entire length of the pulp. Calcification of the dentin is not abnormal, save that the odontoblast layer is rather wavy. The uncalcified predentin is narrow.

Ribs and femur show nothing abnormal.

Litter Y. This litter, consisting originally of eleven rats, was born in the laboratory of stock animals, all the rats previously studied having been obtained from Granby, Mass. The rats were undersized, and stood the operation poorly, only three thymectomized and three controls surviving.

Rat Y_2. Thymectomized Oct. 27, 1913. Weight 10 gm. Gained slowly and remained

undersized. Killed on Mar. 13, 1914, 137 days after extirpation of the thymus.

Autopsy: Internal organs normal save for suppurative foci in the lower lobe of the right lung. Testes large and descended. No alterations of the bones and teeth were recorded.

Microscopic examination: The line of growing cartilage of the *ribs* is broad, with a convex, irregular surface directed towards the shaft. It is composed of eighteen to twenty cells in rows, with masses of cartilage cells projecting amongst the trabeculæ of the spongiosa. These are numerous, broad, with a wide osteoid margin, and high conspicuous osteoblasts. The marrow spaces in the region of the cartilage are narrow, the vessels hyperemic and surrounded by spindle cells.

Upper epiphysis of *tibia:* No definite rhachitic changes. The zone of growing cartilage is slightly narrower than that of the control. The cells are regular in their arrangement, as are the trabeculæ. Bone formation is very active. The osteoid zone about the trabeculæ is slightly increased in width. This is especially clear in the epiphyseal center of ossification.

The epiphyseal line of the *femur* is regular on the whole, but there are a few projections of cartilage amongst the trabeculæ of the spongiosa. The osteoid is increased in amount.

The calcification of the dentin of both upper and lower *incisors* is somewhat defective, but there is no vascularization of the calcium-free dentin. The enamel epithelium is not altered.

Much more striking were the skeletal and dental changes in rat Y_8, the protocol of which follows.

Rat Y_8. Thymectomy on Nov. 1, 1913. Weight at operation 14.6 gm. Following the operation, and until the rat was killed on Mar. 2d, 126 days after extirpation of the thymus, it lagged far behind the remaining rats of the litter in weight and size. The hair was rough and sparse; the head seemed relatively large as compared with the body. On Jan. 17th it was noted that the upper *incisors* were very long and thick as compared with the lower, which were small and delicate. On Feb. 28th the right upper incisor was broken off just beyond its emergence from the gum.

Autopsy: Poorly nourished, stunted male. Weight 42 gm. The internal viscera were normal, with the exception of the right lung, which was atelectatic in its upper portion. No gross remains of thymus. The thorax is greatly deformed by the presence of a deep groove along the line of the chondrocostal junctions. From the pleural surface there are seen, especially on the lower ribs, nodular protuberances at corresponding points. There is thus a pronounced rhachitic rosary. The bones of the lower extremities are softer and more pliable than normal, and there is distinct swelling about the epiphyses of the knee-joints.

Cultures from the heart blood and spleen on slant agar remained sterile.

Microscopical examination: The upper *incisors* were sectioned through the fractured stump. The pulp is hyperemic and largely necrotic. The calcification of the dentin is both irregular and incomplete. The line of junction between odontoblasts and predentin is sinuous, and in many places the odontoblast cells penetrate the uncalcified tissue. The calcified portion of the dentin is laminated, the calcium being in the form of coarse globules. In another section there are alternating zones of calcified and calcium-free dentin. Isolated cells and occasionally capillary loops reach the outer, imperfectly calcified zone. Sections through the unfractured upper incisor show also defective calcification. Near the root, there is the same stratification as in the fractured tooth. In the middle portion, just after it emerges from the socket, the section passes outside the pulp canal. In this region there is a large area of calcium-free dentin. Near the convex surface, within the calcified strata, there are a number of globular yellowish masses. In sections stained with thionin-picric acid, it is seen that the dentin filaments are interrupted at the site of these globular deposits. Near the root, the congested pulp vessels penetrate the uncalcified dentin as papillary ingrowths. About one-half of the dentin on the convex surface of the lower incisors is free from calcium. The odontoblasts are poorly formed and irregular. There is no marked ingrowth of bloodvessels. On the concave side the calcification is still more imperfect.

The zone of growing cartilage of the *humerus* at the lower epiphysis is widened, and irregularly prolonged amongst the trabeculæ. These are very broad and the marrow spaces correspondingly narrow. The trabeculæ are composed in the neighborhood of the epiphysis of a narrow, ossified central portion, distinctly laminated, with angular bone corpuscles, surrounded by a very broad homogeneous, osteoid zone in which the nuclei of the bone corpuscles are larger and more rounded, and quite irregularly distributed. The osteoblasts are conspicuous and well formed. There is no increased osteoclastic resorption. The changes at the lower epiph-

ysis of the *femur* are similar in character, but more pronounced than in the humerus. Numerous sections from four different *ribs* show similar changes. There is marked deformity at the junction of cartilage and bone, where the rib measures 3 mm. in diameter. The junction of the cartilage with the shaft is in most places sharply marked off. There is a large central mass of hypertrophic cartilage, in some places twenty-five cells deep, and two shorter lateral spurs. Near the pleural surface, smaller irregular groups of cartilage cells are surrounded by osteoid-staining matrix. The adjacent cancellous bone is composed of stout trabeculæ formed entirely of pink-staining osteoid, separated by very narrow clefts and spaces. They are ranged, in the region where the rib is sharply angulated, at right angles to the cartilage columns. The distribution of the bone corpuscles through this mass of osteoid is haphazard. Farther along the shaft, the trabeculæ of the spongy bone follow the long axis of the rib. They are all greatly thickened, as is the corticalis, and well calcified only in their central portions. In thionin-picric acid-phosphotungstic acid-stained preparations, the broad osteoid, blue-staining zone appears with great distinctness. The marrow cavity is much reduced in width. Near the epiphysis the marrow is fibrous; farther along it has the normal lymphoid appearance.

Two control rats of the litter, Y_7 and Y_9, showed alterations in the teeth and bones comparable with those observed in the thymectomized rats, though somewhat less pronounced. A third control, Y_{10}, which had complete visceral transposition, was not histologically examined.

Rat Y_7. Control. Killed Apr. 7, 1914. Poorly nourished female, weighing 115 gm. Internal organs show no lesions, with the exception of the lung. The right middle lobe in converted into a mass of cheesy abscesses, separated by scar tissue. The *ribs* show slight beading at the chondrocostal junctions, with angular deformity in the region of the diaphragmatic attachment. The zone of growing cartilage is broad. No gross changes in *femora* or *teeth*.

Microscopic examination: In the upper *incisors* calcification of the dentin is imperfect, both on the convex and on the concave surfaces. The odontoblast layer is broad, but ill defined, and on the concave side cells are seen to penetrate the calcium-free dentin for varying distances. Both surfaces of the lower incisors show alternating layers of calcium-containing and calcium-free dentin. The calcium is deposited in the form of coarse globules.

The growing cartilage of the *femur* is narrow, being composed of only two to four rows of cells in the lower epiphysis. Both in the compact and in the spongy bone, the osteoid margin is very broad and distinct, especially about the perforating vessels. The *ribs* show no deformity in the sections examined, but there is a distinct increase in the width of the osteoid zone about the trabeculæ.

Rat Y_9. Control, male. Killed Mar. 13, 1914. Weight 118 gm. There were no lesions of the internal viscera. The alterations of the *teeth* were insignificant (slight lamination of the calcium on the convex surface of the lower incisors), but there was distinct irregularity and thickening of the cartilage at the lower epiphysis of the *femur* and at the upper epiphysis of the *tibia*. The single *rib* examined was practically normal.

3. Unoperated animals, from "stock" cages, that showed lesions of the teeth and bones identical with those in group 2.

To the foregoing protocols of thymectomized and control rats may be added the brief description of two unoperated rats taken from the stock cages, which showed lesions in the bones and teeth identical with those described above:

The first of these (rat 50) was greatly stunted; there was a marked disproportion between the size of the head and that of the body. The approximate weight was 50 gm. The hair was rough and sparse. The *teeth* were somewhat chalky, but not greatly altered. There was an extreme deformity of the *thorax*, resembling that noted in rat Y_2. There was also marked kyphosis and lateral curvature. There were many whitish nodules along the shafts of the *ribs*, especially in the paravertebral lines. The ribs were very soft, and on cross-section the marrow cavity seemed almost obliterated owing to the great thickening of the cortex of the bone. At the chondrocostal junctions were nodular projections several millimeters in thickness. The *femora* were short, and very broad in the region of the epiphyses. The upper third of the *tibiæ* was bowed anteriorly.

Microscopic examination: The superficial layer of dentin of the upper *incisors* is well calcified; in the middle zone, the calcium is in the form of globular masses of large size, and the inner zone, comprising about one-third of the total thickness of the dentin, is calcium-free. Toward the apex the calcification is more complete. The lower incisors exhibit more striking changes, especially on the concave surface, where about half the dentin is free from calcium. The vessels of the pulp are extremely congested, and the

[1] This table is taken, in the main, from the paper by Morgulis and Gies. The data for magnesium and phosphorus have been added since the publication of that paper.

[2] The percentage data pertain to the elements, not to oxids, and relate to substance dried to constant weight ("water-free").

[3] The rats of the W and Z litters were not mentioned in the protocols.

[4] The lack of available material prevented more numerous determinations of magnesium and phosphorus.

[5] These numerals, though they duplicate the corresponding numbers for the thyro-parathyroidectomy experiments, are independent of the latter.

odontoblast layer is broken up in many places by fresh capillary hemorrhages. Toward the apex of the tooth, the layer of odontoblasts becomes entirely disorganized, with the formation of numerous ragged cavities, possibly the effect of gas formed during decalcification. The enamel epithelium is intact save in one place, where the cells are destroyed by hemorrhage.

The zone of proliferating cartilage of the *ribs* is composed of irregular masses of cells which fail to show the normal alinement into columns, and which extend a variable distance into the adjacent trabeculæ. The neighboring part of the rib is composed of a knob of anastomosing columns separated by very narrow Haversian spaces. The distinction between osteoid and calcified bone is not sharply brought out in the sections, but the rounded form of the bone corpuscles and their highly irregular distribution suggest deficient calcification. The osteoblasts form a continuous flat row covering the trabeculæ. There is no increased lacunar resorption. Beyond this knob of tissue the bone is sharply bent upon itself. A tongue of cartilage grows into this angle from the external surface of the periosteum. The cortex of the rib is greatly thickened and formed of parallel trabeculæ which encroach upon the medullary cavity, which is correspondingly narrowed. The marrow is normal, save in the region of the junction, where it is fibrous.

In order to determine the possible infectious character of this disease, four half-grown and apparently healthy rats were inoculated with a suspension of bone marrow from rat Y_8.

One of the inoculated rats (55), killed twenty-eight days after subcutaneous injection, showed striking alterations in the bones and teeth. There was in this rat no gross deformity of the *thorax*, but an evident widening of the translucent zone of proliferating cartilage, and the adjacent bony part of the *ribs* was opaque and slightly thickened. The *femora* were broad and thick, and so soft that they could easily be cut with scissors. The *tibiæ* were bowed anteriorly.

Changes in the *teeth* were first noted four days before the animal was killed. The basal portions of the upper incisors were found to be distinctly swollen, translucent, grayish, and rounded, sharply marked off from the distal third, which was opaque and chalky white. During the next few days, the swelling and translucency extended almost to the tip of the tooth. The lower incisors were also less opaque than normally.

Microscopic examination: No changes were

found in any of the internal viscera. The *marked defect and irregularity of the dentin* is shown in Figs. 4a, 4b, 4c, and 4d, Plate 2. It is seen that on the convex surface of the upper incisors the irregularity in arrangement of the odontoblasts is such that these have apparently given rise to predentin both on their external and internal surfaces. They are thus disposed in a row on both sides of which is uncalcified dentin, and are connected by numerous cell strands with the pulp. The concave side of the tooth is calcium-free throughout its entire extent, and is pierced in many places by isolated spindle cells and occasionally by capillaries. The changes in the *ribs* and *femora* consisted merely of an increase in the width of the osteoid margins. No definite alterations were found in the cartilages.

periments were subjected by us to chemical analysis. The teeth and bones were prepared for this purpose by the method described in section II (page 281). Calcium was determined as before, *i.e.* by McCrudden's method. Magnesium was determined, in the liquid obtained as indicated in section II, by McCrudden's method.[15] Phosphorus was determined in portions of such liquid by the "official agricultural method."[16]

The accompanying plates (referred to first on page 286, and later in the foregoing protocols) illustrate certain of the statements in the above descriptions. Table 2 presents a summary of data from Dr. Pappenheimer's record and

Data pertaining to the content of Calcium in the Bones and Teeth, for various Groups of the Rats referred to in Table 2.

Groups of rats.	Percentage of calcium.	
	Bones.	Teeth.
1. Non-rhachitic and slightly rhachitic	23.03	27.99
2. Moderately rhachitic and markedly rhachitic	20.21	27.08
3. Completely thymectomized (excluding W_2)[17]	21.34	28.40
4. Control and incompletely thymectomized[17]	22.00	27.83
5. Rhachitic (stock)	20.74	25.96

[17] Rat W_2 (Table 2) evidently belongs to group 4 in this table. If the figures for the calcium content pertaining to rat W_2 are added to those of group 4 in this table, the average values for calcium become 22.22 and 27.87 per cent., respectively.

The foregoing protocols show that lesions of the bones and teeth were observed in thymectomized rats, in controls of the same litters, in stock animals, and in a rat inoculated with bone marrow from a thymectomized rat with lesions of the skeletal system.

There is little question that these lesions resemble closely those described by Morpurgo, in 1900, as infective osteomalacia of white rats. In his subsequent investigations, Morpurgo showed that in young animals, the spontaneous disease takes the form of rhachitis.

Teeth and bones from eighteen of the rats involved in Dr. Pappenheimer's experiments were subjected by us to chemical analysis. The teeth and bones were prepared for this purpose by the method described in section II (page 281). Calcium was determined as before, *i.e.* by McCrudden's method. Magnesium was determined, in the liquid obtained as indicated in section II, by McCrudden's method.[15] Phosphorus was determined in portions of such liquid by the "official agricultural method."[16]

The accompanying plates (referred to first on page 286, and later in the foregoing protocols) illustrate certain of the statements in the above descriptions. Table 2 presents a summary of data from Dr. Pappenheimer's record and gives our analytic results for calcium, magnesium, and phosphorus.

Dr. Pappenheimer's general conclusions from the *histological* data were stated as follows:

Rhachitic changes in the bones and teeth occur in young albino rats as the result of spontaneous disease, possibly of infective origin. This disease is often, but not always, accompanied by an arrest of growth and malnutrition.

[15] McCrudden: *Journal of Biological Chemistry*, 1909, vii, p. 83.

[16] Bulletin 107, U. S. Department of Agriculture (1912); "Official methods of analysis, Association of Official Agricultural Chemists," p. 2.

There is no valid reason for attributing such lesions to the loss of thymic function. In some rats showing the disease, an unusual number of mitoses were found in the parathyroid glands, but no evidence of injury to these structures.

It has not been found possible to confirm the statements of Klose and Magnini as to the fatal effects of complete thymus extirpation in rats.

A general summary of our calcium data, as given in Table 2, is presented on the opposite page.

The values in this summary, and the chemical results in Table 2, make it evident, as we stated in our recent paper accompanying Dr. Pappenheimer's, that the foregoing *chemical* data agree, in the main, with the corresponding histological findings reported in Dr. Pappenheimer's paper. Our results indicate that the bones and teeth of the rats which were found by Dr. Pappenheimer to be moderately rhachitic and markedly rhachitic, contained in general less calcium than those from the non-rhachitic and slightly rhachitic animals. The lack of any particular trend of calcium content in the bones and teeth from the thymectomized rats, as shown by both the individual results in Table 2 and the group averages in the above summary, makes it impossible to ascribe to thymectomy, in these animals, any special influence upon the processes of calcification in the bones and teeth subjected to analysis. The validity of this negative conclusion is emphasized by the low values for calcium content in the bones and teeth from the unoperated rhachitic (stock) animals. That such spontaneously rhachitic rats happened to be among the number selected for Dr. Pappenheimer's experiments, and that rhachitic lesions observed in the thymectomized animals were due to causes independent of thymectomy, are necessary inferences under the circumstances. It is possible, of course, that determinations of phosphate content might have afforded indications of a special influence of thymectomy.[18]

[18] This suggestion was published before our data for magnesium and phosphorus were available. (See page 296.)

It is assumed by Dr. Pappenheimer and by us that the mixed food of the rats, which was given in abundance and eaten freely, was ample in quantity, in quality, and in metabolic availability for the maintenance of the processes of normal calcification in each animal. One cannot be certain of such an outcome in experiments of this kind, however, unless the animals are individually maintained under suitably controlled metabolic conditions on diets of definite composition, of known quantity, and of proved nutritional adequacy. We require also, for correct interpretations of analytic data on calcification, more exact chemical knowledge of the variations in the composition of the bones and teeth of normal albino rats of different ages under given metabolic conditions. It is our intention to investigate in this laboratory, as a part of a plan of research in progress, the facts in these particular connections, with special reference to the possible establishment of definite physiological standards on which further experimental work with albino rats may be conducted more accurately.

As was stated above, our data for magnesium and phosphorus were obtained after the publication of the paper by Morgulis and Gies that accompanied Dr. Pappenheimer's. Our summary of such data from Table 2 (see page 296) facilitates direct comparison with the above summary of the results for calcium, and also with the corresponding individual results for calcium.

The data in this summary appear to justify the conclusion that the proportions of magnesium in the teeth and bones of the rhachitic rats were higher than those of the non-rhachitic animals. The data in this summary are indefinite so far as influence on phosphatation is concerned. As our work progresses additional results in this connection will be accumulated.

In the discussion of his thymectomy data Dr. Pappenheimer referred instructively, as follows, to results pertaining to parathyroidectomy, in accord with our own views in this relation:

> Defective calcification of the dentin, and penetration of the uncalcified tissue by blood-

vessels and isolated cells from the odontoblast layer, regarded by Erdheim and his successors as characteristic of parathyroid deprivation, were observed also in many of the rats in the thymectomy experiments described above. In one rat there occurred a spontaneous fracture of the tooth. Less marked in my rats was the infolding and disarrangement of the ameloblast layer; but this appears to be of secondary importance also in the lesions attributed to parathyroidectomy, and when present is probably due to mechanical causes.

The question arises, therefore, whether Erdheim, who was familiar with the spontaneous rhachitic lesions of rats, was justified in attributing these changes to parathyroid insufficiency. Erdheim has brought forward his transplantation experiments as crucial proof of the part of the parathyroids in normal calcification. The "Transplantations-streife" is believed to correspond exactly in its localization with the period of functional activity of the implanted parathyroid tissue.

This would be entirely convincing were it not for the fact that such alternating layers of calcium-containing and calcium-free dentin not infrequently occur as spontaneous rhachitic lesions. They are associated, no doubt, with remissions and exacerbations of the disease, such as have been described by Morpurgo. Fig. 3 illustrates the striate deposition of the calcium in the incisor of a spontaneously rhachitic rat.

Without wishing to discredit the work of Erdheim, supported as it is by other facts indicating an influence of the parathyroids upon calcium metabolism, one cannot but emphasize the identity of these lesions, attributed to the loss of parathyroid function, with those occurring in the spontaneous rickets of rats.

As regards the infectivity of the disease and the nature of the inciting organism, studies made in coöperation with Dr. J. G. Hopkins have not as yet led to conclusive results. The occurrence of rhachitic lesions in a rat, examined twenty-eight days after inoculation of bone marrow from a spontaneously rhachitic animal, is of doubtful significance, since many of the stock animals killed at this time were found to be rhachitic. The recent experiments of Koch, in which typical rhachitic lesions were produced in puppies by the intravenous injection of streptococci, indicate that the infective factor has to be reckoned with in experiments dealing with the effect of extirpation of ductless glands upon bone development in dogs as well as rats.

Sufficient evidence, we believe, has been

brought forward to show that the bone changes described by Klose are in no way related to the loss of the thymus gland, but occur as the result of spontaneous disease.

The importance of giving due consideration, in experiments of this kind, to the possibilities of "spontaneous rickets," along with many other "variables," can hardly be overestimated.

IV. General Conclusions.

Our data for thyro-parathyroidectomy, while suggesting support of Erdheim's conclusions regarding the decalcifying effects of parathyroidectomy, are inconclusive. The experiments will be continued.

The experiments on thymectomy failed to show that calcification processes were in any way affected by removal of the thymus.

Rhachitic changes in the bones and teeth occur in young albino rats as the result of *spontaneous* disease, possibly of infective origin. This disease is often, but not always, accompanied by an arrest of growth and malnutrition (Pappenheimer).

Our experience has shown that many variables in studies of this kind must be more effectively controlled than previous workers (or we ourselves) have done, to insure reliable foundations for sound deductions regarding specific effects from particular causes.

These studies are in progress.

In the conduct of the calcium determinations we have had the co-operation of Dr. Alfred P. Lothrop, to whom we are greatly indebted for this assistance.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

RADIANT HEAT AND BLUE LIGHT IN THE TREATMENT OF PYORRHEA AND OTHER MOUTH DISORDERS.

By CHARLES C. VOELKER, D.D.S.(Univ.Pa.), Brooklyn, N. Y.

MUCH earnest study and careful scientific investigation have been given, during the last few years, to the different forms of radiant energy as applied to therapeutics; and the results obtained have been so flattering that we are warranted in including them in our list of valuable curative agents. Thus, we have radiant heat from various sources; brush discharges in vacuum; the various forms of light (luminous, or visible, rays); the ultra-violet rays; the N-rays of Blondlot; the cathode rays (or electrons of Crookes), the progenitors of the Roentgen, or X rays; and the alpha, beta, and gamma rays of radium and radio-active substances.

THE PHYSIOLOGICAL MANIFESTATIONS OF RADIANT ENERGY.

The infinite energy of nature is received by and transmitted through the universal ether that fills all space, by means of wave motion manifesting itself in the forms of heat, light, sound, and chemical and electrical actions of different kinds. These varied forms of energy, differing only in the frequency and direction of their vibrations, are transmitted to our consciousness by means of nerves specially organized or attuned to receive them or to respond and vibrate in harmony with the stimuli which they set up. Hence we become aware that we are alive; and this awareness, through the normal functioning of the nerves of the special senses, leads to the production of thought and the wonders of the human intellect. Our tissues, too, seem to have the power of attuning themselves to the differing vibration frequencies coming from sources of complex and mixed vibrations, such as the sun and the electric arc, and of deriving from them the energy required

to maintain their functional activity. "Heat and light," says Langley, "are not things in themselves, but different sensations in our own bodies or different effects in other bodies—are merely effects of this mysterious thing we call radiant energy."

Under conditions which are a part of our normal environment, these heat and light frequencies exert a beneficial influence. But under abnormal or unusual conditions of exposure to the radiations from the sun or the higher frequencies of the Roentgen rays and the radium emanations, inhibitory or depressing effects may be produced. They must therefore be carefully and rationally used as therapeutic agents.

VISIBLE LIGHT AND THERMAL FREQUENCIES AS THERAPEUTIC AGENTS.

In the present discussion on radiant light and radiant heat, we are concerned with the spectral, or light rays, also called luminous rays or visible light frequencies, and the infra-red or heat rays (invisible light rays), also known as calorific rays or thermal frequencies. Since the effects of these two forms of radiant energy upon living tissues are similar, and because they are given off together from such therapeutic instruments as the arc lamp and the incandescent therapeutic lamp, it is in order to treat them together, since both are indicated in several conditions with which the dentist has to deal.

The heat of the sun is transmitted to the body without affecting the temperature of the intervening medium, the ether. It is therefore said to be radiated, or radiant. The same is true of the heat radiated from a source of artificial light, as the incandescent lamp.

Of the thermal frequencies which strike a body, some penetrate and some are reflected in the same manner as are the light frequencies. The absolute reflecting power (the ratio of the quantity of heat absorbed to the quantity of heat reflected) of highly polished metal surfaces stands in the following relationship, the first named being the highest: Silver plate, gold, brass, platinum, steel, zinc, iron, cast iron. Hence, polished silver would seem to be the best reflecting surface for lining therapeutic lamps where the maximum thermal efficiency is desired.

Melloni has shown that certain substances, such as rock salt and carbon disulfid, transmit heat, or are diathermanous; while others, such as copper sulfate and distilled water, are almost athermanous. The terms diathermancy and athermancy, applied to heat, correspond to the words transparency and opacity with reference to light. Rock salt is analogous to transparent glass, copper sulfate to sheet lead. Practical use was made of these facts by the famous Danish scientist, Niels Finsen, in his tube for light treatment by the use of the so-called Finsen rays. He used distilled water in his apparatus to cool the condensing lenses, and copper sulfate to filter out the heat rays, when making use of light energy in the treatment of lupus and other skin diseases.

The infra-red radiations, or thermal frequencies, have been shown to have greater penetrating power, unit for unit, on body tissues than the higher visible frequencies of the spectrum and the invisible ultra-violet and Roentgen rays. The latter are invisible, are without heat rays, and can only be demonstrated from their fluorescent and actinic effects; the infra-red, also invisible, being discerned by means of the thermopile and other heat-registering apparatus.

The value of blue light as a therapeutic agent has been pointed out by Professor Minim of St. Petersburg, Dr. Niels Finsen of Copenhagen, Dr. Margaret A. Cleaves of New York, and by other writers on light therapy and electro-therapeutics, among whom may be mentioned Kassabian, Martin, Hilliard, and Redard.

EFFECTS OF BLUE-LIGHT TREATMENT.

In very elaborate experiments carried out at the Institute of Physiology, in Naples, by Dr. R. Pansini, it was shown that blue light reduces the reactions of

the cerebral cortex and prevents stimuli applied to one motor area from spreading to others, thus acting like anesthetic agents such as morphin, ether, or chloroform when applied to the cortex. In maniacal conditions, blue light produced a transient calmness. Pansini found, moreover, that bandaging the eyes of his subjects made no difference in the effects produced, which tends to uphold his claim that the results produced are due to the penetrative action of the blue light and its action on the circulation.

Dr. M. A. Cleaves is of the opinion that it is the direct action of the blue light upon the blood itself which produces its effects, the light energy being converted into chemical energy, producing increased oxidation from the storage of more oxygen in the red blood corpuscles. She suggests as a theory of the action of blue light that "Because of the powerful action of the chemical frequencies of light upon the blood, the systemic toxic condition which is reacting upon the supreme nerve centers is overcome through the increased oxidation power of the blood" produced by the blue radiations.

Blue glass screens are used in conjunction with the thermal frequencies of the various therapeutic lamps, such as the Minim lamp, the marine searchlight, the Betz lamp, the leucodescent lamp, and the very serviceable portable lamp called the "Multum-in-parvo." Blue glass screens prevent the passage of the ultra-violet frequencies, thus avoiding the unpleasant tanning effects of these rays, which might be objectionable as well as interfere with the therapeutic action of the blue rays. They also keep out the lower frequencies which have irritant effects, such as the red. The total heat radiations are also reduced by the use of the blue glass.

The experiments of Kaiser, reported in the *British Medical Journal,* have shown the value of blue light in killing cultures of the tubercle bacillus and as a resolving agent for tuberculous abscesses. He also regards it as a local sedative and even as an anesthetic. He reports cures of tuberculous skin diseases, such as lupus vulgaris and erythematosus, by means of blue light.

The name "Minim" light is often given to blue light, from the work of Dr. Minim of St. Petersburg, to whose classic essay on the subject we are indebted for much of our knowledge. He believes that blue light acts on the vasoconstrictors, has analgesic properties, and that it will relieve or cure superficial neuralgias. He claims to obtain the best results when the patient is at some distance from the source of light, so as not to be acted upon by the residual thermal frequencies given off from the lamp. He and also others have claimed to produce anesthesias sufficiently profound for the performance of minor surgical operations.

Minim reports a very interesting case of injury to the mouth and throat from the accidental swallowing of ammonia, which was cured by several treatments with the Minim lamp, the rays being applied to the mucous membrane of the mouth and to the front of the neck. Many cases of minor surgical operations under blue light anesthesia are recorded in medical and electro-therapeutic literature. Some of these effects have been wrongly attributed to the ultra-violet frequencies by various writers. When incandescent lamps are used, the ultra-violet rays are prevented from passing by the glass. Thus the effects claimed to be due to the ultra-violet rays, when glass-inclosed sources of light are used, are in reality due to the chemical rays of the spectrum, principally the blue, indigo, and visible violet. Hence we should beware of being cajoled into the belief that vacuum tubes, such as are supplied with many high-frequency machines, are of great therapeutic value due to ultra-violet radiations. Pure quartz, on the other hand, will permit the passage of the ultra-violet rays.

We may sum up the advantages possessed by the higher visible frequencies, the chemical rays, or so-called blue light, in therapeutics, thus:

(1) Bactericidal.

(2) Vaso-motor constrictor, causing local anemia.

(3) Analgesic, and possibly somewhat anesthetic. If the action be prolonged, equalization of the circulation and hyperemia result.

(4) Sedative action on nerves and cortex.

(5) Increased metabolism due to the chemical action of the rays on the blood, increasing oxidation.

THERAPEUTIC ADVANTAGES OF THE COMBINATION OF LIGHT AND HEAT.

Enough has been said, I believe, to show that the two forms of radiant energy, light and heat, stand in close relation to one another, and that pathological conditions calling for the therapeutic exhibition of the one will usually be benefited by the concomitant employment of the other. By combining these two forms of radiant energy we can produce positive chemotactic effects, stimulating metabolism through the hyperemia induced, and promoting elimination through the action of the glands of the skin, while at the same time producing a beneficial reflex reaction through stimulation of the peripheral nerve-endings. Solar and incandescent light and heat have proved of great value in the replacement of tissue waste, as witness the sun-bath and the electric-bath annexes of tuberculosis sanitaria. Both radiant heat and convective heat are now firmly established therapeutic measures in general medical practice.

The effects of the two forms of radiant energy under consideration are both local and general—the general effects being due to the heating of the blood stream, the increased elimination through the skin and lungs, and the sterilizing and oxidizing action of the light rays penetrating into the blood channels. Those light rays which do not penetrate through the periphery of the body evolve heat radiations, in contrast to the X rays, which pass through without heat evolution. The hyperemia induced brings fresh blood to the affected part, with its phagocytes and leucocytes, inducing more rapid resolution and hastening recovery, while the bactericidal effect of light on the pyogenic and other bacteria is too well known to require more elucidation.

We may sum up as follows the physiological effects produced by the radiant light and heat frequencies:

(1) Increase in rapidity of tissue repair by inducing phagocytosis and leucocytosis.

(2) Destruction of pathogenic bacteria.

(3) Removal of waste products by the stimulation of the eliminating organs and the oxidizing action of the blood.

(4) Prevention of stasis in traumatic injuries, as after the surgical scaling of the roots of teeth in pyorrhea.

(5) Analgesic and soothing effects on the nerve terminals in mucous membranes and the skin.

(6) Reflex action on the spinal centers due to peripheral stimulation.

(7) Lowering of arterial tension and relieving congestion.

APPLICATION OF LIGHT AND HEAT FREQUENCIES IN DENTAL PRACTICE.

I have found the use of radiant energy in the form of heat and blue light to be of considerable value in practice, as will be evidenced by the case reports appended hereto. In my hands one of the small therapeutic lamps of the portable type, using a simple blue glass screen, has been used as an adjunct in the surgical treatment of pyorrhea alveolaris and allied disorders of the gingiva, the alveoli, and the mucous membranes of the mouth; in cases of severe pericementitis combined with pulpitis; in neuralgias, of dental and other origin; and in cases of headache, eye-strain, and other painful disorders, such as dysmenorrhea and the neuralgia following appendectomy, it has been of service as a household remedial agent.

In using the lamp without the blue screen, great care must be used not to burn the tissues over which it is applied. It is well to keep the light moving over

the surface to be treated, and if it becomes too greatly heated, to occasionally pass the hand or a folded cloth between the lamp and the part. For use after surgical scaling in pyorrhea, I have found it best to use the blue screen (which must be of real blue glass, which will cut off the lower and higher frequencies), which will enable the operator to get the combined action of the heat rays and the soothing or analgesic effect of the blue rays. The patient is instructed to look directly into the blue screen, the mouth being held open widely, and the lips held out of the way by any convenient method, so that the light and heat rays can reach all parts. Applications of ten to fifteen minutes are given, or less if relief from pain is obtained sooner. I have found, in quite a number of cases of pyorrhea alveolaris and other gingival disorders requiring much severe scaling, which have been under treatment during the last few months, that the great soreness which usually follows this work is much relieved and passes away much sooner if the therapeutic lamp is used; and I believe that the total time required to obtain a cure of these conditions is shortened by its use.

REPORT OF PRACTICAL CASES.

Case I. Mrs. D., graduate nurse, former superintendent of one of our largest hospitals; wife of a physician; age about thirty. The patient had developed an axillary abscess, and had not been without a daily rise in temperature for six weeks prior to her first visit to my office. Her family physician had prescribed autogenous vaccines, which had been given in conjunction with medication, without effecting a cure. She was referred to me by her family dentist, who had not seen her for several years. I found pus flowing from the alveoli of most of her teeth. I told her that from ten to fifteen treatments would be required, using the surgical method of Dr. R. G. Hutchinson, Jr., of New York, the treatments to be of about one hour's duration each. With the third treatment I began the use of the therapeutic lamp after finishing the scaling, to the patient's great satisfaction. She told me at the next sitting that her gums did not hurt her nearly as much the day following treatment as on former occasions; at the fourth treatment she told me that she had been free of her daily temperature rise for two days, but that it had returned on the day of treatment before coming to my office. I gave the patient seven treatments altogether, and dismissed her as cured.

At the fifth treatment, after finishing with the therapeutic lamp, she said: "Doctor, you hurt me enough several times today to make the tears come into my eyes, but since you have used the lamp I feel almost as if I had not undergone a treatment today."

At the last treatment, the seventh, she told me that she had not had a recurrence of her daily temperature rise for a whole week, and that both she and her husband attributed this to the cure of the pyorrhea. She also attributed the axillary abscess to the pyorrhetic condition. A month after her last treatment she reported having had no recurrence of high temperature or pus.

Case II. Miss M., a young woman of about twenty years, developed pulpitis while in Los Angeles, when about to return to New York. She did not seek treatment there, and suffered more or less all the way across the continent. She came to my office immediately on her arrival in Brooklyn. I found a cavity in the lower left third molar, exceedingly sensitive, combined with severe pericementitis and neuralgia extending into the ear. I treated the tooth with arsenical fiber for devitalization, and used the therapeutic lamp on the face, with great relief to the patient. The pain returned after the removal of the pulp, which was very resistent to arsenic and gave considerable pain in removal. The heat and blue light always allayed the neuralgia. The pericementitis, combined with the sympathetic irritation set up in the ear, finally became so unmanageable that it was decided to extract the tooth, which showed that my diagnosis was correct. After extraction the pain persisted for three days, when the patient presented and I gave her another treatment with the lamp, which eased the condition to such an extent that a complete cure soon followed.

Case III. Mrs. V. developed a severe nervous headache, with a strained feeling of the eyes. As soon as the blue rays struck the face a sense of relief was experienced, and the headache also passed off in a short time.

Case IV. Miss S., a woman of about forty-five years, presented with a pyorrhea due to large accumulations of calculus, of both the serumal and salivary types. She claimed to have seen her dentist regularly, but that he

had not scaled her teeth. My opinion is that the tartar had not been removed in twenty years. Several teeth were so loose that I removed them with my fingers. Twenty-two teeth could be preserved. The patient was very nervous, but courageous. I followed the severe scalings necessary with the therapeutic lamp treatment, always with an expression of satisfaction on the part of the patient for my "kindness" in taking the soreness out of her mouth. I told the patient before commencing treatment that it would probably require about fifteen treatments to effect a cure. I dismissed her as cured after nine treatments. I believe that the soothing and healing effect produced on the gums by the use of the lamp was an important factor in bringing about such a rapid recovery in this case.

Case V. Mrs. A., a woman of thirty; very nervous. Severe neuralgia following surgical removal of pulp in an upper bicuspid, extending over the face as far as the temple. Ten minutes' treatment with the lamp relieved the condition, and the patient expressed her great satisfaction in enthusiastic terms.

THE ENTOMBMENT OF A TOOTH IN A GOLDEN CASKET.

By F. M. WILLIS, D.D.S., Ithaca, N. Y.

(Read before the Syracuse Dental Society, November 10, 1914.)

A TOOTH which has been crowned with gold is buried in a golden coffin, and the time of its final dissolution is in direct ratio to the care with which the crown was fitted and cemented. I make this statement deliberately, as it is my honest conviction, after having done such work extensively for more than twenty years.

REASONS FOR FAILURES OF GOLD SHELL CROWNS.

Invisibility of abutments. There are many reasons why a gold-crowned tooth fails; but the main reason is that the tooth is entirely hidden from view, and if trouble ensues it is often not discovered until the tooth is destroyed beyond repair. For my own mouth I constructed a lower bridge, using the second molar and second bicuspid as anchorages, which supported a first molar dummy. The bridge was carefully cemented to place by Dr. E. E. Harrington of Watertown, N. Y., who stated at the time that he never saw a more perfectly fitted bridge. After seven years, the bridge became loose, though there was no sensation whatever in the abutments. The bridge was subsequently removed, when it was found that the molar abutment was entirely gone, except the root, which still remains in my mouth, covered over with copper cement, a black monument to the failure of bridge work. A sufficient number of the best bridges have traveled the same road, in my observation, to make bridge work an uncertain

procedure, owing to the fact that we cannot see what is going on under a gold crown. In my opinion a badly broken-down molar or bicuspid is far better off when partially built up with amalgam or with a gold inlay than when fully restored with a gold crown. In my practice I carry out this principle, and many teeth which were formerly consigned to an early grave in a golden casket are now restored by me to long life and usefulness by being carefully built up with amalgam or a gold inlay.

Other reasons why gold crowns are often fatal to the teeth are—

(1) *The difficulty of so shaping the tooth that a perfect fit may be obtained.* On studying the anatomy of extracted teeth, we find that the circumference of the large part of the crown is from two to five millimeters greater than that of the neck of the tooth. In order to secure a close fit at the gingival margin of such a tooth, it would be necessary to remove all the enamel from the tooth. This difficulty may be lessened by devitalizing the tooth, but the practice of indiscriminately devitalizing the pulps in posterior teeth is rash folly. No dead tooth is as good as a vital one, no matter how carefully the pulp may be removed and the canals filled. A dead tooth proves an uncertain quantity in a sufficient number of cases to render it advisable for us to shun devitalization whenever possible. In rare cases, where a deviated molar is to be crowned with gold as abutment for a bridge, devitalization, with all its uncertainty, is not only permissible but advisable. In many cases, however, where the crown of the tooth leans decidedly, sufficient and preferable anchorage may be obtained by extending the gold band only one-half or two-thirds the distance to the gum margin. Such an attachment is entirely free from the most objectionable features of an entirely covered tooth.

(2) *The practical impossibility of perfectly cementing a crown which extends under the margin of the gum.* This is the vulnerable point in a tooth capped with gold; there is a moist zone around the neck of the tooth, just under the free margin of the gum, which cannot be thoroughly dried, and consequently that portion of the crown is never properly cemented. This can be partially overcome by allowing the crown to be worn for a few days, without being cemented. Then the gum will stand away from the tooth far enough to allow fairly good drying of the neck of the tooth when the crown is cemented. By filling the crown full of cement, as advised by Dr. George W. Melotte, any moisture at the neck of the tooth will be forced away by the oncoming cement.

(3) *Irritation of the soft tissues by the edge of the gold band.* No matter how much care is used in fitting the gold band around the neck of the tooth, it is practically impossible to prevent more or less irritation. Some operators will undoubtedly deny this, but a careful examination will, in a large percentage of cases, show irritation of the gum margin to a greater or less extent. This irritation is not always fatal to the tooth, but it is an unhygienic condition to be avoided, if possible. This difficulty may be reduced by using scrupulous care in fitting the gold close to the tooth, beveling the edges properly, and allowing the gold to extend only very slightly under the free margin of the gum.

(4) *Injurious effect of a large mass of metal upon the tissues.* The presence of a large quantity of metal in the mouth is injurious to the tissues. It increases thermal shock and promotes electrical disturbances in the mouth. Gold is worse than amalgam in these respects, because of its greater density.

(5) *Conspicuousness of appliance.* The comparative ease with which a showy piece of work may be made appeals to the uneducated patient and is profitable to the dentist.

These criticisms concern the ethical dentist and the ten-dollar crown; and if these charges are true, how about the five-dollar crown made by the dental quack, with its miserable shape, its bad articulation, and its fatal effect upon the soft tissues at the neck of the tooth?

THE PATHOLOGY AND ETIOLOGY OF PYORRHEA ALVEOLARIS.

By PERCY R. HOWE, A.B., D.D.S., Boston, Mass.

(Report presented to Section II, Sixth International Dental Congress, London, 1914.)

THE term Pyorrhea Alveolaris has been the subject of much criticism. It is maintained that it does not adequately describe those earlier characteristics of the disease with which we are familiar. It does, however, depict the most active and advanced state of the condition that it designates, and presents, therefore, the most favorable aspect for its study.

It is unnecessary to describe those clinical aspects of this disease that are common to every text-book, but which very properly might come under the topic of this paper, for these are matters of everyday practice. This fully developed pathological condition presents three distinct phases, the consideration of which, in view of more recent developments from laboratory researches, adds to our understanding of the processes involved in its advancement, or, *per contra,* its restraint. I refer to bacterial activity, pathological calcifications, tissue degeneration. These three processes accord with general physiological principles in that while they are distinct processes, yet they are more or less interdependent. With this in mind their separate consideration may be profitably undertaken. Notwithstanding the numerous organisms that have been from time to time reported in connection with this disease, and that have been made the basis of vaccine therapy, yet for reasons which will appear in the discussion of these micro-organisms we must account the greater part of them merely associate forms, pus organisms, or indicative of disturbances of a different nature.

BACTERIOLOGY.

The most recent work upon this disease, done by the distinguished bacteriologist Dr. Hideyo Noguchi,* of the Rockefeller Institute of Medical Research, is of the greatest interest to our profession. By reason of improved cultural methods Dr. Noguchi has discovered a new species of spirochæta, which he has called *Treponema mucosum.* This organism is anaerobic, requires from eight to ten days for its growth, is mucin-forming, and produces odors characteristic of the disease. In form it is above half as large as the *Vincenti* spirillum, its curves being much more regular, and similar to the organisms of syphilis. Further interest in it arises from the fact that it will not grow on healthy tissue, but requires such a tissue as occurs in disturbed metabolic states. It is not strictly parasitic, but exerts a pyogenic action upon the tissue in which the growth occurs. In addition to this, Dr. Noguchi has reviewed and revised the works of other authorities, and has isolated in pure cultures other forms of micro-organisms, among which he finds the *Treponema microdentium* very commonly present, as well as the *Spirillum Vincenti,* together with fusiform bacilli. These, then, are the micro-organisms most intimately connected with pyorrhea alveolaris. They are capable of producing odors similar to those that accompany

* Noguchi, Hideyo, "*Treponema mucosum* (new species), a Mucin-producing Spirochæta from Pyorrhea Alveolaris, Grown in Pure Culture," *Journ. Exper. Med.*, vol. xvi.

this disease, and one is mucin-forming. The infection is secondary, the etiological factor being of metabolic origin, as has long been held, and in which opinion Dr. Noguchi, as a result of his studies, concurs.

The pneumococcus has perhaps been mentioned in connection with this disease as much as any micro-organism, and it has been made the basis of vaccine therapy. For this reason it may be well to give it a brief consideration. It is undoubtedly possible to isolate the pneumococcus from any mouth condition. Fifty per cent.* of the mouths of healthy persons taken at random will show the presence of this micro-organism. Miller† calls attention to an organism similar to the pneumococcus that very commonly occurs in the mouth. Considerable confusion has existed regarding the biology of these organisms, so that they have been referred to as the "pneumococcus-like organisms," and, on account of their morphological similarity to the true pneumococcus, some very elaborate study has been devoted to them, and the attempt made to establish the relationship between them and pneumonia. It has been concluded that some of the organisms cannot be distinguished from the true pneumococcus, either morphologically or physiologically, but that there are others, similar culturally, that react differently in fermentation and agglutination tests. The streptococcus mucosus is a member of the same species, is found freely in the mouths of healthy individuals, reacts similarly in the agglutination tests, and is undoubtedly closely allied with the mouth pneumococci. Other organisms found in healthy mouths are undoubtedly temporarily or permanently modified forms of this class of micro-organisms. These are common mouth bacteria. Hiss‡ states that in seven healthy individuals under observation for study, in repeated tests extending over weeks and months, the pneumococcus was on some occasions demonstrated to be present in the saliva in six out of seven cases, or 85.7 per cent.

So that it may be seen that the weight of evidence is very much against the supposition that this class of organisms is closely responsible for the disease pyorrhea alveolaris, and that if we are to employ vaccine therapy we should base our therapeutic measures upon the teachings of the more recent revisions of the bacteriology of this disease. It would be very interesting to note the effect with vaccines prepared from treponema mucosum, or the Vincenti spirillum.

FORMATION OF CALCARIOUS DEPOSITS.

The next process for consideration is that of the formation of the calcarious deposits upon the teeth. These deposits, referred to as salivary or serumal tartar, according to the medium of their formation, are not widely different from calcarious deposits in other parts of the body, and the principles governing such pathological calcification, whether of the eye, the brain, the heart, the kidney, the liver, or of the intima of the arteries, are, in the main, equally applicable here.

It comes properly under the heading of this paper for us to consider these principles and to support the idea of the connection between these deposits and other pathological calcifications with laboratory evidence.

It has been shown by experimentation that almost any tissue of the body may become the seat of calcification* providing it is degenerate. Cartilage and colloidal material are among those most readily calcified. In the case of the peridental tissues we find them to be of a cartilaginous character, while from the secretions of the mouth we find altered and evascular colloidal constituents, both of which form a most favorable ma-

terial* for calcarious deposition. While these conditions invite calcification, other factors must enter into the consideration of this process, among which may be mentioned over-saturation of the blood or saliva with calcium salts. The blood and the saliva not only contain carbonates and phosphates, either of which would precipitate the other in the test tube, but contain these elements in excess of their solubilities in water, variously stated, but given by one investigator as from two to four times as much. The blood of mammals varies but little in its calcium oxid content, being about 0.011 per cent. to 0.013 per cent. (Abderhalden.) Other investigators give a slightly higher estimate, but according to my analyses the CaO content of the saliva agrees very closely with Abderhalden's estimate for the blood, or from 0.011 per cent. to 0.015 per cent. CaO. There are two factors to account for this quality of holding an excess of CaO in solution that are common to the blood and the saliva. They are the CO_2 and the adsorption property of the colloids. It is mentioned in dental literature that the calcium salts of the saliva are held in solution by the CO_2, and in fact the usual explanation of the deposits of salivary calculus is that the calcium salts are held as bicarbonates, and upon the escape of CO_2 the calcium is precipitated. This explanation is in measure true, but it is hardly a complete one and is open to criticism, for while the free CO_2 in the saliva may hold the calcium phosphate in solution, and the calcium carbonate exist as bicarbonate, so that the escape of the CO_2 would allow both the phosphate and the carbonate to become precipitated, we would expect to find almost universally the constant deposition of the calcium, whereas it is deposited only under specific conditions. Much study has been devoted to the question of the form in which the calcium exists in the blood. and Wells, in extensive researches on calcification, adopts the conclusions of Barillé,* who holds that the calcium phosphate is present in the blood as a carbon phosphate, an unstable compound that decomposes to form a biphosphate and a bicarbonate, and there are many reasons to believe that it is in this form that these salts exist in the saliva:

$$Ca_3P_2O_8 + 4H_2CO_3 = H_2O + P_2O_5Ca_2H_2 : 2CO_3(CO_3H)_2Ca.$$

When the CO_2 escapes or is neutralized, the mixture of carbon phosphate is precipitated; in an alkaline medium the phosphate comes down as tribasic, and in an acid medium, such as the urine, as dibasic calcium phosphate. The more alkaline these fluids become, the less able they are to retain the calcium salts in solution. "It is a well-known fact that, no matter how sclerotic the walls of a vein may become, they rarely, if ever, calcify, so long as there is venous blood rich in CO_2 flowing through them." Hoffmeister and Tanaka† have shown that pieces of ivory are most rapidly absorbed in tissue where metabolism is most active (and where by inference the most CO_2 is produced). Active metabolism is, then, a very considerable factor in calcium deposition.‡ So that while the CO_2 is an important factor in maintaining in solution the calcium salts that are present in the fluids that constantly bathe the parts undergoing calcification, yet it is not the sole factor, for it leaves out of consideration the very important properties of the colloids, of the mucin of the submaxillary and sublingual glands, and the globulin and albumin of the parotid glands, as well as the colloids of the blood. The colloids are supposed to be

held in suspension, while the crystalloids are held in true solution. Part of the crystalloids become concentrated at the surface of the colloids, and the withdrawal of these from the solution allows more to be taken up, so that colloids, by their adsorption property, must here be considered when we look for an explanation of the manner in which it is possible for more salts to enter into solution than is possible in water solubility. That this property of the colloids is even more to be regarded than that of the CO_2 is to be seen by that series of experimentation which has shown that even upon the complete withdrawal of the CO_2 the colloids are capable of withholding these salts from precipitation.

CALCIUM SUPPLY DERIVED FROM FOOD.

In addition to the way in which these two different agents hold the calcium salts in solution in excess, there remains the fact of the supply of calcium through the food, and through the disposition that the system makes of this supply in its physiological processes. The substitution of foods with other bases, as magnesium and strontium, together with a low calcium content, has been proved by experimentation to act in an inhibitory manner upon ossification.

It has been shown that in acidosis the calcium of the blood is utilized to neutralize these fermentative or pathological acids. On this account we should expect to find erosion, rather than pyorrhea alveolaris, during a metabolic irregularity of this character.

On the other hand, excess of calcium in the food leads to its deposition within the bones. (Goitein.)

The calcium excretion is mainly through the intestinal tract. It has been shown that in certain intestinal crises, 60 per cent. more calcium is excreted than is taken in by the food. So that the importance of the influence of this part of the digestive tract upon the calcification process is very apparent.

From repeated examination of the saliva the writer feels that it is a safe statement to make that the calcium content of the saliva is greater in individuals who have attained their growth, and that as the tendency of the system toward excessive retention of these salts increases with age, so does the calcium content of the saliva. The analyses of tartar, both the salivary and the serumal, that I have carried out in my laboratory, show that these deposits contain the phosphate of lime and carbonate of lime in the proportion of from 85 per cent. of phosphate as tricalcium, to 15 per cent. of carbonate. Some magnesium is present, together with fats (neutral fats, lecithin, and soaps), and the stroma in which the deposit has occurred. With respect to the difference between the salivary and the serumal tartar, the only thing that is apparent from my examinations is that of the matrix of deposit. In this connection I have carried out many analyses with a view to determining the presence of urates, and compared them with controls, and I have never been able to convince myself of their presence. I have used the murexid tests and others. It will be seen from these analyses that these deposits, that are so intimately connected with the dental organs, agree very closely with analyses of calcific deposits in other parts of the body, particularly in respect to the proportion of the phosphate to the carbonate,* and with respect to the fats.

No matter in what form the calcium enters the system, or in what form it is deposited, it eventually becomes phosphate and carbonate, and in the proportion given.

In passing, it may be well to state that many analyses give a higher per cent. of carbonate. This is to be attributed to the ashing method, which converts many organic acids and compounds into carbonates. My own work has been carried out by titrations, the CaO estimated as oxalate, the CO_2 by freeing with HCl and KOH absorption, and the P_2O_5 has been determined by uranium, using potassium ferrocyanid as indicator.

---

* Wells, H. Gideon, "Pathological Calcification," *Journ. Med. Research*, vol. xiv.

VARIOUS OPINIONS ON CALCIFICATION.

There has been a division of opinion in respect to calcification among research workers upon the subject. One school is represented by Wells in very elaborate studies upon the subject, viz, that the process is a physico-chemical one, depending upon an unknown selective property of the matrix that holds the calcific deposits. Oskar Klotz* is the exponent of the idea that fats and soaps† are intimately concerned in this process, and Hanes‡ advances a similar but more specific idea in his report upon the "Relation of Lipoid Metabolism in the Calcification of the Chick," in which he traces step by step the process, and shows that the phosphoric acid utilized in calcification is derived from phosphorized fats. Generalizing from his studies, he strengthens his views by reviewing the chemical analyses of the process of calcification in the intima of the aorta (the most frequent site of calcification in man), and demonstrates that the phosphoric acid is here supplied by phosphorized fats *in situ*.

However this may be, I have found neutral fats, phosphorized fats, and soaps present in these deposits, and more in the early stages of the formation, diminishing as the calcification proceeds.

Collecting the soft deposits that precede dense calcification, and also the scrapings of the soft tissue from the roots of freshly extracted teeth of pyorrheal cases, drying over sulfuric acid, and extracting with repeated applications of ether, a very appreciable amount of stainable fat may be found upon evaporation of the ether. Extracting again the tissue that has been treated with ether, with hot acid alcohol, the presence of a stainable fat is further to be found, or a fatty acid freed from a soap combination. After the ether has evaporated in the first instance, if an attempt be made to dissolve the fatty residue in acetone, a portion will float about undissolved, or lecithin, the phosphorized fat. It would not seem farfetched to conclude that with the phosphate content of these deposits, and with phosphorized fat present, and from the studies given above, a part at least of the phosphoric acid radicles might be derived from this source.

One thing more bearing upon this is that I find a very considerable amount of lecithin in the saliva, especially in the saliva of cases where rapid deposition is going on on the lower front teeth, where I have collected the saliva from the submaxillary gland by means of an apparatus that I have contrived and that I am accustomed to use in work of this nature; and using the same stimulus to incite the flow in cases for comparative study, I am able to get an uncontaminated saliva, and to exclude the possibility that the source of the lecithin might be other than through the gland. It seems very probable that this substance has a connection with this calcific formation.

The topic of *tissue degeneration* and its connection with pyorrhea, besides being a necessary requisite for the bacteria that are most intimately concerned in the process, is also a necessary part in this kind of pathological calcification, in the physical sense, as a selective matrix, or, in a chemical sense, as a source of phosphoric acid radicles from its fats. The pathology of the process may be beautifully demonstrated by micro-staining methods, particularly from the tissue upon the roots of freshly extracted teeth selected for the purpose.

By the use of pyrogallic acid the calcification may be seen to be proceeding in definite and detached areas. The phosphates may be seen by staining with silver nitrate. Bubbles of escaping carbonic acid gas may be seen to escape upon treating with strong acid. Fatty

acids and neutral fats are shown by Sudan III and Scharlach R.*

THE QUESTION OF TREATMENT.

It is at this point that a division of opinion is held upon this disease; some believing that these tissues have become degenerate through local bacterial processes, and that by local treatment the disease can be obliterated; others believing that systemic states are the controlling factor.

It is true that a great deal can be accomplished by the constant removal of débris from the mouth, of whatever nature; but the constituents that go to make up the individuality of the blood and of the oral secretions are derived from that division of nutritional processes which is termed metabolic. Whether the secretions of the mouth shall enter the mouth with their proper proportion of inorganic salts, or with the mucin, the globulin, the albumin, or the fats unimpaired and free from morbid metabolites, depends upon systemic phases. And the same thing is true of the blood, Actual analysis indicates nothing else. From the laboratories of research workers an immense amount of data has been, and is, accumulating upon definite and specific actions in the physiological processes of metabolism. Yet while for the present we must speak of the metabolic states that accompany pyorrhea alveolaris as anomalous, still there are certain general principles that are applicable in the causing or the repressing of this pathological condition. Without any attempt to mention them in the order of their importance, we may recall the fact that when the human system is constantly, and for a long period, supplied with more nutrient material than its physiological requirements demand, a portion of the excess is stored as fat, and the other portions appear as partly oxidized metabolites, which the economy makes every effort to neutralize and to eliminate as best it may. As a result of feeding experiments carried out a number of years ago, I called attention to the effect of overfeeding upon the oral secretions, and spoke of having in mind the question of nutritional balance in this connection. And I am still of the opinion that this is one of the general considerations to be taken into account in an effort to suppress this complication.

Another important thing is to give attention to intestinal difficulties—not only on account of intestinal aid in getting rid of nutritional excess, and on account of its effect on the calcium output, but also on account of the many products of intestinal fermentation which pass through the protective defenses of the intestinal mucosa and the toxicclytic action of the liver and permeate the whole system. I have found indican in the saliva during intestinal attacks, and Combe* mentions the effect of intestinal fermentation upon a child who secreted several liters of saliva daily during these crises. So that it is seen how excretory substances appear in the mouth and how the glands are affected in their action by systemic complications. Complete balance studies of inorganic metabolites, and of the organic, show a great deviation from the normal in disease, and confirm the fact that a smoothly working human system is essential to perfect metabolism.

Without any consideration of the effect of different organs upon special bodily constituents, as, for example, the effect of the thyroids or parathyroids upon calcium control, we will say that active metabolism controls directly the CO_2, and we have shown its effect in maintaining calcium salts in solution. The colloids of the secretions we know but little about; drinking large quantities of water reduces their viscidity, however. Calcium in the food affects calcium in the bodily fluids, generally speaking. Fats are indicative of excess

* Baldauf, Leon K., "An Investigation of the Nature of Proteid Soap Compounds and the staining of Pure Fats and Lipoids by Scharlach R and Sudan III," *Journ. Am. Med. Association*, vol. xlix.

* Combe, "Auto-intoxications."

of nutriment, and phosphorized fats are influenced by the action of the liver. It is the writer's practice to accompany efforts at treatment of the systemic phases of pyorrhea by analysis of the saliva, in order that he may proceed more intelligently in his work—and he recommends the practice to others.

A CONTRIBUTION TO THE HISTORY OF EMETIN.

By HERMANN PRINZ, A.M., M.D., D.D.S.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, SCHOOL OF DENTISTRY, UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA, PA.

DRUGS, like many other things which share in the process of evolution of the human race, have their romances. Ipecacuanha, which has been recently introduced by Smith and Barrett in the form of its alkaloidal salt, emetin hydrochlorid, as a curative agent in the treatment of pyorrhea alveolaris, and which from all appearances seems destined to be regarded as a specific for this disease, has had within the last four centuries a most interesting career. Since it has achieved the above-mentioned enviable reputation in our profession, it may not be amiss at this moment to record a few biographic data concerning its oscillations in the art of therapeutics.

Ipecacuanha, also written "hypecacuana" by the practitioners of bygone days—or known as *poaya* by the Brazilians—and commonly referred to as ipecac, is the dried root of what is commercially known as Rio, Brazilian, and Para, or as Carthagena ipecac. The name ipecacuanha seems to be of Indian origin, and may be interpreted as "vomiting-producing weed." It is a native of South America and was introduced in Europe at about 1617. The medical armamentarium of Europe received many notable additions through the various geographic discoveries of the sixteenth century. Especially the then newly discovered America added many most valuable drugs to the materia medica—among which cinchona bark, ipecac, coca leaves, cascara sagrada, golden seal, krameria root, balsam of Peru, and many others, some of which now have become obsolete—may be recorded as the most important representatives.

From an historic point of view, ipecac is first mentioned in literature by a Portuguese friar,* who it seems had resided in Brazil from about 1570 to 1600. He mentions three remedies for the "bloody flux," one of which is called igpecaya or pigaya. The drug here referred to is undoubtedly ipecac. Piso and Marcgraf, in their scientific exploration of Brazil, record the plant ipecacuanha, which they depicted, and they also described its medicinal properties. As stated above, it was introduced in Europe in 1617. Although well known from the accounts given by Piso and Marcgraf, and in common use in Brazil as a remedy in dysentery, ipecac was not employed in Europe prior to the year 1672. At that time a physician named LeGras brought from South America a quantity of the root to Paris, but administering it in too large doses he damaged rather than aided the reputation of this drug.

A few years later a merchant of Paris

* Most of the biographic matter of this sketch is culled from Flueckiger and Hanbury's "Pharmacographia," and various works in the history of medicine and pharmacy.

named Grenier or Garnier became possessor of 150 pounds of ipecac, the valuable properties of which in dysentery he vaunted to his medical attendant Afforty and to Jean Claude Adrien Helvetius, a pupil of the latter. Grenier presented a quantity of this new drug to Afforty, who, however, attached but little importance to it. Helvetius, on the other hand, was induced to prescribe it in cases of dysentery, which he did with the utmost success. He even caused placards to be affixed to the corners of the streets (one of which may still be seen in Paris) announcing his successful treatment with this new drug. Through Grenier he obtained ample supplies from Spain and sold it as a secret medicine. The fame of the cures effected with this drug by Helvetius reached the French court and caused some trials to be made at the Hôtel Dieu. These trials having been fully successful, Louis XIV accorded to Helvetius the sole right of vending his remedy. Subsequently, several well-known personages, including the Dauphin of France, experienced the beneficial action of this drug upon their own bodies. The King became again interested in this drug, and consulted with his physician, D'Aquin, and his father confessor, and through them negotiated the purchase from Helvetius of his secret for a thousand louis d'or, and made it public. The right of Helvetius to this payment was disputed in law by Grenier, but maintained by a decision of the Châtelet of Paris.

In 1696 ipecac was introduced into Germany by the renowned philosopher Leibnitz, who by its use had been cured of a severe case of dysentery. It became known in German literature as "Ruhrwurzel" (dysentery root), and only much later its name changed to "Brechwurzel" (vomiting-producing root). The first title seems to have been in general favor with medical writers of that period, as in the older works on materia medica ipecac is frequently referred to as *radix antidysentaria,* indicating its therapeutic application. Prior to the beginning of the nineteenth century ipecac was not employed to any extent as an emetic; its greatest virtues were extolled in the treatment of the various forms of dysentery and "bloody flux," as it was known, and in similar disturbances of the intestinal canal. It it stated that during an endemic outbreak of dysentery in Nimeguen (Holland) in 1727 many thousands of soldiers became afflicted with this serious malady. The army surgeons administered ipecac empirically as a specific, and Geoffroy's report tells us that "in one day whole companies of soldiers afflicted with this most distressing ailment were cured by ipecacuanha like magic."

Ipecac, in conjunction with opium, forms the principal component of the world-famous Dover's powder, and both drugs share equal rights in the therapeutic fame of this galenic preparation. The inventor of this widely used remedy, Thomas Dover, was born in Barton-on-the-Heath, England, in 1660. He studied under the renowned Thomas Sydenham and obtained his medical degree at Cambridge in 1687. In 1708 he fitted out an expedition to the South Seas, accompanying the ship's crew as their surgeon. It is stated that in 1709 he discovered a sailor by the name of Alexander Selkirk, marooned for four years on Juan Fernandez Island. Selkirk returned with Dover to England, and it is supposed that he is the original of Daniel Defoe's Robinson Crusoe. Dover finally settled in England and assumed the practice of medicine in Bristol in 1711. In 1762 was published his famous work, "Ancient Physician's Legacy to His Country," which among many other interesting material contains the formula of his diaphoretic powder. The chapter on gout contains the recipe in the following words: "Take opium, 1 ounce; saltpeter and tartar vitriolated, each 4 ounces; liquorice, 1 ounce; ipecacuanha, 1 ounce. Put the saltpeter and tartar into a red-hot mortar, stirring till they have done flaming. Then powder very fine. After that, slice in your opium; grind to a powder, and mix."

The botanical source of ipecac was the subject of much dispute until finally settled by Gomez, a physician of the Portuguese navy, who brought an authentic specimen from Brazil to Lisbon in the year 1800.

The chief alkaloids of ipecac are emetin, cephaëlin and psychotoin, but it is only of emetin that the pharmacologic action is definitely known. Emetin was discovered in 1835 by that great French pharmaceutical chemist, Joseph Pelletier, in conjunction with Magendie. To Pelletier chemistry and medicine owe the isolation of not a few of the most important alkaloids, *i.e.* strychnin, brucin, quinin, pelletierin, thebain, narcein, etc. Alkaloidal chemistry saw its birth in 1805, with the discovery of the alkaloid morphin by the German apothecary, Sertuerner of Hanover. Emetin belongs to a class of substances which possess specific etiotropic action against diseases caused by protozoa, *e.g.* quinin is employed against the causative agents of malaria, emetin against the diseases caused by amœbas, and certain arsenic and antimony compounds against syphilis and infections with trypanosomes.

In 1875 Loesch found amœbas in the stools of dysenteric patients, but did not regard them as a cause of the disease. Finally, in 1896, Kartulis apparently settled the question by stating that dysentery and tropical liver abscess associated with dysentery were caused by the presence of the amœba coli.

While ipecac has been lauded again and again in the treatment of this disease, especially in more modern times by Dock, Manson, and others, it was left to Vedder to show that emetin would kill the endamœba *in vitro*. The chain of evidence was finally closed by Rogers, in 1912, when he demonstrated the specific nature of emetin in patients suffering from endamœbic dysentery.*

When we realize that ever since Riggs of Hartford, in 1867, called especial attention to the treatment of pyorrhea alveolaris, which since has been christened Riggs' disease, the greater majority of those drugs which generically are classified as antiseptics, caustics, and astringents—and incidentally not a few other drugs which in reality have no bearing whatsoever on the subject—have been recommended at one time or another by that vague and humorous phrase, "It is of value in the treatment of pyorrhea," the introduction of emetin as a remedial agent for such purposes must be heralded as an epoch-making step in pathology and therapeutics. The discovery of endamœbas in pyorrheal pus, and the subsequent treatment of this disease with emetin, as recorded by Smith and Barrett, and independently verified by Bass and Johns, and by many other observers, is an attainment of patient scientific investigation which is deserving of the unrestricted praise of the dental and medical professions the world over.

---

* In connection with the history of ipecac it is interesting to observe that the record of cinchona bark and its alkaloid, quinin, is an almost complete sequel of the romance of the drug under consideration.

Proceedings of Societies.

Dental Society of the State of New York.

Forty-sixth Annual Meeting.

(Continued from page 215.)

[The postponed report (see Dental Cosmos for February, page 206) of part of the business of the afternoon session of Friday, May 15th—viz, the Report of the Committee on Scientific Research, and its discussion jointly with Dr. Gies' paper—here follows, while Dr. Gies' paper is printed in full at page 276.]

Report of Committee on Scientific Research.

By Dr. W. B. Dunning, Chairman.

Mr. President,—I think it is quite superfluous for me to introduce the gentleman who is to make the address of this afternoon, as he has become our valued friend during the past five years, as well as our honored member. We also are exceedingly fortunate in having with us at this time four eminent investigators capable of discussing this intricate and new subject to be presented by Professor Gies—namely, Dr. Rogers of New York, Dr. McCrudden of Boston, Dr. Price of Cleveland, and Dr. Brown of Milwaukee; and I am sure that the presence of these gentlemen will add materially to the interest of the important subject to be discussed.

As you remember, last year Professor Gies delved into the possible relationship of potassium sulfocyanate to susceptibility and immunity to dental caries, and he stated at that time that, in so far as the laboratory work was concerned, he felt that he had brought the subject to a close. He did, however, make the statement that clinical work would now be in order to establish some facts in regard to the possible effects of the administration of potassium sulfocyanate.

The last time the committee consulted with him in regard to this aspect of the subject, Dr. Gies submitted an outline of what he would consider the correct procedure of such further work, to be carried out either by this society or other investigators. Your committee considers it important to place this upon record, and I shall therefore read his outline at this time:

GENERAL OUTLINE OF PROCEDURE IN A PROPOSED STUDY OF SULFOCYANATE AS A POSSIBLE PROPHYLACTIC FOR DENTAL CARIES. By William J. Gies, Ph.D., Columbia University.

[*I. Explanatory letter, Feb. 4, 1914.*]

Chairman, Research Committee, Dental Society of the State of New York.

Dear Sir,—As I stated to you and your associates, when we conferred here in December, I feel that the proposed study would not be worth while, if it were not based on a plan that would withstand the most searching scientific criticism.

Fully a dozen suitable persons should be selected as subjects, and at least six dentists and as many physicians should be involved in the formal examinations. Twice each of these numbers would be better.

A period of at least a year should be devoted, in the case of each subject, to "control"

examinations, conducted quarterly. The control examinations would establish individual peculiarities beyond any possibility of subsequent confusion of cause with coincidence.

A preliminary conference, between subjects and dentists, should be held about a month before the initial examination of record, for the establishment of necessary standards in both supplies and procedure. Your committee would have to agree upon the selection of standard supplies for the use of both the subjects and the dentists.

It is essential, I think, that saliva for the tests be collected quarterly by the subject in his or her own home, for the removal of psychical influences, and also at a time bearing a definite relation to the last preceding meal for the day, in order to prevent the variations in salivary character that might be due to irregularities in nutrition. More frequent collections of saliva would be desirable.

The proposed salivary examinations are the only ones that seem to bear on the matter in hand. We should be glad to conduct as many such analyses as might be desired of us here in this laboratory.

The estimation, by the dentist at each examination, of probabilities of change in the future condition of the teeth might do much to explain subsequent alterations, if any were noted. The nature of the examinations the dentists should make can be decided by you without any help from me, but my suggestions in this connection may be of some use to you in formulating your own ideas.

The proposed medical examinations should be conducted by the physician, in each case, absolutely independently of those by the dentist, and *vice versa*. The nature of the patient's occupation, and his environment in his occupation, residence, and travels, might explain much in his nutritional condition (and the state of his teeth) that would otherwise be obscure.

The remaining items in the proposed *medical* examination (see Outline herewith; G, 3 to 6) relate to the condition of the teeth, directly or indirectly.

A full report of each dental and medical examination should be forwarded (immediately after the completion of each examination) to the chairman of the Research Committee, so that the data might be recorded in an evolutionary plan for the prompt discovery of any points of significance suggestive of additional features for incorporation into the research. The knowledge that each report would be a closed one and not subject to future revision after further examinations, would make each examiner more judicial in his observations and comment, if that were possible in any case.

The research should be conducted by dentists and physicians in widely separated districts. It would be best to start the work on all subjects on a given date, each series of examinations to be made within a given week on a definite schedule, prepared by the Research Committee and in the possession of all examiners.

It might be very difficult to start this research effectively before your May meeting. At that time co-ordination in plans for, and instructions to, examiners could be effected in oral conferences.

After a year for the establishment of "control," *i.e.* normal, data there should be a year during which each patient would be subjected to sulfocyanate treatment, this year to be followed in turn by a third year under "control" (normal) conditions. My proposals in the outline relate in detail to the work of the first of the proposed three years. Details of sulfocyanate treatment would be the only additions to the plan for the remaining yearly periods, unless the results of the first year's work would require other modifications.

Although most of the suggestions in the accompanying outline need no special explanation, before your committee decides whether you wish to proceed along the lines indicated, I should be glad later, if you desire it, to place, under each item in a copy of the outline, a brief explanatory statement for the benefit of all concerned.

I should be glad to confer with you further on any matter related to this subject.

With kindest regards and best wishes, I am,

Yours cordially,

Wm. J. Gies.

[*II. Outline.*]

Before Treatment with Sulfocyanate.

I. examinations by the dentist.

A. *Conference between dentist and subject about a month prior to the beginning of the formal examinations.*

1. Approved brush and cleansing materials presented to the subject (standard selections).
2. Method commonly used by the subject to brush his (her) teeth (*demonstrated by the subject to the dentist*).
3. Capacity of the subject properly to

brush his (her) teeth *after* special instruction on this point by the dentist (*demonstrated by the subject to the dentist*).

4. Explanation by the dentist, to the subject, of variability in the secretion of saliva and its reasons.
5. Demonstration, in detail *by the dentist*, of the standard method of collecting saliva for use in the chemical tests (materials to be supplied to the subject).
   - .1—Preliminary flushing of mouth with water, with subsequent "resting", period.
   - .2—Chewing of *standard* flavored gum as *uniform stimulant*.
   - .3—Collection of saliva through funnel into bottle in *standard time*.
   - .4—Necessity for preventing evaporation, or admixture with extraneous liquid, explained to the subject.
   - .5—Method of shipment or transportation of saliva to the chemist indicated.
6. Demonstration in detail, *by the subject*, of capacity to follow directions 5.1—5.5, inclusive.

B. *First formal examination.*

7. General condition of the teeth *before* their thorough cleansing by the dentist.
8. General condition of the teeth *after* their thorough cleansing by the dentist (7).
9. Number and position of sound teeth and of fillings.
10. Condition in detail of teeth and fillings individually.
11. Probability of decay, within *estimated* periods, at suspected points in the *teeth*.
12. Probability of deterioration, within *estimated* periods, at suspected points at the edges of *fillings*.
13. Prevailing dental conditions that might tend to favor decay at particular points.
14. *Special* oral conditions and influences that may be noted, whether they appear to relate to decay or not.
15. Condition of other parts of the mouth:
    - .1—Gums.
    - .2—Tongue.
    - .3—Oral surfaces in general.
    - .4—Throat and nose.
16. Saliva (chemical and mechanical qualities) collected by subject at home at a *given hour* (by standard method—5), following *standard meals* for the *day of examination* and the day before; chemical analysis by standard methods.
    - .1—Volume.
    - .2—Viscosity.
    - .3—Reaction (quant've), both as to acidity & alkalinity.
    - .4—Total solids.
    - .5—Sulfocyanate content.
    - .6—Chlorin content.
    - .7—Fermentation index.

C. *Quarterly re-examinations.*

17. Items 7 to 16 (above) repeated.

II. EXAMINATIONS BY THE PHYSICIAN FOLLOWING, WITHIN A DAY OR TWO, THE EXAMINATIONS BY THE DENTIST.

To be noted at each quarterly re-examination: C to G (3 to 6).

A. Age.
B. Sex.
C. Weight and height.
D. Occupation.
   1. Nature.
   2. Environment.
E. Residence (environment).
F. Extent and duration of travel, if any (within three months).
G. Health at time of, and between, quarterly examinations.
   3. Diseases: any and all kinds observed, acute and chronic.
      - .1—Dates of attacks.
      - .2—Duration.
      - .3—Degree (severity).
      - .4—Medication (nature and duration).
      - .5—Convalescence (duration).
   4. Nutritive condition.
      - .1—Well or poorly nourished.
      - .2—Appetite.
      - .3—Constitution.
        - .01—Muscular equipment.
        - .02—Heart and circulation.
        - .03—Obese.
        - .04—Anemic.
        - .05—Nervous state.
        - .06—Skeleton.

.4—Dyspepsia.
.5—Constipation.
.6—Diarrhea.
.7—Condition of nose, throat, tongue and oral membranes.

5. Features of daily food selection.
.1—Kinds of food usually constituting the meals.
.2—Character of desserts.
.3—Special dietary fondnesses (gratified).
.4—Kind and quantity of food eaten before retiring.

6. Habits affecting appetite and nourishment.

DURING TREATMENT WITH SULFOCYANATE.

I. EXAMINATION BY THE DENTIST.

Items 1, B, 7 to 16 inclusive (above) followed at each quarterly examination.

II. EXAMINATION BY THE PHYSICIAN.

Items II, C–G, 3 to 6 inclusive (above) noted at each quarterly examination.

AFTER THE CONCLUSION OF THE TREATMENT WITH SULFOCYANATE.

I. EXAMINATION BY THE DENTIST.

Items 1, B, 7 to 16 inclusive (above) followed at each quarterly examination.

II. EXAMINATION BY THE PHYSICIAN.

Items II, C–G, 3 to 6 inclusive (above) noted at each quarterly examination.

The Chairman then introduced Prof. WM. J. GIES of Columbia University, who addressed the meeting, his subject being "Studies of Internal Secretions in Their Relation to the Development and Condition of the Teeth."

[This paper is printed in full at page 276 of the present issue of the COSMOS.]

Discussion.

Dr. JOHN ROGERS, New York. It is becoming quite evident that the dentist's responsibility to his patients is steadily increasing. The onset of many chronic disorders is quite frequently first manifested by disease of the teeth, and the dentist must now have some conception of the early symptoms of what may later prove some very troublesome or incurable disease.

Dr. Gies has summarized much of the physiology of the ductless glands, hence I shall confine myself chiefly to the thyroid, which, from its anatomical position and its susceptibility to enlargement as well as its seemingly important relationship to the teeth, should be familiar to every dentist.

Any enlargement of this gland which renders it perceptible to sight or touch represents an abnormality. The best evidence which we have suggests if it does not prove that this increase in size is at bottom not a disease but an attempt of nature to compensate for greater demands on the part of the body for the thyroid secretion than the gland of natural size can supply. It seems probable that some individuals have thyroids which are more capable of functionating than those of others, and when larger amounts of thyroid activity are required than the organ of normal outline can supply, nature has provided that the gland can undergo a compensatory hypertrophy. It is very common to note that, just before or during the period in which these changes become apparent in the neck, the patient has been subjected to more than the usual amount of stress, or, more exactly expressed, to more than the usual amount of fatigue.

The early symptoms of these thyroid disturbances are all those of ordinary fatigue, and throughout all stages of the process there are sensations of nervous and physical weakness, and at the beginning there are generally evidences of more or less deficient functionation in nearly all the organs of the body. At this period, as well as later, it is very common to observe caries of the teeth, and the cause should not be sought locally, but in the constitutional disturbance. An enlarged thyroid is extremely easy to detect, and in its presence suspicion should immediately be aroused.

From a simple compensatory hypertrophy with mild disturbances of nu-

trition, thyroid disorders may advance in any one of three directions; either into the common goiter, which ordinarily means a permanent degenerative change in the organ, with or without other symptoms; or into myxedema; or into the stage of hyperthyroidism and later exophthalmic goiter. If the first compensatory hypertrophy is recognized, and its significance understood, much trouble can generally be prevented, and the dentist has peculiar opportunities in this service.

The pathological physiology involved in these thyroid abnormalities is for the most part unknown, but some recent experiments help to explain part of the symptoms. The thyroid, through the secretion by which alone its function is performed, seems to be intimately concerned with the chemical processes underlying the production and expenditure of energy, hence its apparent relationship with the phenomena of fatigue. Dr. Gies has referred to the experiments of Gudernatsch, who, by feeding thyroid tissue to tadpoles, has caused the animals to metamorphose into complete frogs within a few days; the normal metamorphosis requiring from six to eight weeks. If the tadpoles, on the other hand, are fed only upon thymus gland, they remain always tadpoles. They grow to giant size, but show no attempt to metamorphosis. But if, at any time during this period, the thymus-fed tadpoles are put upon a thyroid diet, their metamorphosis occurs almost at once. They can be changed from tadpoles of any desired size into fully formed frogs. Reversing the way in which they are fed, however, does not make the frog reverse its development; —once a frog, always a frog.

These experiments prove the immense importance of the thyroid in growth and development, particularly in the changes which take place in the metamorphoses of childhood into youth and adolesence, and they help to explain the hypertrophy of the thyroid which is so commonly observed in young people. It appears to be an enlargement of a presumably weak organ to compensate for demands for secretion to promote the nutritional processes incident to growth. During this time caries of the teeth is both common and troublesome, and if associated with goiter or thyroid enlargement the caries may be remediable by appropriate constitutional treatment. The therapeutics which seem indicated in the early stages, by the way, are of a protective and supporting nature, rather than destructive, or surgical removal of the gland.

If the thyroid is enlarged and there are no constitutional symptoms other than fatigue and dental caries, it is perfectly logical to help out the supposedly overworked gland by advising rest and freedom from nervous strain, and at the same time to prescribe thyroid feeding. As ordinarily practiced, this is by no means free from danger. The explanation of these risks involves a discussion of the metabolism of iodin by the thyroid, and is long and involved. It is enough to say that the presumable fatigue of the thyroid, which accompanies its forced activity in supporting an excessive production and expenditure of energy, means a fatigue of its epithelium, which interferes with the production of the thyroid secretion. Iodin seems to be an essential constituent of this secretion, and if the epithelium from which it comes cannot metamorphose iodin, any blood excess of this element produced by feeding it in the form of tablets of thyroid substance (which always contains iodin), or in the form of potassium iodid, must damage the thyroid epithelium. It seems too "tired" to perform its biochemical duties. Clinically, it very often does harm instead of the good one would theoretically expect. In our experiments at the Cornell Medical College we have attempted to overcome these difficulties by employing what seems to be the active principle of the thyroid. We have used the proteins which can be recovered from an aqueous extract of the thyroid, and standarized them according to their iodin content,

and we have also used a liquid which seems to be still nearer to the active principle. Neither of these substances, however, is perfect, but both are much better and safer than the desiccated gland substance.

The investigations in which I have been interested, while as yet inconclusive, strongly suggest that the physiology of the thyroid and other ductless glands involves the relationship of the nerve terminals to each cell and its nearest blood supply. It seems possible that each ductless gland, through its secretion, controls the metabolism in each cell of some inorganic element, and that the secretions overlap, so to speak, in this influence. The thyroid, for example, may control the metabolism of calcium and potassium, while the thymus may control that of calcium and sodium, or of potassium and magnesium, and when either gland fails in its duty the tissues in which these elements are most important show a corresponding failure.

All the evidence we possess seems to indicate that the effects of the thyroid, or more exactly, of its secretion, are exerted upon the terminal filaments of some portions of the sympathetic nervous system; that it has a profound effect upon the nutrition of practically every organ in the body, and—which is not least in importance—upon the nutrition of the teeth.

Dr. Francis H. McCrudden, Boston, Mass. When I began to study bone diseases nearly fifteen years ago, I was greatly hampered by the prevailing view that bone is dead tissue not undergoing metabolism, and made little progress until I recognized that bone is not dead tissue, but alive, and, like other tissue, undergoing a continuous process of resorption of old and apposition of new. Since this conception proved of fundamental importance in our bone studies, and since teeth are very similar in composition and structure to bone, I should like briefly to present the conception:

In the disease known as osteomalacia the bones become soft and fragile as a result of a decrease in calcium salts—a decrease generally held to be the result of the solvent action of acid. Chemical analysis convinced me that this process cannot be a simple decalcification, for there is not only a relative but also an absolute increase in the amount of osteoid tissue and lime salts, and so I was obliged to conclude that new osteoid tissue and magnesium has been laid down. The result of metabolism experiments and of histological examination, too, are in harmony with this view, for experiments in which intake and outgo were determined showed a loss of calcium and a retention of magnesium and of the elements of osteoid tissue, and histological examination showed an abundance of osteoblasts and other evidence of young new tissue in the lime-free bone.

These findings made me examine more closely the whole evidence relating to the nature of bone metabolism, with the result that I was forced to conclude that bone does undergo metabolism. The fact that osteomalacia can be produced artificially under certain conditions by the use of a diet poor in calcium is evidence that the skeleton needs a continuous supply of this element. Further evidence of bone metabolism is seen in the fact that the lamellæ, which are so disposed as best to withstand strains, shift their position as, in the course of life, the weight to be borne and the direction of the strain vary. Evidence of anabolism is seen in the formation and calcification of the callus after fractures, and evidence of catabolism in the loss of calcium salts by the bone in starvation and in the thinning of bone during disuse.

In the light of this conception, it becomes easier to understand the nature of the process in osteomalacia. Old bone is continuously resorbed and new bone laid down just as in health, but the new bone is poor in calcium. The reason of the poverty in lime salts was found to be due to a diversion of the calcium to other uses. In the most common form of osteomalacia, namely, puerperal osteomalacia, the salts are diverted to the

growing fetus and the milk; in the rarer cases, in nulliparæ and in men, some cause of a flux of calcium such as multiple osteomata, heteroplastic bone formation, severe arterio-sclerosis, and bladder stones of calcium oxalate can nearly always be demonstrated, thus bearing out the conception of the etiology.

A flux of calcium once started does not end as soon as the need ceases for over-production. The factor responsible for the continued production of immune bodies after an infection leads to a continuation of the flux for a variable period afterward, and it is this tendency to over-production which makes puerperal osteomalacia the most common form, for the disease occurs in women after several rapidly succeeding pregnancies and long periods of lactation, the flux of calcium continuing from one period of gestation to the next, and finally becoming continuous.

Rickets and dwarfism are forms of disturbed calcium metabolism. Rickets is a disturbance similar to osteomalacia. Dwarfism of one type is due to an inadequate content of the blood in calcium following great losses through the feces; dwarfism of other types is the result of an inabilty to properly utilize calcium for bone growth.

The normal metabolism of bone is analogous to that of muscle—a continuous process of resorption of old and apposition of new. The skeleton acts as a store of calcium, and loses this element when it is needed elsewhere, so that the store in the bones varies with the needs of the rest of the body, just as the subcutaneous store of fat and the glycogen store of the liver. Mild forms of osteomalacia are often seen in skiagraphs of bones supposed to be normal, and examination of the bone in women dying during pregnancy reveals similar changes in nearly all. But bone has a very high factor of safety, and osteomalacia gives rise to symptoms only after a long-continued drain of calcium, especially in persons in whom the degree of over-production is great.

It is to be noted that osteomalacia and allied conditions are not primarily bone diseases, but disturbances of calcium metabolism in which the bone becomes involved—a distinction of importance owing to its possible bearing on dentistry. Any bone or bones, or parts of bones, may be involved. The names rickets, osteomalacia, osteitis deformans, osteoporosis, etc., refer chiefly to localization and distribution of the lesions. In puerperal osteomalacia the pelvic bones are first attacked, the ribs next; in non-puerperal osteomalacia it is more commonly the extremities and ribs; in osteitis deformans, parts of the skull and femur; in severe arterio-sclerosis, parts of the skeleton nearest the most severely sclerosed arteries. In rickets the lesions are found at the junction of the epiphyses and diaphyses and underneath the periosteum; in osteomalacia, in the interior of the bone in proximity to the Haversian canals. As for the teeth, one observer has pointed out that the zone of uncalcified dentin is increased in width in severe cases of rickets, and another observer has noted the same in the spontaneous rickets of rats. As I have already remarked, the incidence of mild forms of osteomalacia is much greater than commonly believed, and this, it seems to me, has a distinct bearing on dentistry. The bones, on the one hand, with their high factor of safety and great protection in the interior of the body, may well be somewhat below par and nevertheless functionate; in the teeth, on the other hand, which are exposed to severe mechanical and chemical violence and have a low normal factor of safety, if judged by the incidence of diseased teeth, any condition like osteomalacia, which still further decreases that factor of safety, must be relatively important.

Calcium metabolism is under the control of certain glands of internal secretion. Removal of the parathyroid leads to mobilization of calcium and to rickets, and the gland has been found affected in osteomalacia. The hypophysis controls directly the metabolism of the epiphysis; hypoplasia of this gland leads to dwarfism; hyperplasia in youth to

giantism, later in life to acromegaly. The form of dwarfism known as cretinism is the result of hypoplasia of the thyroid. Status lymphaticus, a condition of generalized hyperplasia of the lymphadenoid tissue, is accompanied by infantile anatomical peculiarities. The relations of the thymus and pancreas to dwarfism, though less definite, are suggestive.

There is more direct evidence of the control of the calcium metabolism of the teeth by the parathyroids in the studies made in Weichselbaum's laboratory in Vienna. After removal of the parathyroids, the dentin of the gnawing teeth of rats was found poor in calcium. In extending these observations, Toyofuku found not only the dentin but also the enamel affected by the operation, and he observed further that the grinding teeth, which do not grow and wear off like gnawing teeth, are also somewhat affected, if the animals are not too old. If the experiments had been continued longer, perhaps the effect on the latter would have been greater. Still later, Erdmann showed very strikingly how removal of the parathyroids is followed by formation of layers of dentin poor in lime salts, to be succeeded by layers of normal dentin when the transplanted parathyroid again began to functionate.

If studies in bone metabolism throw light on the teeth, dentistry may reciprocate. As Stein pointed out last year in the Dental Cosmos, examination of the localization of the syphilitic hypoplasia of teeth, together with a knowledge of the time of calcification of the teeth in intra-uterine life, enables one to date the onset of the infection at the fourth month of intra-uterine life. Similar studies on congenital forms of dwarfism associated with deformed teeth, and almost certainly disturbances of internal secretions, might be able to give a lead for the study of these conditions.

Dr. W. A. Price, Cleveland, Ohio. The spirit of this hour is one of the most refreshing and encouraging symptoms of dental progress. I want to assure Dr. Gies that the limit of the support of the National Dental Association is the limit of the support of the profession of the State of New York. The National Dental Association, through its Foundation Research Commission, is after the truth. They have no compromise with the man who desires to get royalties to spend on himself, but they are willing to give assistance to him who would rather be shown that he is wrong than that he is right.

In experimenting on animals with a diet which was as nearly calcium-free as we could make it, even to the third decimal, we undertook also to make simultaneous observations of parallel conditions in the human being, studying them from the clinical standpoint. Infants cannot obtain lime salts from the same sources as most animals; for example, rabbits and guinea-pigs can obtain it from lettuce the first day after birth; calves from grass from six weeks to a few months after birth, adult rabbits even from calcium carbonate. Investigations indicate that the human infant can obtain calcium salts only from animal protein for several months after birth, and later from vegetable protein and soluble carbohydrates, and probably much later from insoluble carbohydrates. In our studies of human beings in whose diet we have lowered the calcium content for a time, we selected cases of hypoplasia, and in almost every case in which an accurate history could be secured, the diet had not been normal during the first one or two years of life. The observer was struck immediately by the characteristic markings of the first third of the lower incisors, and the first fourth of the upper incisors in regard to the shape of the teeth and the external structure of both the enamel and dentin. We also found that these markings correspond in different teeth very closely with the developmental periods of these structures. We also came to the conclusion that the markings corresponding with those of Hutchinson's teeth have probably been over-emphasized. In fact, I question whether that symptom is of much value as a diagnostic means in heredi-

tary syphilis, because in many, if not all cases, there is a hypoplasia similar to that observed in patients with a definite history without any syphilitic complication. These hypoplasias nearly always affect not only the enamel but also the dentin. To cite an example: A child, who had been normal for the first few years of life, exhibited an almost normal formation of the enamel of the incisors. Beginning at about three years of age and continuing to about the sixth or seventh year, the child had an increasing complication which finally proved to be a constriction of the cardiac opening into the stomach. There was a continual regurgitation of food, and the child was slowly starving to death during the period when the dentin of the root should have been formed. The treatment of the child was unsuccessful for a period of time, and the condition was finally diagnosed by injecting bismuth subnitrate into the esophagus and stomach. It was found that the food did not enter the stomach but lodged in the esophagus. The condition was rapidly growing worse until an operation was performed, and in a few months the boy was able to swallow and retain food.

The general deductions from these hyperplasias are these: We have found that they are constantly related to imperfect nutrition during the period of the first three years of life, and in almost every case a history of artificial feeding was secured. We found that infants fed on baby foods poor in calcium content or normal proteins and solid carbohydrates, and rich in insoluble carbohydrates, exhibited the characteristic condition of hypoplasia. In fact, this was so marked that we could almost pick out the food that the child was fed upon; this is in accord with the researches made by the Swiss government, which found that those soldiers who had been normally breast-fed could march longer and tolerate greater hardships. In the same manner we found, by compiling cases of all ages for a period of ten years, in people under thirty years of age, about 1 hypoplasia in 75; in people between thirty and sixty years, about 1 in 100, and in people over sixty years, about 1 in 500. We also found that, in several cases, the typical marking was present. In one case particularly, the mother acknowledged that she had deprived the child of breast-feeding so that she might not be bothered with nursing him.

Another point that I wish to speak of is the relationship of the ductless glands, and particularly the hypophysis, to the development of the dental tissues and the dental arch. The case which I shall present is a very unusual one. A boy fifteen and a half years of age presented all the typical symptoms of disordered functional activity of the pituitary body. He had been normal until four years of age, when he became affected with cerebro-spinal meningitis; as a result the development of his maxillary bones was almost the same as that of a child four or five years of age, and the development of the teeth has been abnormal since that time. The fact that the upper arch occluded inside of the lower arch may be a factor which increased the pressure on the pituitary. Regardless of whether it did or not, here is a remarkable feature of this case: When we widened the space between the maxillary bones, and brought the maxillary bones downward and forward to a distance of one-half or three-quarters of an inch, as shown by the skiagraph, immediately the boy's whole physical, mental, and moral condition changed. I wish now to refer for a moment to the separation of the maxillary bones. The left nostril was entirely occluded. A rhinologist had spent half an hour trying to pass moisture through it by the aid of adrenalin. Inside of thirty days, he could pass a lead pencil into the nostril, and the patient was able to hold the mouth closed and breathe through the nostril which originally had been entirely closed.

The boy showed all the characteristic symptoms of a disordered pituitary condition. He was infantile in development at fifteen and a half years of age, about like a child of six or seven years of age, and his reproductive organs were en-

tirely infantile. He kept asking for something to drink, and seemed to be sleepy all the time. The conditions in this case correspond exactly with the findings of Dr. Cushing, who removed the pituitary body in dogs and found that they remained infantile, especially with regard to the reproductive organs. In other words, a puppy from which the pituitary body was removed did not have the reproductive organs develop. The dog became slow in his actions, in the same manner as was observed in the case of this child. When we began treatment the child immediately began to develop mentally to such an extent that he wanted to play with boys near his own age, whereas previously he had played with toys in the same way as a child of five or six years of age. In twelve weeks that boy's reproductive organs went through almost the complete cycle which marks the development from childhood to adolescence. Instead of having for playmates children of five or six years of age, he wanted my lady assistant to go to a dance with him. He lives in another town, and while, before treatment, he had to be taken back and forth, he is now able to go to the train and travel that distance alone. A pathetic feature in this case is that the development of his reproductive organs has been such that the boy has become almost a "bear." His mother and sisters say that he must be sent to a school where there are no women.

The significance of all this is very great. Here is the case of a boy with arrested maxillary development, an interlocked condition of the maxillary bones, and there seems to be no doubt that this condition had much to do with pressure on the pituitary body, because there was an immediate improvement upon widening of the maxillary arch. Is not that also an answer to the question of why children seem to become brighter after orthodontia treatment? When we go deeper into this subject, the question arises as to the relationship of the deposition of the calcium forming the maxillary bones to the obstruction of the pituitary body. Was there, in the case described, any constriction around the infundibulum by the process of skull-tissue formation after the attack of cerebro-spinal meningitis? Whether there was a lack of proper secretion that reduced the organ in size, or whether there was an interference of the intricate functioning of the glands of internal secretion of the pituitary body acting as the center of control of the thyroid and parathyroid glands, we cannot say.

Thus the whole problem brings us back to the question of research. So far as the National Association is concerned, the aim of the commission for this work is to encourage just such work as Dr. Gies has been doing, and at the same time to gather all the data possible and make them available for others doing that work. In other words, in the last analysis the ambition of the commission is to bring about the greatest good to the greatest possible number.

Dr. G. V. I. Brown, Milwaukee, Wis. I have come a long way to hear this report, and will have to go home again in a few minutes, but I would have traveled many times as far to hear the report we have just listened to. It has given me pleasure beyond description, and it will be of inestimable benefit to the community, unless I am much mistaken—because I feel sure that this is but the beginning of the work, and that we will go on until definite results are reached.

Personally I have become tired of reasoning by analogy, of working on an empirical basis—and I think we all have. Unfortunately, once the idea of this ductless gland system gets hold of one, it is almost impossible to get rid of it; it is so insidious that it shakes one's very foundations for reasoning, and one is completely at sea; this, after fifteen years of very active work in one direction, is my own personal position. The real value of this report, as I understand it, lies in its all-embracing character. It reaches every point, every center, every interest with which we have to deal, and it wipes out once and for all every line of distinction between the various branches of the medical profession. There can be no longer any such

distinction once the purport of these secretions is understood, even in so far as we now comprehend them.

Whichever one of these particular glands is involved, we note, in a certain measure at least, certain physical indications which are similar to those due to the other glands, and the investigation of the relationship of these glands to each other is now our most difficult problem. There is no question that in this functional balance there is a correlation of these glands which is essential to the perfect working of the whole, and some writers have claimed that there are certain definite characteristics not only of each of the glands themselves, but of different part of these glands, as for example in the posterior and anterior lobes of the pituitary. We know from experiment that by the use of extracts and removal of portions of these glands, certain more or less definite results are obtained. We note some of these effects following castration. We note, in some cases, hyperthyroidism, or other diseases and affections of other ductless glands, and it is for that reason above all others that there is greater necessity for beginning on a solid foundation such as has been laid for us today with great patience.

I admire Dr. Gies' patience in making this clear to us almost as much as I admire his scientific knowledge. With great patience and profound understanding he has laid a foundation upon which we can build a structure which, if we do not allow ourselves to be carried away with over-enthusiasm in regard to any results we have obtained, will some day be the controlling structure in the science of medicine.

I want to speak for just a moment of the clinical demand for this knowledge. Only the other day, in one of our large cities, I was taken into a hospital and found a young girl lying with a twenty-five-pound weight on her feet, being treated for extension of the hip. There was a shortening of two inches, and an endeavor was being made to effect an extension by mechanical means; the physician said that, curiously, there was no lesion in the hip which the X ray would show, and that there had not been any destruction or any suppuration. I asked him if he had ever looked at the back, and he said, "No." I had the girl sit up, and she exhibited the shoulderblade characteristic for all these cases, also the peculiar development of the feet and ankles, and, of course, a narrow contracted arch, with narrow nares and mouth-breathing. There was a complete picture, quite similar to some of the cases shown by me last year, of unequal development of the halves of the body. In this case, first of all, a knowledge was needed of the underlying factors responsible for the ill-development. This child's parents were lavishing every effort to bring her back to nervous stability; her case was not so bad as that of cretinism described, but the clinical picture is somewhat similar. I have among my patients a child who is developing apparently normally, but whose speech center is not active; she does not try to talk. There is no doubt about such nervous instability in this case; the child is looked upon as being defective. Now, with the present light on these matters and the scientific stimulus in this field, there is hope that in the future we shall far exceed our present curative resources.

In one of the cases we showed last year, one of dementia precox, it seemed difficult to say whether that case could be treated, but today the man is well. He has been restored to his family, has had a child born, and is apparently well. The picture of these cases is the picture of other less serious cases. Then there is that other type of extreme nervousness and excitability, the wasting of muscular and other tissue, and no doubt bone as well. In our experiments on dogs, we produced the same general symptoms, and we had difficulty in keeping them alive longer than six months, because of their susceptibility to infection. In these dogs, showing evidences of disordered pituitary glands, we expected to find microscopic changes in the pituitaries which we would be able to recognize, but, when we went to examine them,

we found that we did not know what the normal pituitary was. We had no standard to go by. All this presents to us a large and unsettled problem which will have to be worked out by experimentation, and I hope that I may live to see the final result of what today's transactions are the beginning; if I do, I shall have lived to see the end of most ills to which mankind is heir.

Dr. L. M. Waugh, New York. I do not believe that, in my professional career, I have more enjoyed two hours than those just past. It seems that all the disappointment which one sometimes experiences when reflecting that he has gotten into an occupation which is dominated merely by the mechanical and not based upon an underlying knowledge of science is removed by just such experiences, which inspire one with the hope of something that is yet going to be sufficient to satisfy the life-work of the man who is ambitious from the broader standpoint.

I shall not attempt to discuss the paper, although I have been attracted by the important problems concerning tooth calcification and bone development in the structures of the jaws and face. I can only sit in admiration and calm satisfaction over the advancement that is promised to us. The fact that eminent scientists in the forefront of research have been willing to come before us dentists and give the best of their knowledge, it would seem, promises something for which I have yearned ever since I have been engaged in dental practice. The beneficent possibilities of our work seem as far-reaching as those of any other branch of the healing art. In taking up a single part of our work as a specialty, I have been guided by the feeling that concentration offers the possibility of scientific work by the application of just such bigger thoughts as we have heard today. In orthodontia, it seemed, there were greater possibilities for the application of these principles than in any other branch of dentistry, but today I am awakened to their important bearing upon all phases of dentistry.

Dr. Price told us about the wonderful results following the removal of pressure upon the pituitary body which had caused the arrest of growth in that tiny gland, with resulting malocclusion. That particular case furnishes another evidence of the fact that in too many instances we have been blindly treating the symptom and not the cause. Also, in acromegaly and many other perversions, the application of these enlightening researches promises great possibilities for the improvement of oral function. When Dr. Brown said that the application of these scientific principles to mouth conditions would tend to obliterate any line of demarcation that might separate certain branches of the healing art, I believe he stated a truth and augured a most desirable relationship which will result in better professional service.

This is most gratifying to me, as it must be to all who have embraced the privilege of aiding in this research movement. You and I cannot possibly do valuable scientific investigation and at the same time attend to a supporting practice. Therefore I have experienced great comfort in contributing my mite in money toward the employment of those who have, by special training, been prepared for research and who are giving their entire time and best energies to it. As each new discovery shall be established and given to us as a guide for better practice, I shall feel the utmost gratification in the fact that, having supported the work in a material way, I am morally entitled to the newer and better knowledge which this research may give to dentistry and to our patients.

Dr. E. S. Davenport, New York. I wish to say a word of recognition of the value to the profession of this research work—which is, I believe, but just beginning. There are few dentists who are educated sufficiently to take an active part in the accomplishment of work of this character. We are all interested and will be more and more so, I am sure, in the development of this work, but most of us are unable to con-

tribute very largely to its scientific progress. There are men, as we have seen this afternoon, who are able, trained investigators, giving their lives to original research, and to them we must entrust the continuation of this valuable work.

While we are individually anxious and willing to contribute to the extent of our ability to the funds which are so essential, it seems to me we should not depend upon ourselves alone for the necessary money, but should each try to interest one or more patients of wealth in this splendid cause. We all have patients more or less philanthropically inclined who would consider it a privilege to contribute to so important an object, and my desire is to call your attention to that phase of the situation. A number of years ago the late Benjamin Lord, one of New York City's best dentists, so interested his patients that the New York Institute of Stomatology was able to establish a research department under the supervision of Prof. Wm. J. Gies of Columbia University, and that department has been continued and financed by the so-called "Lord fund," largely formed by the contributions of Dr. Lord's patients.

Dr. Gies (closing the discussion). It has been a very great pleasure to listen to this enthusiastic discussion, in which the principle underlying our plan of research has been indorsed with unanimity, and in which so many facts of intimate and suggestive relationship have been presented. I came here with some of the emotions of a missionary to the Fiji Islands—with abounding confidence in the saving grace of our gospel, but with nervous fear of seeing my finish in the soup! Instead of an end of our ministry, there are cordial intimations to make the sermons louder, longer, and more learned. I am sure it is confidence in the *potentialities* of our profession of faith—confidence in the promise of a heavenly dental hereafter through continuance in such research—that accounts for the optimism of this earnest discussion and the cordiality of this audience toward each speaker.

We shall proceed with every hope that devoted application to the study of our many problems will afford results of lasting and material benefit. It will be a great stimulus to earnest endeavor to anticipate the enjoyment of future occasions of this happy and instructive character.

Dr. Dunning. I move that a vote of thanks expressed by a rising vote be extended to Dr. Gies, and to the gentlemen who have taken part in this very interesting discussion.

The motion was carried.

The next annual meeting of the society will be held in Albany, on the second Thursday in May 1915.

EASTERN ASSOCIATION OF GRADUATES OF THE ANGLE SCHOOL OF ORTHODONTIA.

Fall Meeting—New York, November 28, 1914.

THE fall meeting of the Eastern Association of the Graduates of the Angle School of Orthodontia was called to order in the Great Northern Hotel, New York, N. Y., by the president, Dr. A. W. Crosby, New London, Conn., at 9 o'clock Saturday evening, November 28, 1914.

Dr. Crosby introduced as the speaker of the evening Dr. V. E. SORAPURE, New York City, who read a paper entitled "A Note on the Treatment of Habit Spasms."

[This paper is printed in full at page 266 of the present issue of the COSMOS.]

Discussion.

Dr. F. L. STANTON, New York. The essayist's paper seems to me to be a very important one. I can state from experience that respiratory exercises seem to help children to overcome the habit of spasmodic mouth movements. I would like, however, to ask Dr. Sorapure if it is not possible in giving exercises to adhere too strongly to abdominal breathing—because it does seem to me to be quite important to lay stress on thoracic breathing. Is it good policy to teach only abdominal breathing? In the children whom we saw this afternoon there is no question as to their having round shoulders, narrow chests, etc. All these symptoms would be more or less constant in such patients; why, therefore, stop with abdominal breathing?

Dr. SORAPURE. The question is interesting, and has not been overlooked. Our object in these cases is relaxation. Thoracic breathing is, of course, necessary and invaluable in exercises, but here we want complete relaxation, and we can procure this best by abdominal breathing. You know that in sleep the breathing is hardly perceptible; there is no muscular effort whatever, and only the diaphragm moves. Altogether, we get an effect approaching sleep where every muscle is relaxed—that is the object of this exercise.

In regard to thoracic breathing, we have not used it as Dr. Stanton has outlined exactly, although I think we should combine the two, and I shall try some experiments along that line. What we do is to give exercises for thoracic breathing. The average individual is not apt to do that, and it is not, on the whole, the best form of breathing, because it does not reach all of the lungs; but, in order to deepen the chest, improve the condition of the scapula, etc., we teach active exercises, holding up the hands this way [demonstrating], extending the arms, etc., improving the condition of the thorax, and keeping down the tendency to a return of the tics.

Dr. H. C. FERRIS, New York. In cases of stuttering, where the subject is able to read plainly when alone for an hour or two at a time, but in the presence of a third party or under any little stimulation stutters tremendously, how does this treatment apply? Or how do we explain that condition?

Dr. SORAPURE. Those conditions are more or less explained in the fact that, when the patient is reading, he rarely produces his own ideas, pauses when he thinks, and speaks during expiration. We all speak during expiration. We must fill our lungs with air and, as the air is expelled, we produce speech. In pausing to think, one is apt to get incoordinate action if one attempts to speak

during inspiration. By prolonging the breathing I think we tend to overcome this tendency. I have had many cases of this character come into the clinic. I recall the case of a little girl who, when she came to the clinic, could not tell her own name and address or the name of any member of her family, but upon being shown the trick of holding the breath and using the expiratory stage for conversation, she could tell in half an hour the names of her whole family.

Dr. C. A. Hawley, Washington, D. C. It is very difficult to discuss this paper practically without some experience in the method described, but the essayist's deductions are extremely interesting and reasonable, and in accordance with many facts which have been well known. The essayist says that this treatment involves some elements of a psychic nature, and we remember that the East Indians, who are adepts in psychic states, cite as one of their fundamental conditions the control of breathing, and insist upon deep breathing before any of these psychic states can be induced. The control of habits seems to involve something of that nature that needs to be controlled. While, as the essayist says, his treatment has been likened to hypnotism, although it includes nothing of that element, yet it seems to approach that form of treatment which developed out of hypnotism and is called "suggestive" therapeutics. Years ago the men who attempted to control disease and habits by hypnotism found that hypnotism as generally known was not necessary, but that merely a condition of passiveness was required. Instead of making the patient's will absolutely non-existent, the object was to control his will. The procedure, as I understood it, consisted in placing the patient in somewhat the same condition as this treatment does, viz. laying him in a prone position, completely passive, with every muscle of the body passive, yet so that the mind be not vacant, but endeavoring to follow the suggestions of the operator. Under these conditions, I think it is a fact well established in medicine that great results, the actual control of the functions of the body, have been accomplished, and it seems especially reasonable that habits could be controlled in a similar manner. Hypnotic treatment has fallen into disuse, I presume largely because of the time it requires and because of all the difficult preparations that are needed. For instance, the room must be completely quiet all the time to induce that passive state. I understand that the biography of the leader of Christian science shows that she, at one time, was an earnest student of suggestive therapeutics, and perhaps acquired in that work something of the technique—and we all agree that some wonderful results have been obtained.

Another method has been used, and I think is being used today for controlling habits of children by talking to them in their sleep. It is claimed that if one goes to the bedside of a child who is asleep and talks to him very quietly, being careful not to waken him, certain habits, certain dispositions of the mind can absolutely be controlled by that means, without any conscious knowledge of the child. Dr. Thomson J. Hudson, in some of his work which has attracted considerable attention, has made special note of that fact. His explanation is that we are dealing with the subconscious mind of the child, and not with the conscious mind at all. All these facts, it appears to me, strengthen the statements which have been made this evening, and show the reasonableness of the method. This treatment, it seems, has the greatest success if it is administrated by an operator who controls all favorable conditions, viz, a quiet room, quiet surroundings, etc. It is a fact recognized in medicine that it is very difficult to dissociate the psychic element of a remedy from its real physical effect. Physicians frequently accomplish results through psychic methods. They give a medicine which they know will have no therapeutic effect, but depend upon that as a sort of carrier of the psychic effect which possibly aids the patient appreciably. I have certainly heard of no

other development of this method which gives better promise of the control of these habits.

Dr. R. W. Strang, Bridgeport. The thought comes to me, How many of these habits which we orthodontists have to deal with are "spasm habits"?—in other words, are habits such as to be amenable to the treatment which the essayist suggests as being successful for spasm habits? Will the essayist define a spasm habit for us?

Dr. Sorapure. Any habit which is persisted in becomes a spasm habit. A mouth habit which is acquired by imitation, or is the result of an irritating tooth, or a tubercular gland in the neck, or probably some thickening around some nerve passing through a foramen; any impression that lasts sufficiently long to increase the conductivity of the nerve, to increase the irritability and the readiness to response—any spasmodic contractions which become habitual we call spasm habits. It is one of those loose terms that include a dozen or more different phenomena.

Dr. Strang. We are, then, dealing with spasm habits. I am much impressed by Dr. Sorapure's statement that the child does not know that he has a habit. We have all had difficulty in inducing *parents* to admit that their child has certain habits, but I did not realize that the child himself was so unconscious of the habit. Therefore I have made one mistake in dealing with these habits by telling the child to stop his habit without first carefully showing him what the habit is, and just what muscular movements will counteract it. In such an analysis and synthesis as the essayist suggests I can see a ray of hope for obtaining control of a bad habit, and I am thankful to the doctor for his suggestion, for I believe that it is a reasonable basis upon which to build more successful treatment.

Dr. A. P. Rogers, Boston, Mass. I have enjoyed this evening's paper very much. This subject has for a long time been an interesting one to me. I have tried to observe children closely in an effort to determine the basis of certain habits. I would like the essayist to explain to us what he understands to be the mental basis for habits. My observation has been that frequently a feeling of embarrassment in children of certain types will produce unfavorable habits. I have in mind a little girl who, on the slightest occasion of embarrassment, will bite her lip. Other forms of habits are noticeable under similar conditions; for instance, a little boy who, under slight embarrassment, will hold his tongue between his teeth and against one of his cheeks. Studious children, contrary to our conception, are frequently observed to hold their mouths open to a greater extent than some who are not so studious. I know of one young boy of fourteen years, who, while at mental work, persists in keeping his mouth open. Therefore I would like to hear something in regard to the mental state in its relation to this form of muscular habit.

Dr. Sorapure. It is difficult to suggest any explanation, because there are so many reasons that may explain this habit. One may think that originally it is probably due to some temporary reflex irritation. Of course, one has to fall back on the old explanation that, if a nerve or a particular nerve root has been subjected to any form of irritation, its conductivity is increased, and the damage is done. We have all observed the habit of children, when trying to write, of following the movements of the pen with the tongue, and very often we find cases which may be traced to carious teeth. The sharp edge of a tooth will drive the tongue to the other side of the mouth, and we find a tendency to this movement when the child is embarrassed. In other words, if the influence of the traveling of the motor impulse from the arm center to the face center, and in particular of the carious tooth driving the tongue to the opposite side, is kept up for a month or so, the tongue will involuntarily pursue that particular course. Probably other explanations may come to mind later, but that is the only one that occurs to me at this moment.

Dr. F. T. Murlless, Jr., Hartford, Conn. Recently a young girl, fifteen years of age, came to me, who in most respects was a rather unusual child—very bright and capable, but who had the habit of sucking her finger. There seemed to be no particular predilection as to which finger, but she had indulged in this habit so frequently and persistently that really a very bad facial deformity resulted. The problem of directing the teeth into proper position was not a specially hard one, but the grave difficulty in this case lay in the habit. I found, in talking about this case to the family, that there had been occasions on which members of the family had remained in the room with the child for several nights while she slept, and had stayed awake, in the effort to keep the child's fingers out of her mouth. This made the child wakeful, and without doubt only served to fasten the habit. I would like to ask the essayist if there is any hope of overcoming this habit, and how?

Dr. Sorapure. I feel sure that there is hope in that direction. Occasionally a child who can be reasoned with and shown that the habit is harmful can overcome such a habit. The first measure consists in directing attention to the habit. Very often such a habit is unconsciously indulged in; moreover the child might derive a great deal of satisfaction from it. In this case, I think, the child should be submitted to a trustworthy psycho-analyst. This case seems to be one in which there is an undoubted sexual basis, and a careful psycho-analysis should reveal the cause and point the way to treatment. Some of these habits we may help in overcoming by appealing to the pride of the child.

Dr. Murlless. I was surprised to see that this child's pride seemed to have nothing to do with her habit.

Dr. H. E. Kelsey, Baltimore, Md. I was much gratified by what I saw this afternoon and what I heard this evening, and it brought to mind many individual cases which have perplexed me in the past, and one in particular, which has come to me recently with a very serious open bite in front. When I asked the child, in the presence of her mother, whether she had a habit of forcing the tongue between her teeth, the mother answered in the negative and the child in the affirmative in almost the same breath. This was a case where the child recognized the habit, and I found that when a few months ago she discontinued the habit of thumb-sucking, this habit of forcing the tongue between the teeth was immediately adopted as a substitute and was having a worse effect on the arches than the original habit, though the child had no idea thereof.

Now, it has occurred to me that common sense is a large factor in the method pursued by these two gentlemen, their idea being not to induce the child to undertake to overcome the most difficult thing first, namely, the well-established habit, but to teach it how to first gain control of the whole body through proper breathing and relaxation of all the muscles, including, of course, those associated with the habit spasm. The custom of nagging at children for the purpose of stopping a habit seems to me like beginning at the wrong end, and has probably been one fault of our treatment of such cases. This method we have seen tonight seems to begin the other way; it teaches the child how to get almost complete control of his various muscles and of all the muscles, and then gradually brings him to the state where he can combat this very troublesome condition. This feature has impressed me more than anything else I saw, and I feel that we can apply it favorably in a great many cases that have perplexed us in the past. If it is possible for us to learn to apply this treatment ourselves, I think it would be of great benefit, in the absence of anyone else who would do it for us; but I really think that it could be better done by a specialist.

Dr. Rogers. I would like to ask where we can find literature on this subject? Have any articles on it been published in the medical journals?

Dr. Sorapure. The literature on this

subject is not easily found. I have published one paper, I think last year, and a great many dissertations on this subject are scattered throughout the literature, appearing here and there, but I cannot say offhand where to put one's hands on anything at the present time. I had intended looking up some of the literature before presenting my paper, but did not have the time to do so.

Dr. GROSSMAN. Speaking of the question of the consciousness of the habit in these children, in two of the cases which I showed this afternoon, and particularly in the second case, there was distinct evidence of the child having bitten the lip continuously, and still you heard the child say that she had no such habit. This shows that this habit was subconscious, that the child did not know that she had it, and that attention must be called thereto, otherwise one cannot expect to correct it.

Dr. MURLLESS. I move that a rising vote of thanks be extended to Drs. Sorapure and Grossman for their attendance this evening, and for the clinic this afternoon. (Motion carried.)

Following the paper by Dr. Sorapure, Dr. F. T. MURLLESS, Jr., read a paper entitled "Cervical Adenitis as a Complication in Treatment."

Motion was then made and carried to adjourn.

PENNSYLVANIA STATE DENTAL SOCIETY.

Forty-sixth Annual Meeting, Philadelphia, June 30, July 1 and 2, 1914.

(Continued from page 205.)

THURSDAY—*Morning Session.*

The meeting was called to order Thursday morning, July 2d, at 9.30 o'clock, by the president, Dr. Seip.

The first order of business for the morning session was the report of the Necrology Committee, by Dr. WM. H. TRUEMAN, chairman, on the deaths of Dr. John W. Moffitt and Dr. Frederick W. Amend, Jr.

[Obituary notices of Dr. Moffitt and Dr. Amend have appeared in the DENTAL COSMOS, at pp. 641 and 393, respectively, of vol. lvi, 1914.]

The next order of business was the reading of a paper by Dr. THOMAS P. HINMAN, Atlanta, Ga., entitled "Technique for Some of the Problems in Casting."

[This paper is printed in full at page 241 of the present issue of the COSMOS.]

Discussion.

Dr. DUDLEY GUILFORD, Philadelphia. I have had much pleasure in listening to this paper, in which the essayist shows a great deal of thought and experience. I do not wish to take exception to what has been presented, but every practitioner has his preferences in the matter of methods, and in discussing a paper it is more profitable to bring out different methods.

Dr. Hinman is an advocate of the burnished or swaged gold matrix in casting. This is a good method used by many operators, but personally I have seldom found occasion to use it. It is true that the gold matrix often gives a better fit in mesio-occluso-distal inlays than the usual method, and I have been interested to know just why that is. To my mind it cannot be due to any controlling influence of this thin gold matrix upon the contracting of the gold;

it is too thin for that. Dr. Hinman believes that the matrix overcomes the contraction. My opinion is that, in burnishing or swaging the matrix over the cavity surface, invariably a certain amount of spring is produced, therefore it is impossible to burnish the matrix so that it will fit tightly. That little spring allows for the contraction of the gold and produces a better fitting mesio-occluso-distal inlay. I much prefer to make a wax model on the tooth, because I am sure then that the margins are absolutely correct. My method consists in making a wax pattern in the cavity, and then with a burnisher pressing slightly on the occlusal surface. This spreads the wax a little; afterward I reburnish the margins with a warm burnisher. The result is that the interior of the cavity is slightly enlarged, while the margins are exact. When this wax model is cast, if the casting is done properly, the inlay will go to place every time.

I agree with the essayist that a great deal depends on the technique of casting. In the first place, I like to use a double investment, as that has a great deal to do with the accuracy of the result. I use Dr. Lane's investment over the wax model, carefully excluding air-bubbles so as to secure a smooth surface, and over that I use a hard investment made from red birdsand and plaster, one part of plaster to two parts of red birdsand. I find that this investment will stand almost any heat without cracking. As soon as the investment has set, I heat it rapidly; this to my mind is an important point. As soon as it stops smoking I make the casting, using a centrifugal machine. Care should be taken not to overheat the mold, as I find that five minutes' more heating than is necessary makes a difference in the result. I believe that much of the trouble experienced is due to overheating of the mold.

Another point of importance in casting in a green mold is, never to allow the mold to stand overnight, but always to cast in a few hours. I believe also in the centrifugal machine, as there is less washing away of the mold than in other machines, for the reason that the centrifugal machine starts gradually and the gold flows very slowly in the beginning into the cavity until it is full; then, as the machine increases its speed, pressure is exerted and the gold is driven home, so that there is not much washing away of the sharp edges.

Dr. Hinman's method of making a hood attachment is interesting and useful. His method of making attachments for bicuspids is also very good, but I have found the Carmichael crown to be most satisfactory. In that preparation the tooth is cut rather less than Dr. Hinman suggests. The preparation of the tooth for this attachment is no doubt familiar to most of you. It consists in cutting a groove mesio-distally across the occlusal surface of the bicuspid and extending this groove up to the gingival line on both the mesial and distal surfaces. When this has been done, the lingual portion of the tooth is "coned," so that the wax pattern will draw, and the finished attachment will go to place without leaving a space at the neck of the tooth. The wax pattern for the crown is then made, and I will outline to you a method by which this can be done very quickly. A strip of thirty-six gage copper or phosphor bronze is bent around the tooth, and the ends are held together with the fingers, so that there will be a space of about 1/32 or 1/16 of an inch between the band and the tooth. Then a piece of wax is mounted on the end of a probe and heated rather rapidly, for the purpose of having the exterior of the wax quite soft, while the interior is fairly hard. While the matrix is being held around the tooth, this piece of wax is put in place and forced between the band and the tooth by pressing it home. By this method I can make a Carmichael crown in wax in a short time. Usually the tooth preparation and the making of the wax pattern requires less than an hour. I proceed with this pattern in the same manner as with mesio-occluso-distal inlays, that is, I spread it with slight pressure on the occlusal portion and

then burnish the margins, and I have no trouble in making the casting go to place. I find that I can obtain results in this way, and I simply wish to present this method as an alternative of that presented by Dr. Hinman.

I think the essayist's conception in regard to restoring the natural size of the root-end is excellent. We see many cases of recession caused by food packing into the interproximal space due to the fact that the restoration has not been properly made, and we can make a better-looking crown by this method. The essayist's method of casting the cusp for hollow metal crowns is very good, but not particularly new.

In every way the paper is an excellent one, and it has given me great pleasure to hear it.

Dr. C. S. Van Horn, Bloomsburg. It has been said that the highest compliment that can be paid an essayist is to disagree with him. After a careful perusal of his paper, I find that I can pay Dr. Hinman that high compliment.

In a series of papers, which were published in the Dental Cosmos, I have given the profession a technique for casting which is rational in that it fully considers fixed conditions and takes advantage of the physical effect of heat upon the materials with which we have to work. In that series of papers, the impression and model method was discarded, for the reason that—"A perfect impression demands that all lines of draft be at least parallel, no undercuts being permissible, and that the impression be withdrawn without the slightest rocking in any direction. The greatest diameter of the crown of molars and bicuspids is through the horizontal plane at or near the contact point, and this means that all exterior walls of the tooth have a more or less pronounced tendency toward the spheroidal in form. The taking of an impression of the interior of an approximo-occlusal or mesio-occluso-distal cavity and the exterior of the affected tooth involves a series of procedures not consistent, as a universal practice, with either conservative dentistry or mechanical principles; for, in many cases, one of two things must occur: Either a sacrifice of tooth structure is made in order to eliminate the natural undercuts, or else the impression is distorted when being forced over the bulge of the tooth. This distortion may perhaps be slight, yet the concrete fact remains that a discrepancy occurred, and that whenever such a condition does occur, it will be in proportion to the extent to which the natural protrusions obtrude upon the line of draft."

It was further pointed out that impression compounds are just as susceptible to the physical effect of heat as are pattern waxes. Hence an impression of a tooth cavity will not be of the same size at room temperature as when it is in the mouth—unless the room temperature be the same as body temperature. Therefore, a casting of the same size as the impression of the cavity at normal body temperature demands an expansion of the impression by having it at a temperature sufficiently above normal body temperature, when the model material is being built in and hardening, to compensate for the uncontrollable shrinkage in the gold.

The essayist says: "It is essential that the margins, at least, of all gold inlays be made of pure gold." To this end he swages or burnishes a .003″ pure gold matrix on the model, trimming the matrix to overlap the cavity margins about 1.32″, and casting, after investment, into this gold matrix. One superiority claimed by the essayist follows: "Another decided advantage is gained because the matrix into which the alloy is cast seems to prevent, to a considerable degree, the *shrinkage that is so apparent in the ordinary casting.*"

We feel that Dr. Hinman is deceiving himself respecting the value of the gold matrix. The reason why a .003″ gold matrix has no effect upon the shrinkage of the mass is that pure gold, alloyed gold, or gold-platinum, when in a state for casting, is in a liquid condition, which means that it is many degrees above the normal fusing-point. When this superheated gold comes in contact with that thin film of lining, it—the

matrix—is fused to the mass. Hence, when the cooling stage begins, the casting as a whole—matrix and alloyed gold—shrinks as a mass in precisely the same manner and to the same extent as though no matrix had been used. If the matrix and the cast gold did not fuse together, there would be no union between the two, and the gold matrix could easily be stripped from the casting. The 1/32″ overlap is a very bad feature for the reason that it makes burnishing to the margins an impossibility, and furthermore, the finishing at the cervix in those cases which extend far beneath the free margin of the gum tissue is attended with great uncertainty, and possibly irreparable injury to the gum tissue and pericemental membrane.

If it is desirable that a gold inlay have greater strength than 24-karat, we use iridio-platinum wire, either square, round, or half-round, bent to the desired shape, coated with pattern wax, place it in the cavity, and form the pattern over it. When the casting is completed, we have a 24-karat gold inlay reinforced with iridio-platinum, a structure similar to reinforced concrete.

If there is any one branch of dentistry in which casting reigns supreme, it is crown work, because by using the so-called all-porcelain crown in conjunction with a cast cope, we are nearing the ideal in that we eliminate the ill-fitting band, and at least approach continuity. But since this form of crown is not mentioned in the essayist's paper, we are forced reluctantly to pass it.

While it is true that a large proportion of the bands which encircle roots are ill-fitting, nevertheless they are frequently necessary as abutments in bridge work.

When a banded crown with a Steele's facing is indicated, our technique is slightly different from that described by the essayist, in that the facing and backing are ground to alinement, and the backing is soldered to the projecting end of the post; pattern wax is flowed where desired, carved, polished, invested, and cast. Tacking the backing to the projecting end of the post produces a rigid skeleton, and greatly facilitates the operation. It is to be noted, in passing, that we do all work, wherever possible, directly in the mouth, objecting to all unnecessary transfers to models.

We object to the practice of crowning vital teeth, and especially so when used as abutments for bridges. First, because a large percentage of the pulps subsequently die, and secondly, because a proper preparation of the root can rarely be effected.

Several years ago, in the DENTAL COSMOS, we described a crown useful at times. It may perhaps be of some interest to note the various steps in the construction of that crown, as is clearly shown in these specimens. [Passing specimens.] Another crown I have found use for as a bridge abutment, and one which eliminates insult to the gum tissue in that it is bandless, is shown in this specimen, in which a Steele's facing and the casting process have been used. When we use hoods at all, which is rarely, we cast them from a wax pattern, and if extra strength be desired, iridio-platinum bars are used as previously described for inlays. We never have used a hood or any other form of abutment for a dummy which is attached to but one side in cases of normal occlusion, for the reason that the force of occlusion will throw the dummy out of alinement, usually doing considerable injury to the gum tissue.

From our point of view, Goslee teeth are rarely indicated in bridge work. Their so-called strong feature, which is their inherent strength, is their real weakness. Their strength is secured through the bulk of porcelain, but as the porcelain mass is increased, the bulk of metal in our bridge skeleton must be decreased. We have yet to see a bridge made up of Goslee teeth which did not show a lamentable weakness in the approximal attachments, the triangular bit of metal at that point being insufficient to support the strain imposed.

While a full review of the essayist's paper is not possible in the time allotted, we submit this brief discussion of the more prominent features, for the sole

purpose of endeavoring to stimulate thought and direct activities along lines of least resistance, to the end that in all our work we give due consideration to fundamental principles.

Dr. Wm. W. Booth, Pittsburgh. Dr. Hinman's paper covers a great many of the difficulties arising in the making of inlays, crowns, and bridge attachments which undoubtedly arise in casting, and describes well the advantage of using a swaged lining. I am confident, however, that some of the difficulties encountered with inlays not going to place after being cast are due principally to technique, viz, some little manipulation done wrongly in the making of the model, in the mixing of the plaster, in the heating of the investment, or the casting. Until some investigator will show us what to do in every case, what line of technique to follow exactly, we will never be sure of a casting. I have had mesio-occluso-distal inlays go perfectly to place, but I have had more of them just a little off. To illustrate, the other day I had two large mesio-occlusal inlays to cast. The wax was the same in each and handled in the same way, Taggart's investment was made for both by my assistant in one mix, and the result was one smooth inlay going beautifully to place in the cavity, the other having a great many little bubbles. Again, another large inlay cast in a hurry was about as smooth and perfect a casting as I have ever seen. I am sure that a perfect filling can be made by casting, and when someone tells us in simple words how to do it every time, I hope to take a good vacation to celebrate the occasion. I am sorry that Dr. Hinman has not evolved some technique for casting.

The method advocated by him, of using a swaged lining, is undoubtedly the best method to follow in difficult cases, this lining to be swaged in an amalgam model. Hood attachments I have used for some years, swaging them directly into the tooth. Lately I have been greatly helped, and have saved time by taking an impression in modeling compound and immediately pouring a model of Dr. Barnes' Quick-model. This is immediately sufficiently hard to swage 24-karat plates upon, making the final adaptation in the cavity.

Anyone who has not used the different applications of this hood attachment as described by the essayist will certainly find this paper very valuable. Another very good point mentioned is the proper contouring of bands. When a band is fitted closely to a root which is denuded of its enamel, that proper contour must be restored in fitting a crown of the proper width. There is no question that a band left flat and uncontoured above the cervix will cause further recession.

Dr. Hinman has given us a very excellent subject to discuss, and we shall be glad to adopt some of his methods. As a comment upon the technique for the different crowns, especially as to the gold crown method of casting over 30-gage platinum, I think this procedure rather expensive for the average practitioner and not a time-saver. Gold of 22-karat can be cast over 22- or 24-karat very nicely, and the cervical contour filled in with 22-karat solder, if one does not bring the casting up to the edge of the band.

The silicates I have used to advantage in some cases for filling-in the surface of a crown, also in building up the face of a large inlay.

Dr. L. J. Weinstein, New York. With Dr. Hinman's permission I should like to start an argument with Dr. Van Horn. He has taught me what little I know about expansion and contraction of wax in inlay work, and he has either made an error or forgotten something. He has taught me that it is not so much the contraction of the gold that makes imperfect inlays, as it is the contraction of the wax; consequently a matrix that is rigid enough to prevent expansion in the wax would eliminate to a certain extent the contraction of the gold. I am simply taking Dr. Van Horn to task for his own teaching.

We have heard of three different methods of making inlays, each method being apparently satisfactory to its advocate, and I will describe a fourth method.

Generally, pure gold is too soft for large inlays when a masticating surface is involved, and a strong hard gold is wanted. In all of the three methods mentioned the edges have to be burnished, but the more rigid the gold the more difficult it is of adaptation. I have used a number of times a method shown to me by Dr. Gillett of New York. He first casts a thin gold shell of pure gold for the cavity surfaces, and burnishes that to the cavity margins. He then takes an impression with the shell in place, and casts an inlay of solder; the two portions are now soldered together and inserted as one inlay. No contraction occurs in this procedure, for the reason that the bulk of gold expands sufficiently to more than compensate for the contraction of the solder used, and with all due respect to Dr. Van Horn's method, which I admit is superior to the three methods mentioned, I think this fourth method to be superior to his.

If we imagine for a moment that no contraction of the gold in the investment occurs, then theoretically we should obtain perfect inlays. But this is not the case. I claim that the fault lies more in the technique and the materials than in the actual movement of the gold or wax. As Dr. Hinman stated, in using several investments heated for different periods, he observed various degrees of distortion, which certainly proves that the manner in which the molds are heated influences the casting. There must be a difference in heating a mold twelve minutes or two hours, and allowing it to stand from twenty-four to forty-eight hours. These points must be taken up rationally and determined, because they apply to all kinds of casting. Surely these preparatory steps should not be taken in an empirical manner. In other words, it is easier to control these preliminaries than to control the movement of gold; there is no reason, then, why these factors should not be investigated, and the proper procedure determined upon.

One other factor in casting inlays, which is an important one, is the temperature of the gold at the time when it enters the mold. Dr. Taggart advocated the use of golds alloyed with copper in preference to platinum, for the reason that, at high temperatures, platinum alloys form a silicate with the silicate in the investment compound. I do not quite agree with this argument chemically, but I think it is not so much a question of what alloy is employed, as at which temperature that alloy strikes the investment. The fusing-point of silica quartz is 3300°, therefore we must see in every case that the investment is kept down to a point of a little over 3000° F. If in casting we superheat pure gold, which melts at 2000°, by 500°, there is not much difference between the temperature of the gold and the investment, and some union may take place, causing a rough casting. The utmost precaution must therefore be used against superheating the gold, and I think the best insurance policy we can have against this is the use of the gas blowpipe, for the reason that we can only reach a certain limit of heat, which is not sufficient to fuse the investment.

(Dr. Weinstein then showed a number of lantern slides illustrating his methods of casting inlays, making crowns, etc.)

Dr. Van Horn. I am averse to discussing the discussion of a paper unless I happen to be the essayist; furthermore, when I do enter a discussion, I always endeavor to confine my remarks to the text. Dr. Weinstein seemingly overlooks this latter fact, and brings in extraneous remarks respecting the physical properties of pattern wax under varying thermal conditions. We would again point out that Dr. Hinman confines his remarks to the indirect method; he is working outside of the mouth, and wax is constant in its dimensions in a constant temperature. The little change which might occur in the temperature of the room during the time of working the wax would be so small that it would not have any appreciable effect, hence there would be no change in the wax pattern. If Dr. Weinstein will review the articles referred to, published in the Dental Cosmos, and will then analyze my present discussion, I feel certain that

he will have a clearer understanding of the conditions involved and the results that obtain.

Dr. W. A. Capon, Philadelphia. Everything in dentistry has been and likely will be a matter of evolution, to a great extent. We have seen a great many changes. It was only a short time ago that all we had to do was to advocate some new method of root-filling and intense interest was displayed at dental meetings; yet, while the importance of that topic is very great, we have shifted much of our interest to the gold casting process—and goodness only knows where it will end! First of all, I am pleased to say that Dr. Hinman is a practitioner of wide experience, and we gain much by his presence. I fully agree with him in regard to casting under various conditions and with all sorts of appliances, for with any one of the hundred or more different machines and methods for casting, the results depend upon the technique, after all. If we do not follow a certain technique, we cannot produce satisfactory results.

Casting with sharp-edged steps in the cavity is a problem which few operators probably have ever taken seriously. In other words, in making steps in the formation of a cavity, it must be remembered that this form is to be reproduced in the investment, and these sharp edges, in a soft and breakable substance, are liable to brush off and cause a misfit of the inlay. This point I learned from Dr. Hinman six years ago when he read a paper at Baltimore. In the preparation of cavities we should exclude also the sharp right-angle corners on the gingival border advocated by so many teachers, because of our inability to introduce the wax in these places accurately.

With regard to pressure in casting, I will say that I am familiar with the majority of machines, ranging in price from one hundred dollars to almost as low as five cents. I use the Taggart machine, also the Jameson centrifugal machine, but to the students at the University of Pennsylvania we teach the use of the Seymour machine, because it is simple, and the results are quite wonderful. I am not advertising any appliance, but I would say that cost does not make the difference between machines as far as results are concerned, if the necessary detail is correctly followed. In making some specimens recently, I again became convinced that we can obtain as good gold castings with a cheap machine as with the Taggart machine. The pressure applied in casting is an important factor. In using the Taggart machine quite recently, I have been able to produce some beautiful castings with three pounds' pressure. The essayist advocates a pressure of about five pounds, and I agree with him that that is quite sufficient. When we first started this work, we used from fifteen to twenty pounds' pressure, but we know now that that is too much. Very little pressure is necessary for accurate casting.

The heating of the mold is another consideration that has been duly emphasized by the essayist. When we first started to do this work, we heated the mold almost to red heat, but we had to abandon that practice. I have been following the direction of Dr. Taggart chiefly, and he, with many others, asserts that the best work can be produced with a cold flask. I had the pleasure of attending the great meeting of the Illinois State Dental Society's golden anniversary, and I wish everyone present had been there, as it was the greatest meeting ever held by dentists. One of the principal features of the meeting was the clinics, and probably two-thirds of these demonstrated the casting process. All sorts of methods and ideas were presented—so much so that, when it was all over, I felt considerably confused. One clinician said that we could cast best with 22-karat solder, and he was one of the best practitioners in Chicago. Another clinician stated that we should never use pure gold under any circumstances; another used platinum alloy. One genius from Minneapolis showed a large brass tooth in which a mesio-occluso-distal cavity had been prepared, and during the meeting he had several

men try to make an absolutely perfect casting for this brass tooth. While I am of the essayist's opinion, that the making of a casting to fit a model of a hard metal is much more difficult than casting to a softer material, at any rate this clinician had a half-dozen castings that would probably be generally accepted as having an adaptation so nearly perfect that they were beautiful. The clinician asked a professor in one of the western colleges to cast an inlay to fit the cavity in the brass tooth. The instructor said that this would be easy. This occurred on Saturday morning, and at one o'clock Sunday morning he was still trying to make a casting that would fit perfectly. He cast about eighty-five gold inlays, and then gave it up. This is what we have to contend with in a great many instances, if we want a perfect casting. So far as the solution of the problem is concerned, I am sure that we shall have to take a little hint here and there, and pursue the method by which we can procure the best results. If Dr. Hinman gets better results with the use of a matrix for the wax than another practitioner, this does not mean that his method is wrong, but it means that each operator can produce best results by different methods, for in this, as in every domain of dentistry, the personal equation has to be taken into consideration.

With regard to the use of the matrix —and I do not think many operators have had more experience in making matrices than I—I claim that the matrix has another advantage, namely, that we shall have a border to burnish, which we all prefer. If a matrix of that kind is used first, then the surplus edge can be burnished at the gingival border, and we need not be afraid of the cement washing out. I speak from experience in this matter, because hundreds of my porcelain inlays have stood the test for twenty years, the margins having been prepared in this manner.

Dr. Hinman (closing the discussion). I am very much delighted that my paper has created so much discussion. With reference to Dr. Guilford's discussion and his method of making the Carmichael hood, I would say that I cannot make satisfactory mesio-occluso-distal inlays or hoods by the direct method, because I have never been just sure that I could take an accurate impression of a mesio-occluso-distal cavity in the mouth with wax, unless I surround that tooth with a continuous band matrix. Dr. Guilford may be able to accomplish this, but I am not. In pressing the wax into a mesio-occluso-distal cavity, the wax has a tendency to spread away from instead of hugging the margins, and especially is this true if one allows the patient to bite into the wax, which spreads it out worse. This is why the method seems inaccurate to me. The method suggested of expanding the wax form or matrix seems to me to be very inaccurate, and I prefer to use the metal lining.

As to Dr. Van Horn's criticism of the indirect method and the impossibility of taking an impression of a mesio-occluso-distal cavity in a typically formed tooth, I will admit that this is very difficult, but I cannot admit that it is impossible to take an accurate impression, for I know I can do it. We must remember in taking impressions of teeth that not all present what we may call the typical form; but there are a great many that anyone can easily take an impression of.

In reference to the matrix overlapping, I fear that Dr. Van Horn misunderstood me when I said I overlapped the matrix; I fear he has the idea that I leave that overlap. Nothing is further from my practice than to leave that overlap in the finished inlay. The only reason why I put it there is that, in casting, the metal may not flow over the margins. The casting is returned to the metal model and finished down by cutting off the overlap of pure gold. Iridio-platinum staples in mesio-occluso-distal inlays have been used by me to a considerable extent. Dr. Price tells me that such a staple has very little value when we cast pure gold over it. It does not to any great extent control the shrinkage or strengthen the inlay, although it must have some such influence.

As to Dr. Van Horn's reference to placing crowns on vital teeth, this is a question which, if opened for discussion, would be interminable. There are a great many cases in which it would be folly to attempt to crown a vital tooth. It would be suicide not to devitalize the pulp and fill the root-canals in a great many instances, but in some cases, I believe, we are warranted in putting crowns on vital teeth.

In reference to the single attachment, that is, what we call the wing bridge; Dr. Van Horn does not advocate this form of bridge, but rather protests against its use. This is simply a question of occlusion. I have followed this plan in selected cases for many years, and have seen some cases where the occlusion was not properly cared for, and the tooth that held the attachment was rotated in its socket and thrown out of alinement; but when the occlusion is taken into consideration and the proper adjustment of the single dummy is made, I believe satisfactory results can be obtained.

As to casting on porcelain, I have to say that Dr. Van Horn may be able to accomplish that satisfactorily, but I cannot, and I am very much afraid that a great many of us are casting directly against porcelain, which is an extremely dangerous procedure. If everything is exactly right, then we may be able to cast against porcelain, but I have never been able to do it satisfactorily.

In answer to Dr. Booth, who complains that I have presented no new technique of casting, I have to say that I did not go into the technique of casting because I felt that you were all familiar therewith, and I have nothing new in that line to offer. I assumed that all are familiar with certain facts and factors in the casting process. Dr. Booth also speaks of the price of the cast crown. I did not consider the question of price, but simply the question of how to obtain the best results.

Dr. Weinstein speaks of the combination of silicon with gold in casting, especially when the oxyhydrogen blowpipe is used. I have found, if we are making a direct casting from a direct wax form or matrix, that with the button that is left for one casting, it is inadvisable to attempt to cast another inlay using the same button, on account of the combination of silicon with the gold, or if we are using the nitrous oxid blowpipe, to employ a combination of nitrogen with it. Gold never seems to give a perfect casting after it has been fused once, and I think we should use a fresh button of gold for each casting. Dr. Weinstein evidently casts in a hot mold in making a gold crown; I cast in a cold mold. Sometimes, to be sure, the gold does not flow completely around the cervical border, and then we have to make an addition of solder as he indicates. The method of lapping the gold with the Goslee teeth is very admirable; although I omitted to mention it. I have always followed the plan of lapping the gold considerably, just as much as in mesio-occluso-distal inlays, with the only difference that Dr. Weinstein grinds the porcelain and narrows the saddles, which I think is an admirable method. In dowel crowns, he points out, it is easier to make a second dowel to hold the crown instead of using the pin as it passes through the cap. It is only in a few cases that this is necessary. Dr. Weinstein refers to soldering the dummies separately. That has been my practice for years. I finish each dummy separately and then assemble the dummies and solder them together. These are placed on the model and it only remains to attach the dummies to the distal and mesial attachments; in this way, to a great extent, we prevent or control the shrinkage which causes a misfit. This is absolutely necessary when an inlay or a hood attachment is used as an abutment.

One point which Dr. Capon mentioned I should like to emphasize, viz, that it is imprudent to leave a narrow neck in the occlusal step, as the gold, in flowing in, knocks off the sharp corners of the investment. Dr. Capon also calls attention to the futile effort of an operator to fill a mesio-occluso-distal cavity in a metal model. I have been working

for years along a different line; instead of using metal, I have been using a simple mesio-occlusal cavity cut in a porcelain tooth, and I have never found anyone who could cast an inlay to fit that cavity, and I have attempted it many times myself. The difference between this porcelain and a natural tooth is that, when we force an inlay in the natural tooth, the dentin expands, the tooth is flexible, while the porcelain tooth possesses no flexibility.

In closing, I wish to say that my purpose in presenting to you these different attachments and the methods which I use in casting was to show procedures which I have been following, and which might be adopted by some of you to advantage. I will, this afternoon, show the complete technique of casting the hood abutments, which I always cast in a matrix. I appreciate the honor which you have bestowed upon me in asking me to appear before you, and wish to thank you cordially for the courtesy and attention you have shown me since I have been here.

The next order of business was the installation of officers, after which the motion was made and carried to adjourn until the next annual meeting, to be held June 22 to 25, 1915.

(To be followed by Clinics.)

CORRESPONDENCE.

SOLVENTS OF GUTTA-PERCHA.

To the Editor of the Dental Cosmos:

Dear Sir,—On page 225 of the Dental Cosmos of the current year you have published an excerpt from an article originally published in the *British Dental Journal,* London, December 15, 1914, entitled "The Action of Oil of Cloves and Other Oils on Gutta-percha Points," by H. Humphry, Dartmouth. Besides the inaccuracy of the experiments to which you call attention in a footnote, the article contains various statements which do not conform to known chemical facts. The author states: "Oil of eucalyptus . . . dissolved the gutta-percha, oil of cinnamon and oil of cajuput caused no change, while oil of cloves caused a large increase in size in all directions."

As a matter of fact, oil of eucalyptus *and* oil of cajuput dissolve gutta-percha. Both oils contain as their principal active constituent a body chemically known as cineol, and pharmaceutically respectively as eucalyptol and cajuputol. A good oil of eucalyptus should contain 60 per cent., while oil of cajuput contains a somewhat less amount of cineol. This cineol is *the* agent which dissolves gutta-percha. Oil of cloves and oil of cinnamon do not contain cineol, but other active constituents, of which eugenol (oil of cloves) and cinnamic aldehyd (oil of cinnamon) are the chief representatives. Both oils have apparently no solvent effect on gutta-percha.

Sincerely yours,

Hermann Prinz.

EDITORIAL DEPARTMENT.

OPPORTUNITY.

IT is generally conceded that one of the chief factors of success in life is preparedness—readiness to take advantage of the opportunity when circumstances create the opportunity. Indeed, the ambitious man, the one who efficiently carves out his way to success, he who is the so-called architect of his own fortune, does not wait for circumstances to create opportunity. He makes opportunities for himself. Nevertheless the ready-made opportunity not infrequently presents itself, and the wise man who has realized the importance of preparedness, who has the keenness of vision to recognize the opportunity which occasion presents, the ambition and willingness to seize the occasion at the opportune time, is the one who succeeds beyond the average of his fellows, and who ultimately solves his life problems in terms of success.

But opportunity knocks at the door of the community, the state, and the nation. It offers its allurements to groups of men

as well as to individuals, and the relationship of preparedness to success applies equally to all.

Dentistry is no exception to the general rule. Comparatively recently the profession of dentistry has had presented to it the opportunity to render an inestimable public service through the channels of oral hygiene. It is unquestionably true that the success of dentistry in this connection depends definitely upon the preparedness of our profession to answer in terms of demonstration the question now being asked by the public and by the medical profession, To what extent may we depend upon oral hygiene for the relief of certain bodily ills and for the prevention of disease?

The answer in the affirmative is gradually and certainly forthcoming. The oral hygiene movement is the result of a comparatively slow evolutional growth. The axiom that clean teeth will not decay is centuries old, but it is only recently that any comprehensive understanding of the widespread application of this axiom has been possible, and it is only recently that the general recognition of the importance of the involved problem has created the opportunity for public health dental service which the dental profession has been called upon to meet.

Opportunity, therefore, may be the product of a slow evolutional process, or it may develop suddenly in the revolution of the wheel of circumstance. For a half-century we have in various parts of the world endeavored to impress upon those concerned in the administration of state and national affairs the importance, indeed the necessity, for dental service in connection with those employed in the government defense. The importance of dental service in connection with the armies and navies of the world has been urged by the dental profession in all civilized countries—in many instances with little or no result; in others it has received more sympathetic attention, and in a few instances has been experimentally adopted.

Suddenly the greater part of the civilized world is engaged in mortal combat; the most devastating war in the history of the human race is now in progress; gunshot wounds of the head and jaws in countless numbers require the skill and specially trained services of the oral surgeon and the dental expert. The health and not infrequently the lives of soldiers are jeoparded by the

lack of oral hygiene. Bodily infections in wounded soldiers arising from uncleanly mouths are unnecessarily increasing the death-rate in military hospitals, and the demand arises everywhere in connection with military hospitals for the special service that only dentistry and oral surgery can render. The opportunity needed to convince all concerned of the justness and practicality of the demand made by the dental profession for the past half-century for a recognition of the importance and efficiency of the service which they are able to render under the circumstances existing is now signally confronting us.

Again, the question of successfully solving this problem involves the factor of preparedness upon the part of the dental profession to take advantage of the present opportunity. Moreover, in the present instance the humanitarian side of the problem looms before us in colossal proportions. Every dental practitioner knows full well the extreme suffering and distress which arise from gunshot wounds and dental and oral injuries received in battle. These cases necessarily make a strong appeal to the sympathies of those who best understand their urgency, and while we may not at present be able to furnish a sufficient number of skilled operators to practically care for these cases, we can all of us contribute to their relief and treatment in a material way through the agencies set forth in the announcement appended to this communication.

It is hoped by the committee in charge of this movement that every dental practitioner who reads this appeal will regard it as *his* opportunity to do two things: First, to practically manifest his allegiance to the best interests of his profession; and second, to practically express his sympathy for a class of suffering humanity whose affliction comes nearest to him in a professional way, so that the combined help of the dental profession in this connection may be practical evidence of the faith of the dental profession in its contention for the establishment of adequate dental service in connection with the armies and navies of the world.

The Appeal.

At the meeting of the American Institute of Dental Teachers held at Ann Arbor, Michigan, on January 26th, it was decided to take steps that should result in the raising of a fund to be used through the Red Cross Society in giving relief and aid to the soldiers in Europe who are

suffering from oral and dental injuries. The president was instructed to appoint a committee to take charge of this matter. President F. W. Gethro, under this instruction, appointed the following Executive and General committees:

Executive Committee.

Henry W. Morgan, E. A. Johnson, Ellison Hillyer, John F. Biddle, *Sec'y;* C. R. E. Koch, *Chairman.*

General Committee.

E. C. Kirk, Philadelphia
J. H. Kennerly, St. Louis
H. C. Miller, Portland, Ore.
D. M. Gallie, Chicago
John F. Biddle, Pittsburgh
E. T. Darby, Philadelphia
Alfred Owre, Minneapolis
B. Holly Smith, Baltimore
E. A. Johnson, Boston
Frank Holland, Atlanta
D. M. Cattell, Memphis
Frederick R. Henshaw, Indianapolis
S. W. Bowles, Washington
E. H. Smith, Boston
A. H. Hipple, Omaha
Ellison Hillyer, New York
Truman W. Brophy, Chicago
D. H. Squire, Buffalo
H. E. Friesell, Pittsburgh
Henry W. Morgan, Nashville
I. N. Broomell, Philadelphia
Wallace Wood, New Orleans
Frank T. Breene, Iowa City
H. L. Banzhaf, Milwaukee
J. G. Sharp, San Francisco
G. V. Black, Chicago
W. T. Chambers, Denver
H. M. Seamans, Columbus
J. D. Patterson, Kansas City
N. S. Hoff, Ann Arbor
C. N. Johnson, Chicago
H. L. Wheeler, New York
L. E. Ford, Los Angeles
C. R. E. Koch, Chicago
H. B. Tileston, Louisville

The Executive Committee is contemplating the issue of contribution certificate booklets. Each booklet will contain twenty certificates or coupons certifying that the holder thereof has contributed twenty-five cents to this fund. This certificate will be neatly lithographed, something like national currency. It will be printed in lilac ink—the color of the dental profession—and bear upon its face the Red Geneva cross.

It is hoped that the dental schools, dental students, and dental societies, as well as the profession at large, will become sufficiently interested in this propaganda to secure a large enough fund through these small contributions to secure real relief for the class of war sufferers for which it is designed. That it may aid in the establishment of several special hospitals or wards devoted to dental and oral surgical injuries, within the belligerent zone of Europe, is the ultimate purpose of this movement.

It is expected that these booklets will be ready for distribution on or before March 1st. Applications for them may be made to Dr. John F. Biddle, of Pittsburgh, Pa., secretary of the Executive Committee; or to Dr. C. R. E. Koch, 31 West Lake st., Chicago, chairman of the committee, before March 1st. After that date all the members of the Executive Committee and General Committee will be in a position to supply them.

Review of Current Dental Literature.

Conducted by RICHARD H. RIETHMÜLLER, Ph.D., D.D.S.

SOME CONSIDERATIONS AFTER 13,000 ADMINISTRATIONS OF NITROUS OXID. By Dr. W. L. Jones.

[*American Journal of Surgery*, New York, January 1915.]

NITROUS OXID AND OXYGEN DOSAGE IN ANESTHESIA. By Dr. Karl Connell, New York.

FRACTIONAL REBREATHING IN ANESTHESIA—ITS PHYSIOLOGIC BASIS, TECHNIQUE AND CONCLUSIONS. By Dr. E. I. McKesson, Toledo.

[*Northwest Medicine*, Seattle, September 1914.]

NITROUS OXID AND OXYGEN ANESTHESIA. By Dr. H. L. Geary.

In his record of thirteen thousand administrations of nitrous oxid and oxygen, Jones reports but one fatality on the table in an extra-hazardous risk. While a large percentage of these cases were for dental operations, quite a number concerned major surgical operations in bad subjects. The youngest patient was four weeks, the oldest eighty-six years, the operations being for cleft palate and prostatectomy respectively. The writer's experience with nitrous oxid and oxygen in brain surgery corroborates Teter's findings, satisfactory anesthesia being maintained by 92 parts of nitrous oxid and 8 parts of oxygen. Experiments during these operations proved conclusively that discoloration, dilatation, and protrusion of the brain occurred only in the presence of oxygen deprivation, and assumed dangerous proportions only when asphyxia was imminent. Jones has met with occasional instances of acapnia in anemic, asphyxia in plethoric, obese, and alcoholic subjects; but all these cases responded promptly to artificial respiration and perflation with oxygen.

McKesson's findings as to blood pressure during four thousand nitrous oxid and oxygen anesthesias are also corroborated in Jones' experience, and he has observed that any imperiling turgescence of bloodvessels, even in the presence of arterio-sclerosis, must be the result of either asphyxia or pushing the anesthesia beyond the depth required for surgical interference. For safe and satisfactory results with this technique of anesthesia, the writer suggests that the anesthetist should bring as much skill to its administration as the surgeon does to the operation. He offers his records and the desperate character of many of the cases tabulated to controvert the efforts of some surgeons to condemn this method indiscriminately.

Ether in small amounts for the purpose of relaxation was required in from 20 to 25 per cent. of the cases recorded.

The conclusion reached by Jones is that, while nitrous oxid and oxygen anesthesia does not make the work of the surgeon easier, it is immeasurably better for the patient than any other form of general anesthesia. Connell maintains that the effect of a given nitrous oxid and oxygen mixture is constant on normal man. The anesthetic effect is in a degree inversely as the proportion of the oxygen. The ultimate gas tension which the drug establishes is not at present an available gage of dosage. The only available gage of qualitative dosage is the proportion of oxygen with which the drug is administered. The action may be differentiated into consecutive levels or zones of anesthesia, according to the average amount of oxygen present in the tidal gases. For analgesia in normal man, the proportion of oxygen in the tidal gases of breathing may exceed 20 per cent. Below this, the consciousness becomes gradually abolished until at 16 per cent. the patient slowly becomes unconscious. From 14 to 11 per cent. there is sufficient anesthesia for surface operations; from 11 to 8 per cent. for abdominal surgery, associated, how-

ever, with slight asphyxia and without proper muscular relaxation. Below 8 per cent. the mixtures are useful only for induction of anesthesia, and below 6 per cent. they become so highly asphyxial that they should not be used even for tooth extraction. Higher percentage of oxygen is required when the tidal volume is below the average, or the oxygen-carrying capacity of the blood is diminished. At least 6 liters of fresh gases per minute are required for smooth anesthesia and to establish normal excretion of carbon dioxid and other gaseous waste products; preferably 8 to 10 liters per minute of a uniform mixture is supplied in a continuous flow. By continuous flow and known dosage with accurate and constant measurement and control, the level of each patient may be found rapidly, and after the first fifteen or thirty minutes anesthesia may run continuously without further adjustment. Unsupplemented nitrous oxid and oxygen anesthesia is ineffective to block the centripetal stimuli of operative trauma. Nitrous oxid and oxygen anesthesia is most advantageously supplemented by ether. Light ether anesthesia, the light subconscious zone of ether, a tension of from 15 to 25 mm., in conjunction with the subconscious or light subconscious zones of nitrous oxid and oxygen anesthesia, 14–16 or 16–20 per cent. of oxygen, is physiologically the most advantageous of all anesthetic states. Owing to present complexity and inaccuracy of administration, the average nitrous oxid anesthesia, even when it is effectively supplemented, possesses no practical advantage over properly induced and well maintained ether anesthesia, according to Connell.

McKesson states that rebreathing during the administration of nitrous oxid and oxygen will not only control the tendency of preliminary alkaloidal medication to decrease the rate and the volume of pulmonary ventilation, but will also, in association with overventilation with oxygen and carbon dioxid, combat the effect of morphin in preventing the elimination of ether from the system, if ether is used. Rebreathing is a perfecting detail in the administrative technique of nitrous oxid and oxygen anesthesia, and the fractional method of rebreathing made possible by the writer's fractional rebreathing bag affords a practical means of measuring the tidal respiration. This method selects automatically those gases coming from the upper air-passages to be returned for rebreathing, and eliminates from the apparatus the latter portion of the exhalation coming from the alveolar portion of the lungs, which contains six per cent. carbon dioxid, and is poor in anesthetic properties. This method has the further advantages that it controls the tension and elimination of concomitant etherization when employed; it prevents the rapid breather from using more gas per minute than he would of air if normally asleep; it makes the light breather increase the depth or volume of respiration, thus securing a better absorption of the anesthetic and a more satisfactory plane of narcosis; it reduces gas consumption to accuracy, and to an economic basis which puts the technique within reach of all.

Geary enumerates the many advantages of nitrous oxid and oxygen anesthesia, which are in his opinion as follows:

(1) Comfort of the patient during the period of induction and elimination plus the absence of postanesthetic vomiting. The patient passes quickly and very quietly into deep anesthesia, and in the majority of cases surgical anesthesia may be induced within three minutes.

(2) It has practically no odor, and when administered to the patient warm with oxygen in the proper percentage, he is hardly aware that he is taking an anesthetic, especially if he has ever taken ether or chloroform.

(3) Nausea rarely occurs, when there are no other nausea-producing factors.

(4) It is not irritating to the respiratory passages nor to the kidneys.

(5) It does not cause fatty degeneration of the liver cells, and has no effect upon the lungs, provided it is administered warm.

(6) It does not produce any harmful effects upon the phagocytes, and is therefore indicated in infections.

(7) The patient is fully awake and in possession of his mental faculties within a few minutes after the anesthetic mask is removed.

(8) Subsequent administration has, as a rule, no harmful effects.

(9) Its administration is indicated in patients suffering from infectious diseases, and those having a low resisting power.

(10) Its rapid elimination from the system. The rôle of shock is far less than that of ether or chloroform.

(11) The patient is plunged into a deep surgical anesthesia within a few minutes,

passing through the stage of excitement very quickly.

(12) It does not produce an accumulation of mucus and saliva.

The disadvantages of this anesthesia are very few in the hands of a highly skilled anesthetist, and they should be looked upon by the modern surgeon not only from a scientific point of view, but from the patient's standpoint, and that of a good prognosis. They may be enumerated as follows:

(1) To obtain the best results a trained expert is required who fully understands the action of the two gases, the symptoms of the patient, the fundamental principles of anesthesia, and the minute adjustment of the apparatus.

(2) Deep relaxation in some cases is not easily produced.

(3) It requires an expensive and accurate apparatus for its scientific administration, and one that is equipped with an ether attachment, so that ether may be given if occasion demands it.

(4) The anesthesia is somewhat lighter and more transient than that produced by chloroform or ether.

(5) It requires much watchfulness and skill on the part of the administrator to produce an even narcosis.

(6) The zone of anesthesia is narrow, with consequent uncertainty of muscular relaxation and freedom from reflex movements.

As a rule, a child of only a few years is not a good subject for nitrous oxid and oxygen. Children are hypersusceptible to both nitrous oxid and oxygen; in other words, they are easily asphyxiated even from a small quantity of nitrous oxid, and they readily respond to an overdose of oxygen, which brings them out of the anesthetic.

[*Deutsche Medizinische Wochenschrift*, Berlin, 1914, No. 30.]

CHRONIC COPPER POISONING CAUSED BY THE WEARING OF A POOR GOLD ALLOY IN THE MOUTH. By Prof. Dr. Erich Harnack, Halle.

The writer, whose name stands among the first in toxicology and pharmacology, reports a case in which he was called upon to give expert testimony. The patient, a young woman who had enjoyed excellent health, had a stationary gold bridge inserted in her mouth in 1908, and from that time on had been suffering with progressive cachexia. She first developed gastric and intestinal troubles, associated with vomiting and complete loss of appetite; later on she had severe spasms of colic and muscular tremor, dyspnea and severe coughing, and finally, since 1912, muscular debility and extreme cachexia. She also claimed that the color of her hair had changed. When the bridge was removed in January 1913, an intense odor as of verdigris was observed, which persisted for three weeks in the root-canals, which showed a greenish discoloration. Upon the removal of the bridge, the woman's condition gradually improved to normal.

Chemical analysis of the bridge showed it to contain about 70 per cent. base metals, chiefly copper and zinc, hence that only about one-third of the bridge consisted of gold—hardly 8-karat. Harnack diagnosed the case as one of slowly progressing systemic copper-zinc intoxication, caused by the bridge, with presumably ultimately fatal result. The intoxication is caused by the acids formed by fermentation, and putrefaction in the root-canals produced organic copper compounds which entered the circulation. The writer advises that dental bridges should always be made of a gold of high purity, never of inferior alloys containing copper and zinc. Such low-grade alloys, in his opinion, are more dangerous than pure copper or zinc, since the contact of the oral fluids with such alloys may produce electric currents and the formation of absorbable metallic compounds.

The discoloration of the hair, which is observed the earliest in blondes, Petri attributes to a deposition of microscopic copper-bearing crystals upon the hair cuticle, their number decreasing toward the root, which itself remains free therefrom.

[*Deutsche Monatsschrift für Zahnheilkunde*, Berlin, February and July 1914.]

ROOT-CANAL TREATMENT WITH SUBLIMATING SUBSTANCES. By Zahnarzt Bauchwitz, Stettin.

THE PROBLEM OF ROOT-CANAL FILLING. By Karl Elander.

Adding a modification to the many methods of root-canal filling already in vogue, Bauchwitz argues that some bactericidal medicaments lose their crystal form and volatilize, penetrating the finest canaliculi, and in these sublimate again, being precipitated in the root-canals in crystal form. His formula consists of benzoic acid 5, boric acid 5, and

iodoform 1, this mixture being heated in a specially constructed appliance over an alcohol flame, the ascending vapor being guided into the root-canals, where it penetrates to the finest extremities and is precipitated upon the canal walls as an antiseptic filling. The lumen of the canal is filled with the soft paste. No suggestion is made in regard to the hermetical sealing of the root-apex.

Elander emphasizes the importance of asepsis rather than antisepsis in the filling of root-canals. He uncompromisingly demands aseptic methods of operating and aseptic obturation of the canal, for the reason that antiseptic root-fillings lose their efficacy sooner or later. After a thorough mechanical removal of the pulp tissue, the root-canal is wiped with concentrated trichloracetic acid, and then filled with formic geranium oil and asbestos, this in turn to be covered with a mixture of 10 parts of gutta-percha, 75 parts of quartz, and 15 parts of zinc oxid. This soft and plastic mass is introduced into the canal with a Donaldson broach and an amalgam plugger, and is claimed to be denser than dentin. The writer asserts that it can easily be removed with a bur and by rinsing with chloroform. The writer considers the extirpation of a pulp from the point of view of treatment of a fresh wound, which must be touched only with aseptic instruments, and be treated under the most rigorous precautions of asepsis.

[*Therapie der Gegenwart*, Berlin, December 1914.]

INFLAMMATION OF THE ORAL MUCOSA.

By Prof. Dr. F. Williger.

The writer devotes a passing word to the amazing resisting power of the mucous lining of the mouth, which is in such marked contrast to mucosa in other parts of the body. When the oral mucosa, however, is damaged by a defective tooth or general febrile disease, the secondary stomatitis which may develop is depressing, and measures for its cure are imperatively needed, and give great relief. Even when there is no actual inflammation, proper care of the mouth may ward off secondary parotitis, besides its effect on the appetite and spirits. Not only the teeth, but the gums and tongue must be wiped off with the finger wrapped in a thin layer of cotton. The best way, in the writer's opinion, is to cut a piece about 4 by 10 cm. out of sheet cotton, and then peel off a very thin layer to wrap around the finger, and dip the finger in a mouth-wash. By using plenty of the fluid, the mouth can be thoroughly cleansed without hurting. The patient can do this himself when perseveringly trained until he does it right. Three times a day is as often as it should be done, merely rinsing out the mouth after eating at other times. Williger regards it as the criterion for good nursing when the patient's mouth is found clean at the doctor's visit. In contagious diseases, a wad of cotton held with forceps must be used instead of the finger. The mouth-wash must be such as softens up rapidly phlegm and thick coatings, and nothing seems to be better for this than a heaping teaspoonful of sodium bicarbonate stirred into a glass of warm water, supplemented by hydrogen dioxid not stronger than a teaspoonful of the latter to a glass of warm water. Medicated chewing gum also promotes the natural self-cleansing of the mouth. Williger emphasizes that before beginning mercurial treatment the teeth should be put in good order, and all tartar removed.

Ulcerative stomatitis he treats by swabbing with undiluted hydrogen dioxid, repeating this until the fetor has disappeared. The tartar is then removed, not too forcibly, and the ulcerations are swabbed and rubbed quickly with an eight per cent. solution of zinc chlorid. The patient rinses his mouth every hour with the warm, weak hydrogen dioxid solution, and cleans out the mouth besides three times a day with the cotton-wrapped finger. Then the rest of the tartar is removed, and by the third day the ulcers are healing and at the end of a week the cure is complete. Instead of the zinc chlorid, a mixture may be used consisting of a little iodoform and a few drops of alcohol with enough of an 80 per cent. solution of lactic acid to make a thin paste. The tooth-brush hitherto used must be burned.

Aphthous stomatitis requires just the reverse, viz, avoidance of every irritating substance, and merely warm sodium bicarbonate or boric acid solutions to be held in the mouth for five minutes, the mouth thus to be rinsed out six times a day. The aphthæ can be touched with 3 per cent. boric acid glycerin, which is liked by children. Drug stomatitis may range from simple edema to blisters and necrotic patches. It requires mild treatment.

RÉSUMÉS OF PAPERS PRESENTED AT THE SIXTH INTERNATIONAL DENTAL CONGRESS,

London, Eng., August 3, 1914.

SECTION I.—*Dental Anatomy, Histology, and Physiology.*

CALCIFICATION OF THE ENAMEL. By Univ.-Prof. Dr. Med. O. Walkhoff, Munich, Germany.

Calcification of the enamel depends upon the ameloblasts only before the eruption of the teeth. Most anomalies in the structure of the enamel are brought about by arrests in the development while the ameloblasts are active. Anomalies of the enamel structure are important with regard to caries.

SECTION III.—*Dental Surgery and Therapeutics.*

PYORRHEA ALVEOLARIS. By Dr. Maurice Roy, Paris, France.

The essayist gives a definition, and maintains that pericemental abscesses are really pyorrhea abscesses. He indicates how to recognize initial lesions of alveolar pyorrhea.

Senile alveolar absorption is the initial lesion of pyorrhea, which is always present and precedes all others, being due to absolutely constitutional complaints. All causes stated to be local are only accessory causes. Pyorrhea is caused by the first lesion, but will not reach the advanced stage unless local accessory complications arise. Prophylactic treatment therefore depends chiefly upon general treatment.

The normal function of teeth attacked by pyorrhea is a desirable element, and therefore should be restored if destroyed. Hygienic conditions are essential in the treatment of the disease, and the dentist must carefully study his patient for its prophylactic treatment.

A COMPARISON OF INLAYS WITH FILLINGS. By Zahnarzt H. W. C. Bödecker, B.S., D.D.S., M.D., Berlin, Germany.

In presenting this subject, the intra-oral conditions have been chosen as a basis of comparison for the various fillings, as these conditions are the most important factor in determining predisposition or immunity to primary and therefore also to secondary caries. These conditions depend upon the chemical composition of the saliva, the hygienic condition of the mouth, and upon the histological structure of the dental tissues. The fillings are compared, with the following point in view: What effects have intra-oral conditions upon the various filling materials, and can the fillings in any way influence these conditions?

SECTION V.—*Dental Prosthesis.*

THE MOVEMENTS OF THE LOWER JAW IN RELATION TO DENTAL PROSTHESIS. By Docent Bloch, Copenhagen, Denmark.

This paper tends to prove how difficult it is to imitate with any degree of exactness the movements of the lower jaw, none of these movements taking place about any fixed axis. The essayist points out the difficulty of recording movements of the jaw. He maintains that these movements do not take place about any fixed axis, and emphasizes the impossibility of constructing articulators capable of imitating the movements in action, concluding that all "anatomical" articulators are of little practical value.

SECTION VII.—*Oral Surgery and Surgical Prosthesis.*

SURGERY OF THE MAXILLA: POST-OPERATIVE TREATMENT BY IODIC FILLINGS. By Dr. B. Landete, Madrid, Spain.

After operation upon the maxillæ, there remain bony cavities which we commonly fill with medicated gauzes, and which take long to become definitely cured, and in the meanwhile require constant care.

To avoid this inconvenience, the essayist has tried the filling of the bony cavities with different iodic pastes, the results being exceedingly satisfactory.

He has used for the purpose Mosetig's iodoform mixture, but objections on account of the smell have induced him to change the formula. The paste consists of iodol-iodocresol-azodolene-nosophene, etc.—10 per cent. of these products to be mixed with 50

parts of spermaceti and 50 parts of cinnamon and lemon essences, etc. He still uses local anesthetics to avoid pain when filling the alveolus of the teeth extracted on account of periodontitis.

He uses a glass syringe previously warmed, in order to make the paste fluid, as it becomes hard when cooling.

SECTION IX.—*Oral Hygiene, Public Instruction, and Public Dental Services.*

DENTISTRY IN THE ARMY. By R. M. WORMALD, L.D.S.ENG., DENTAL SURGEON TO TROOPS, PRESTON BARRACKS, BRIGHTON, AND GARRISON, NEWHAVEN; HON. ASST. DENT. SURG. BRIGHTON, HOVE, AND PRESTON DENT. HOSP.; DENT. SURG. TO BRIGHTON AND DISTRICT PUBLIC DENTAL SERVICE, BRIGHTON, ENG.

The teeth of the British soldiers are in a terrible condition, and more attention ought to be given to dentistry in the army.

The treatment given at present is of a go-as-you-please character, there being no system or order.

It is very short-sighted policy of the government not to provide an efficient dental service by having commissioned dental surgeons holding the same rank and status as an officer of the R.A.M.C.

Up-to-date dental treatment is essential to keep up the fighting strength of an army, because men with a non-efficient dental apparatus are soon *hors de combat* on account of their inability to masticate the hard biscuits, which have been found the only reliable food on such occasions.

An efficient masticatory apparatus would help in no small degree to fight one of the deadliest foes in war, *i.e.* fever.

A well-organized dental service in the army would bring about many blessings, not only to the soldier individually, but to the nation as a whole.

PERISCOPE.

Removing Modeling Composition Adhering to Vessels.—Particles of modeling composition often stick to the floor and the walls of the vessels in which the water is heated for softening the compound before taking the impression or separating the cast from the impression. To remove these particles, a soda solution is boiled in the vessel, when the compound will come off by itself.—*Technische Rundschau.*

The Future Rôle of Orthodontia.—With preventive measures, healthy environment, earlier treatment, and higher ideal, even comparatively slight malalinements of individual teeth will be corrected. Such defects will not be neglected as being merely of esthetic importance. I look to the time when the Greek ideal of physical perfection may be recovered, and when a stigma will rest upon any parent who allows his child to grow up with any remediable deformity perpetuated. In certain classes of the community, this condition obtains today. All that is necessary is wider and more general knowledge and appreciation. Prevention will reduce the amount of curative work to be done, and we hope that what has to be done will come so much more and more under the fostering care of the state that nearly every child may reach maturity so perfectly equipped in health, physique, and the beauty that comes of these, as to make him one of a finer race of citizens than the world has yet seen, able to acquit themselves like men, and do for the next generation what has been done for them. —N. G. BENNETT, *Ash's Canadian Monthly Circular.*

Avoiding Bubbles in Casting.—The investment compound is not painted on the wax model, but dropped thereon from a toothpick wound with a wisp of cotton and charged with investment compound. The investment may also be squirted upon the model from a syringe. If all other steps of the casting process are carried out carefully, the cast will be perfectly smooth, and the inlay will go to place without grinding.—*Zahnärztliche Orthopädie und Prothese.*

A Mild Caustic.—We not infrequently find gum tissue around the margins of a root grown up into ragged prominences. These may be gotten rid of by applying a little burnt alum.—*Edwards' Dental Quarterly.*

Arresting Post-extraction Hemorrhage.—In post-extraction bleeding, a tampon of cotton saturated in a five per cent. solution of iodin in chloroform is introduced into the empty alveolus, inducing prompt arrest of the hemorrhage.—*Edwards' Dental Quarterly.*

Receding Gums.—Glycerit of tannin, made by dissolving 1 oz. of tannic acid in 4 oz. of glycerin by gentle heating, is applied to spongy or debilitated gums as a tonic astringent lotion. It condenses the soft gums and re-establishes the nutritive functions.—*Dental Surgeon.*

Dissolving Plaster from a Vulcanite Plate.—The last traces of plaster can be entirely removed from a plate by placing it in a solution of hydrochloric acid two parts, and water one part, for five minutes. The plate is then cleansed with a stiff brush.—*Australian Journ. of Dentistry.*

Tincture of Benzoin.—If from any cause the alveolar process has been exposed, pain can be instantly relieved by covering the exposure with a pellet of cotton saturated with tincture of benzoin. The application is also valuable in relieving the painful eruption of third molars.—*Dental Surgeon.*

Protecting Gums in Polishing.—To protect the gums from encroachment of polishing strips, cotton root-canal points are drawn into the interdental spaces as far as they will go. This not only protects the gums, but prevents cutting of the rubber dam, with its subsequent annoyances.—O. L. Beeson, *Nebraska Dental Journal.*

Causes for Failures in Nitrous Oxid and Oxygen Analgesia.—There are eight reasons why not all operators who employ analgesia are successful. These are lack of self-confidence, unfamiliarity with the minute regulation of the apparatus, the placing of too much dependence upon a mechanical appliance, unfamiliarity with the fundamental principles of producing analgesia, overlooking of the necessity of using pure gases, ignorance as to how to introduce analgesia in new patients and obtaining their absolute confidence, the use of an impractical nasal inhaler, and disregard of suggestive therapeutics.—A. E. Smith, *Northwest Journ. of Dentistry.*

Taking Impressions with Modeling Composition.—When the composition has been properly molded on the tray, the external surface of the tray is immersed for a few seconds in cold water, thus preventing the heated metal from causing discomfort and pain to the lips. After drying, the surface of the modeling composition is dusted with French chalk of fine quality, and the impression is taken. This method produces an impression of very fine definition, the composition does not stick to the teeth, and the result is pleasing to both dentist and patient.—P. M. Coughlin, *Commonwealth Dental Review.*

Care of Bridge Work.—The proper care of dental bridge work is often and indeed usually wantonly neglected by the patient. The dentist, however, is largely responsible for failure to observe the same degree of hygiene in mouths in which either fixed or removable structures are worn that is and should be observed in the mouths of those who are so fortunate as to possess a full complement of good natural teeth. To this end the dentist should properly instruct the patient as to the necessity for and best means of keeping the mouth and the work in a thoroughly sanitary condition, as an invariable practice and a religious duty.—H. J. Goslee, *Dental Summary.*

Mouth-Breathing: Its Causes and Results.—Nose-breathing has three purposes, viz, to warm the inspired air, to add moisture to it, and to remove from it mechanical, chemical, and bacterial impurities. Infection with tubercle bacilli is predisposed to by mouth-breathing. Some of the results which may follow mouth-breathing are as follows: (1) Changes in the thorax, which, especially in the child, may result in want of expansion of the highest and lowest areas of the lung; ultimately, apical induration may result. (2) Anemia, which is secondary to disturbances of digestion resulting from insufficient mastication, and to poor appetite. (3) Mental damage, which may be quickly removed as the result of adenectomy.

As the most common cause of mouth-breathing, postnasal adenoids come easily first. Other causes are nasal synechia, hypertrophic rhinitis, and deviation of the nasal septum. As to disturbances of development of the jaws and teeth in children affected with adenoids, it is still a matter of discussion what in these anomalies is cause, what consequence, and what merely an accompaniment.—J. W. Samson, *Zahnärztliche Orthopädie und Prothese*, per *Universal Medical Record.*

An Adjunct in Pressure Anesthesia.—Sometimes when attempting to extirpate pulps under cocain pressure anesthesia, the pulps remain sensitive, as in idiosyncratic cases. I find that 95 per cent. alcohol instead of cocain acts immediately in producing the desired anesthesia in such cases.—A. S. Cambage, *Commonwealth Dental Review.*

Removing Modeling Compound from Impression Trays.—An easy method of removing modeling compound adhering to the tray after the impression has been removed consists in melting a small portion of dental wax in the tray, and then wiping out with a cloth. This will leave the tray clean and bright.—R. Purcell-Cohen, *Commonwealth Dental Review.*

Caries and Constipation.—According to Dr. Nevrezé, systematic caries is associated with other pathological conditions of the organism. The case reported is that of a boy, age thirteen, whose lower incisors showed an exacerbated sensibility. Owing to the fact that caries of these teeth but rarely occurs at this age, there must be some relation between the caries and an organic disease. When a bottle-baby of six months he had suffered from enteritis with diarrhea. At the age of three years he was again affected with enteritis and obstinate constipation, which had persisted since that time. The coincidence of the constipation with the period of calcification of the follicles of the lower incisors is striking. According to Vannier, constipation during infancy is a symptom of a tuberculous process of decalcification, with deposition in the intestine of mineral substances—calcium, iron, silicon—which interfere with secretions and consequently with the normal peristalsis. Simultaneously with the occurrence of the intestinal troubles there was infection of the developing teeth, with lacunar spaces, and the occurrence of caries was hastened by the increased virulence of the bacteria of the oral cavity and the lessened resistance of the tooth substance against bacterial invasion.—*Monde dentaire*, per *British Dental Journal.*

Hints, Queries, and Comments.

Obtaining a Good Plaster Impression for Upper Denture.

I have found the following method to be useful for obtaining a good plaster impression for either a partial or full upper denture. The plaster should be spread with a spatula against the palate and around the "heel" and the frenum before inserting the tray partially filled with mixed plaster, which is then carried to place in the usual way. The result is an impression free from air-spaces, and if the plaster has been introduced at the proper consistence, and before the setting process has proceeded to a point which interferes with the flow of the plaster batter, the result will be an accurate impression, not only of the teeth themselves, but of all the irregularities and the textural peculiarities of the gum tissue.

M. J. Linderholm, D.D.S.

Farmington, Iowa.

Gas-Lighter for Lighting Bunsen Burners.

To avoid the expense and untidy appearance of matches, a patent gas-lighter proves very satisfactory for lighting a Bunsen burner, which is so handy at the operating chair.

Wright B. Lee, D.D.S.

Eugene, Ore.

Preserving Inlay Casting Flasks Clean.

If, after casting, the investment material is jarred out of the casting flask while it is still warm, and the flask is wiped with a dry cloth, it will not rust or muss the sink, as when the flask is thrown into water. Five minutes after casting, no distortions are to be feared in a cast inlay; the warm investment material will easily come out, and the clean flask is ready for the next case.

Wright B. Lee, D.D.S.

Eugene, Ore.

A QUERY FOR THE PROSTHETIST.

THE patient in question has the upper two centrals and two laterals missing. The space between the remaining two canines is too broad for the insertion of four artificial teeth, and too narrow for that of six teeth, if that were possible from an esthetic point of view. What is to be done?

JULIUS PENSAK, D.D.S.

Brooklyn, N. Y.

METHOD OF STRENGTHENING A MODEL FOR SOLDERING BRIDGE WORK.

A VERY useful method of strengthening a model for soldering bridge work is employed in using bright steel screen wire, in suitable size, thoroughly embedded in the plaster investment.

S. T. NEILL, D.D.S.

Clinton, Mo.

OBITUARY.

DR. C. R. BUTLER.

[SEE FRONTISPIECE.]

DIED, December 15, 1914, at Cleveland, Ohio, in the eighty-third year of his age, CHARLES RICHARD BUTLER, D.D.S., M.D.

In the passing of Dr. Butler the dental profession loses one of its most esteemed members: the public loses one who for more than sixty years rendered humanity most excellent service.

Charles Richard Butler was born in Portage county, Ohio, June 28, 1832. His early life was spent on a farm, and later he became a brass and bell founder. When quite young he began the study of dentistry and medicine as a student of Dr. M. L. Wright of Cleveland. After three years of pupilage and practice, he was fortunate in being taken up by that enthusiastic and incomparable teacher, Dr. W. H. Atkinson, who fathered him as a student, assistant, and partner. Dr. Butler became known the country over as "Charlie," sometimes "Charlie Butler." In 1858 he was graduated from the Pennsylvania College of Dental Surgery, and in 1865 was graduated from the Cleveland (W. R. U.) Medical College.

He was taken by Dr. Elisha Sterling as an assistant in general surgery, becoming as well coached in the technique of general surgery as in dentistry—and he was ranked with the most skilful operators in the dental profession.

Dr. Butler was one of the charter members of the Ohio State Dental Society, which was organized in 1866, and was next to the last of the charter members to pass away.

He was president of the Ohio State Dental Society in 1875; president of the American Dental Association in 1888; president of the Cleveland Dental Society and an active worker in these and the Northern Ohio Dental Society. He served on the Ohio State Board of Dental Examiners from 1874 until 1892. In 1886 he was elected a member of the board of directors of the Ohio State Dental Society, and continued to serve in that capacity up to the time of his death.

Dr. Butler designed and gave the profession a number of instruments; plug finishing burs, mallet pluggers and excavators, many of which are still in use. His ability and love for doing fine work led him to the study and mounting of precious stones. Many close friends have much enjoyed viewing the product of his avocation and will long remember the enthusiasm and fondness with which he would show his collection.

Dr. Butler served his profession well as an ardent worker in our societies, while at the same time he rendered his *clientèle* most valuable service. The man will long be remembered, for he was a most kindly, courteous, and cheerful Christian gentleman. We regret that we shall no more see his face in our midst, but we are thankful to have known him. His death occurred on December 15th, after a few hours' illness.

He was a Knight Templar, and thirty-third degree Scottish Rite Mason, his funeral, on

Friday, December 18th, being in charge of the commandery at Cleveland.

H. R. C. W.

DR. J. MORGAN HOWE.

Died, November 13, 1914, in New York City, N. Y., in his seventy-first year J. Morgan Howe, D.D.S., M.D.

In the demise of Dr. J. Morgan Howe, the dental profession has lost a most active and prominent member.

The family of Dr. Howe lived in Sudbury, Mass., for six generations. His grandfather, Dr. Bezaleel Howe, served as captain in the guard of Gen. George Washington throughout the war of the revolution. His father was Dr. John Moffitt Howe, a dentist who practiced in New York City, where the deceased was born on October 19, 1844. In 1853 his father moved to Passaic, N. J., where he practiced until 1867, at the same time enjoying prominence in the educational affairs of that state.

After serving his dental apprenticeship with his father, the deceased started the practice of his chosen profession in New York City in 1867. He received the degree of M.D.S. from the New York state board, and that of M.D. from the New York Homeopathic Medical College in 1879.

The deceased was elected a member of the Odontological Society in 1879, and served for several years as corresponding secretary of this organization. He was one of the charter members of the New York Institute of Stomatology, and three times president thereof. He was a member of the Quill Club from 1895 to 1913.

In 1866 Dr. Howe married Miss Emma Rowe of Passaic, N. J., who died in 1904. In 1911 he married Miss Payne, who, together with three daughters and one son by his first wife, survives him.

During the latter years of his life, Dr. Howe was in charge of St. Bartholomew's Clinic, which he had organized. He was a firm believer in the strictest adherence to the code of ethics, and violently opposed to patents, nostrums, and secret formulæ. He was earnestly engaged in scientific investigation, and was one of the prime movers in the research movement started by the Institute of Stomatology and continued by the First District Dental Society, into which the Institute became merged.

DR. EZRA SPRAGUE HOLMES.

Died, November 11, 1914, in Reeds Lake sanatorium, whither failing health had forced him to move from Grand Rapids, Mich., Dr. Ezra Sprague Holmes, in his ninety-sixth year.

Almost a centenarian, after a life of untiring usefulness, Dr. E. S. Holmes of Grand Rapids, Mich., passed away on November 11, 1914, in Reeds Lake sanatorium, where he had been sojourning but four days in search of recuperation and new health. The deceased was born in Lockport, Niagara county, New York, on July 15, 1819. He took up his residence and practiced his chosen profession in Grand Rapids, Mich., in 1865, and was an important factor in the dental and scientific spheres of that city and state. His reputation as a practitioner was so great that he was offered a chair in the dental department of the University of Michigan, which honor he declined because of his large and exacting practice. He was president of the Grand Rapids Dental Society for two terms; also of the Michigan State Dental Society for the same period of time. As a sign of appreciation the Grand Rapids Dental Society changed its name to the E. S. Holmes Dental Club. He was the founder and for many years president of the Kent Scientific Institute, which developed into the Kent Scientific Museum.

Until his last illness, in which he was faithfully attended by his only surviving daughter, Miss Jennie W. Holmes, the deceased was in remarkably robust health, and displayed alertness of mind and a vivid interest in all matters pertaining to natural science, the study and promulgation of which played such an important part in his fruitful life-work.

Death of Dr. H. B. McFadden.

With great regret we announce the sudden death, from pneumonia, of Dr. H. B. McFadden, which occurred February 14th. A brief sketch of his career will be presented in the next issue of the Cosmos.

Society Notes and Announcements.

DENTAL SOCIETY MEETINGS: March, April, and May.

MARCH.

Oklahoma State Dental Association. Oklahoma City. Five days: March 15th to 19th.

APRIL.

Connecticut State Dental Association. Hartford. Three days: April 20th to 22d.

Kansas State Dental Association. Topeka. Three days: April 27th to 29th.

Michigan State Dental Society. Grand Rapids. Three days: April 15th to 17th.

Mississippi Dental Association. Jackson. Three days: April 20th to 22d.

Odontological Society of Western Pennsylvania. Pittsburgh. Two days: April 13th and 14th.

South Carolina State Dental Association. Columbia. Four days: April 27th to 30th.

Southern Minnesota District Dental Society. Mankato. Three days: April 12th to 14th.

MAY.

Dental Society of the State of New York. Albany. Three days: May 13th to 15th.

Illinois State Dental Society. Peoria. Four days: May 11th to 14th.

Indiana State Dental Association. Indianapolis. Three days: May 18th to 20th.

Lake Erie Dental Association. Cambridge Springs, Pa. Three days: May 20th to 22d.

Massachusetts Dental Society. Boston. Three days: May 5th to 7th.

Susquehanna Dental Association of Pa. Wilkes-Barre. Three days: May 18th to 20th.

Texas State Dental Association. Galveston. Four days: May 19th to 22d.

Examiners' Meetings.

Massachusetts Board of Registration. Boston. Three days: March 3d to 5th.

OKLAHOMA STATE DENTAL SOCIETY.

The next meeting of this society will be held in Oklahoma City, March 15, 16, 17, 18, and 19, 1915.

The meeting will be conducted somewhat along the same lines—the postgraduate plan—that has proved so valuable in this state the past few years.

The principal lecturers will be Drs. J. H. Prothero and W. H. G. Logan of Chicago. Dr. Prothero's lectures will be confined to important phases of prosthetic dentistry, while Dr. Logan will give lectures on modern methods of treating pyorrhea and on local anesthesia.

Reputable dentists from out of the state are welcome to this meeting, but are required to pay a fee of five dollars for the lectures and clinics.

C. R. Lawrence, *Sec'y*,
Enid, Okla.

ODONTOLOGICAL SOCIETY OF WESTERN PENNSYLVANIA.

The thirty-fourth annual meeting of the Odontological Society of Western Pennsylvania will be held at the Monongahela House, Pittsburgh, Pa., Tuesday and Wednesday, April 13 and 14, 1915.

The first regular session of the society will open on Tuesday at 10.30 A.M. The Executive Council will meet at the hotel at 10 A.M. for the transaction of business in the interest of the society.

The clinics and exhibits will be at the Monongahela House. Exhibitors are cordially invited to visit this meeting, and requested to make early reservation for space. Address Dr. Leslie Waddill, Jenkins Arcade, Pittsburgh, Pa.

A cordial invitation is extended to all ethical dentists in Pennsylvania and adjoining states.

King S. Perry, *Sec'y*,
719 Jenkins Bldg., Pittsburgh, Pa.

SECOND DISTRICT (N. Y.) DENTAL SOCIETY.

You are invited by the Second District (N. Y.) Dental Society to attend a dinner and meeting on Monday evening, April 12, 1915, in the new Hotel Bossert, Brooklyn, N. Y.

Reserve this evening for a meeting that will signalize a marked advance in scientific dentistry. Dr. Elmer S. Best of Minneapolis, Minn., will read his paper on "The Responsibility of the Dentist in Pulpless Teeth." This is the result of over two years' experiment, study, and trial. Some of the ablest men in the medical and dental professions will discuss this problem.

The dinner, an informal one, will be $ per person. Tables for six and eight will be reserved upon receipt of check made payable to Arthur M. Hunter, treasurer of the dinner committee, 67 Hanson Place, Brooklyn.

A. M. Nodine, *Chairman*,
F. C. Walker,
A. H. Hunter, *Committee*.

MICHIGAN STATE DENTAL SOCIETY.

The next meeting of the Michigan State Dental Society will be held at Grand Rapids, April 15, 16, and 17, 1915.

F. Ward Howlett, *Sec'y*, Jackson, Mich.

MISSISSIPPI DENTAL ASSOCIATION.

The fortieth annual meeting of the Mississippi Dental Association will be held in Jackson, April 20, 21, and 22, 1915.

M. B. Varnado, *Sec'y*, Osyka, Miss.

SOUTH CAROLINA STATE DENTAL ASSOCIATION.

Note Change of Date.

The annual meeting of the South Carolina State Dental Association will be held at the Jefferson Hotel, Columbia, S. C., April 27 to 30, 1915.

Special public session, devoted to the relationship of defective teeth to the public health, will be held in the afternoon and evening of April 29th.

P. D. Brooker, *President*,
Columbia, S. C.
E. C. Dye, *Sec'y*,
Greenville, S. C.

CONNECTICUT STATE DENTAL ASSOCIATION.

The fifty-first annual meeting of the Connecticut State Dental Association will be held at Hartford, Conn., April 20, 21, and 22, 1915.

Charles H. Riggs, *President*,
Hartford, Conn.
Elwyn R. Bryant, *Sec'y*,
New Haven, Conn.

KANSAS STATE DENTAL ASSOCIATION.

The Kansas State Dental Association will hold its next annual meeting at Topeka, Kans., April 27, 28, and 29, 1915.

A most unique program will be presented. Dr. Thos. P. Hinman of Atlanta, Ga., will be the guest of honor.

A. L. Benton, *Sec'y*,
Garnett, Kans.

SOUTHERN MINNESOTA DISTRICT DENTAL SOCIETY.

The Southern Minnesota District Dental Society will hold its annual meeting April 12, 13, and 14, 1915, at Mankato. A literary and clinical program will be carried out.

G. W. Norbis, *Sec'y*,
Tracy, Minn.

TEXAS STATE DENTAL ASSOCIATION.

The thirty-fifth annual meeting of the Texas State Dental Association will be held in Galveston, Texas, May 19, 20, 21, and 22, 1915. The special feature of this meeting will be postgraduate lectures and clinic work.

Dr. G. Walter Ditmar of Chicago will present modern scientific bridge work and removable partial dentures, with preparations, technique, and principles involved. Dr. B. F. Thielen will present "Plate Work." Dr. T. G. Duckworth, "Orthodontia." Dr. R. D. Griffis, "Nitrous Oxid Analgesia and Anesthesia." Dr. Julian Smith, "Pyorrhea." Dr. J. M. Murphy, "Local Anesthesia."

Exhibitors are requested to attend, and to write to Dr. A. L. Frew, Dallas, for space. General clinics, on last day. Clinicians will write Dr. W. H. Nugent, Fort Worth. For any other information write the secretary.

C. M. McCauley, *Pres.*, Dallas.
W. O. Talbot, *Sec'y-Treas.*, Fort Worth.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

THE forty-seventh annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May 13, 14, and 15, 1915.

The Executive Council will meet at the Hotel Ten Eyck, Wednesday afternoon, May 12th, at 3 P.M., for the transaction of business.

The first regular session of the society will open on Thursday at 10.30 A.M. The literary program will be rendered in the auditorium of the Educational Building. Headquarters for Officers and Executive Council will be at the Hotel Ten Eyck.

The clinics and exhibits will be at the Hotel Ten Eyck. Exhibitors are cordially invited to visit this meeting, and requested to make early reservations for space. Address Dr. O. J. Gross, Schenectady, N. Y., for space.

A cordial invitation is extended to all ethical dentists in New York and sister states.

A. P. BURKHART, *Sec'y*,
52 Genesee st., Auburn, N. Y.

ILLINOIS STATE DENTAL SOCIETY.

THE fifty-first annual meeting of the Illinois State Dental Society will be held at Peoria, May 11, 12, 13, and 14, 1915.

J. N. BARCUS, *President*,
HENRY L. WHIPPLE, *Sec'y*.

LAKE ERIE DENTAL ASSOCIATION.

THE fifty-second annual meeting of the Lake Erie Dental Association will be held at Hotel Bartlett, Cambridge Springs, Pa., May 20, 21, and 22, 1915.

J. F. SMITH, *Sec'y*,
Erie, Pa.

INDIANA STATE DENTAL ASSOCIATION

THE next annual meeting of the Indiana State Dental Association will be held in Indianapolis, on May 18, 19, and 20, 1915. A distinctive feature of this meeting will be that the program will be made up exclusively of Indiana dentists. A cordial invitation is extended to members of other dental societies to attend the meeting.

A. R. ROSS, *Sec'y*,
Lafayette, Ind.

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA.

THE fifty-second annual meeting of the Susquehanna Dental Association will be held at Irem Temple, Wilkes-Barre, Pa., May 18, 19, and 20, 1915.

GEO. C. KNOX, *Recording Sec'y*.

MASSACHUSETTS DENTAL SOCIETY.

THE fifty-first annual meeting of the Massachusetts Dental Society will be held May 5, 6, and 7, 1915, in the Hotel Somerset, Boston, Mass.

A. H. ST.C. CHASE, *Sec'y*.

LOUISIANA STATE DENTAL SOCIETY.

THE next Louisiana State Dental Society meeting will be held in New Orleans, La., June 3, 4, and 5, 1915, at the Grunewald Hotel.

P. W. TROWBRIDGE, *Sec'y*.

NORTH CAROLINA DENTAL SOCIETY.

THE next annual meeting of the North Carolina Dental Society will be held at Wrightsville Beach, June 23, 24, and 25, 1915.

R. M. SQUIRES, *Sec'y*,
Wake Forest, N. C.

NEW HAMPSHIRE DENTAL SOCIETY.

THE next meeting of the New Hampshire Dental Society will be held at the New Hotel Weirs, Weirs, N. H., June 22, 23, and 24, 1915.

C. S. COPELAND, *President*,
L. I. MOULTON, *Sec'y*.

MISSOURI STATE DENTAL ASSOCIATION.

CHANGE OF DATE OF MEETING.

THE Golden Jubilee meeting of the Missouri State Dental Association has been postponed until June 10, 11, and 12, 1915. Elaborate preparations are being made to celebrate the semi-centennial meeting of this association on an elaborate scale. See special announcements in the next issue of this journal. For information address

S. C. A. RUBEY, *Sec'y*,
1017 New York Life Bldg., Kansas City, Mo.

MASSACHUSETTS BOARD OF REGISTRATION.

A MEETING of the Massachusetts Board of Registration will be held in Boston, March 3, 4, and 5, 1915. For applications and further information apply to

G. E. MITCHELL, *Sec'y*,
14 Water st., Haverhill, Mass.

SOUTH CAROLINA BOARD OF EXAMINERS.

THE next annual meeting of the South Carolina State Board of Dental Examiners will be held at Columbia, S. C., beginning at 9 A. M., Tuesday, June 15, 1915.

All applications must be in the hands of the secretary not later than June 5th. Application blanks and instructions from

R. L. SPENCER, *Sec'y*,
Bennettsville, S. C.

EXAMINATION OF DENTISTS FOR THE U. S. ARMY.

THE Surgeon-general of the army announces that examinations for the appointment of acting dental surgeons will be held at Fort Slocum, New York; Columbus Barracks, Ohio; Jefferson Barracks, Missouri; Fort Logan, Colorado; and Fort McDowell, California, on Monday, April 12, 1915.

Application blanks and full information concerning these examinations can be procured by addressing the Surgeon-general U. S. Army, Washington, D. C.

The essential requirements to securing an invitation are that the applicant shall be a citizen of the United States, shall be between twenty-one and twenty-seven years of age, a graduate of a dental school legally authorized to confer the degree of D.D.S., and shall be of good moral character and habits.

Acting dental surgeons are employed under a three years' contract, at the rate of $150 per month. They are entitled to traveling allowances in obeying their first orders, in changing stations, and in returning to their homes at termination of service. They also have the privilege of purchasing certain supplies at the army commissary. After three years' service, if found qualified, they are promoted to the grade of dental surgeon, with the rank of first lieutenant, and receive thereafter the pay and allowances appertaining to that rank.

In order to perfect all necessary arrangements for the examination, applications must be in the possession of the Surgeon-general at least two weeks before the date of examination. Early attention is therefore enjoined upon all intending applicants. There will be nine vacancies to be filled.

UNITED STATES PATENTS

PERTAINING OR APPLICABLE TO DENTISTRY

ISSUED DURING JANUARY 1915.

January 5.

No. 1,123,830, to ERIC ZINCKE and CLINTON H. BULL. Dental cabinet.

No. 1,124,099, to WILLIAM A. ADAMS. Dental casting apparatus.

January 12.

No. 1,124,299, to ALBERT B. COSAD and CHARLES F. WISE. Dental saliva tube.

No. 1,124,498, to CHARLES W. MILLAR. Dental inlay holder.

No. 1,124,728, to JAMES F. HARDY. Dental broach-cutting machine.

January 19.

No. 1,125,168, to FRANK E. PERKINS. Right-angle handpiece.

No. 1,125,532, to EARL HIMMEL. Tooth-brush.

No. 1,125,576, to MORTON MAIER. Bridge measuring device.

DR. HENRY B. McFADDEN

THE

DENTAL COSMOS.

VOL. LVII. APRIL 1915. No. 4.

ORIGINAL COMMUNICATIONS.

DENTAL AND FACIAL PROSTHESIS IN THE PHILIPPINES:

Prosthetic Noses, Upper Lips, Lower Lip, Ear, Eyes, and Obturator.

By LOUIS OTTOFY, D.D.S., Manila, P. I.

(Report presented to Section VII of the Sixth International Dental Congress, London, 1914.)

IN 1905 I reported a case of an "Artificial Nose for a Chinaman," which was published in the May 1905 issue of the DENTAL COSMOS. As I desire to have all the prosthetic cases of this nature made by me up to the present time published *en groupe,* I here insert the article with the illustrations:

"Wee Cheong, the subject of this article, claims to have lost his nose when he was a child, as the result of a blow inflicted by a playmate. There is nothing extraordinary about the substitute which I made for him, except that it is the first work of this kind in the Philippine Islands, and possibly the first substitute of its kind ever made for and worn by a native of the celestial kingdom.

"The substitute is retained in position by the spectacles above and by two small rubber hooks extending into the nostrils below. It is made of vulcanite and has been artistically painted by a famous native portrait artist. He has reproduced the color—a muddy yellow—to perfection, and added some of the defects of other portions of the face in the form of discoloration of the skin, which, however, does not show in the illustrations.

"The photographs (unlike most of those which I have seen) from which the illustrations (Figs. 1, 2, 3, and 4) are made have not been retouched in the slightest degree, and the partly imperfect adaptation of the lower portion of the piece is shown as it really exists. This is due to the fact that the remains of the nostrils are very small, and admitted of but little attachment. Within ten feet the substitute cannot be recognized, and it is, indeed, discernible only on close inspection, the deception being aided by the fact that of all things the last to look for on a Chinaman's face is an artificial nose. The man without the piece is extremely repulsive.

"Anyone who is observant will have noticed in Manila that such injuries as

Fig. 1.

Fig. 2.

the loss of arms and legs are extremely rare, due to the absence of factories, no night trains. On the other hand, repulsive defects of the face, the loss of large portions of the soft tissues, including the nose, hare-lip, etc., seem to be

Fig. 3.

Fig. 4.

street-cars, railroads, etc. The only railroad in the islands runs its trains slowly, and only in daytime, there being met with greater frequency. I am of the opinion that this is not necessarily due to a larger number of these cases, but

to the fact that no remedy is applied, and the loss sustained is often greater than would be the case in almost any part of the United States or elsewhere where surgical aid would intervene. Practically nothing has been done here to remedy hare-lip in early age; and other affections of the face usually terminate by exhaustion rather than surgical or medical interference."

In connection with this case it is only just to state that the observation I made to the effect that this is the first case of an artificial (prosthetic) nose made for a Chinaman, or in the Philippines, is, in view of subsequent information, not correct—albeit it is, so far as I know at the present time (1914), the first practicable and serviceable case.

A Chinaman who has seen the photographs from which the above illustrations were made, informed me that he knew one of his countrymen for whom an artificial nose was made by a Filipino dentist. After considerable search the man was found, and he had in his possession an artistic substitute, carved of wood, very light, and of excellent form and color. It was intended to be retained *in situ* in the lower part by a metal screw which extended into the nostrils, and for retention on the bridge of the nose it depended on some sticky substance; at the time the piece was given to me, the substance last used was shoemaker's wax. The Chinaman stated that he could not keep it in place with any kind of wax, as in this climate the wax would soften or melt, and for that reason the substitute was of no practical value.

Finally, another interesting point which may be mentioned in connection with Wee Cheong's case is this: He went to Amoy, China, for the New Year's festivities, as many of the Chinamen are wont to do annually. Finding a friend who was minus a nose, Cheong sold his own nose to him, trusting that on his return I would make another nose for him, like the first one—gratis. This I at first declined to do, and by the time I repented, inquiry developed the fact that Wee Cheong had returned to China to live and eventually to die among his countrymen.

Including the above case, I record in this report seventeen cases of prosthesis of various nature, made for sixteen individuals, as follows:

	Cases.
Prosthetic noses	9
" upper lips	3
" eyes with surrounding tissues	2
Prosthetic lower lip	1
" ear	1
Obturator for cleft palate	1

I trust a description of these cases will be of interest; they certainly indicate to what extent the results of civilization have penetrated into remote sections of the world. Some of these substitutes are worn by people who less than a generation ago were hardly known to the white man.

Prosthetic Nose No. 2.

This is a Filipino fisherman of Malabon, Rizal province; September 1908. In this case, as in all others, it is impossible to ascertain the cause of the disease which resulted in the loss. I am of the opinion that they are not of a syphilitic nature (except case No. 8), but that they are the result of some type of lupus. This man is forty years of age, and states that when he was twenty a sore appeared on one of the alæ of the nose, and that this continued to spread and spread, and that for nearly three years the process of destruction continued, until it involved the entire nose, mouth, lower part of the face, and the palate. The condition at present shows the total loss of the nose, cicatrization of a considerable part of the face, and destruction of the lips to such an extent that the attempt to open the mouth results in a round orifice the size of an American quarter-dollar. A cleft extends through the entire palate, three-quarters of an inch in width, with loss of the uvula and the entire upper denture.

I arranged with a surgeon to extend the opening of the mouth at the angles,

and also arranged for free care of the man at a hospital, it having been my intention to make for him an obturator and upper denture when the mouth should be enlarged for that purpose. The man, however, was timid, and fear led him to forego the operation, although he was assured that it would be painless.

Fig. 5.

Fig. 6.

The first nasal substitute I made for him was retained in place by gold springs which extended into the nostrils. But when the springs were tightened so as to hold the piece firmly against the

Fig. 7.

Fig. 8.

face, the margins of the orifice were irritated, and when the pressure of the springs was released the piece could not be retained in place. Hence the nose shown in the illustration is held firmly in position by a hook of vulcanite below, and by the spectacles above. None of these or of the preceding and succeeding photographs are retouched, or in any way altered or improved, so that they indicate, as nearly as the camera can reproduce them, the improvements as well as the defects. (See Figs. 5, 6, 7, and 8.)

Prosthetic Nose No. 3 and Lower Lip.

This case is an exceedingly interesting one. These substitutes were made in October 1909, at Daet, Ambos Camarines province. The woman, Apolonia Panotes, was forty-five years of age, married, and claimed that twenty-one years ago she was attacked with a disease, which ran its course, and left the ravages only imperfectly shown in the pictures —unsatisfactory photographs which I obtained through a native photographer. Such a diagnosis is very unsatisfactory, but it is the best obtainable. This case is especially interesting because of the remarkable improvement in the appearance of the patient, notwithstanding the imperfect transmission of the improvement in the full-face view. A face minus the nose is in itself a painful sight to behold, but in the case of this woman the loss of the lower lip made her appearance hideous, reminding one of the dead.

The accompanying illustrations give a full face and a profile view, with and without the substitutes. The photographs cannot convey the hideousness in its full enormity, because, in the first place, the skin of the entire face except the forehead is covered with ugly blotches, having on the dark-brown background of the Filipino skin, rings and circles of what appear to be cicatrices, such as I have seen as the result of prairie fires in the territory of Dakota, years ago; they are white and red blotches, in places running into each other, so that there is really no distinguishable color, except that the native

Fig. 9.

brown prevails. The eyelashes are absent, in one of the eyes the sight is wanting, the cornea is white and bulg-

Fig. 10.

ing, while in both of the eyes the conjunctiva is intensely hyperemic.

There are no remains of the nose or

nostrils and there seems to be no cicatrix to indicate that she ever had a nose.

Fig. 11.

In place of the nasal organ there is merely a depression. All the upper

Fig. 12.

teeth are missing. Beginning at the angle of the mouth, the lower lip is missing, the loss taking a semilunar form, so that at the median line (the deepest part) the loss extends down one inch from where the margin of the lip should be. By reason of exposure to the air the gums have receded until the teeth are denuded of gum and bone to the apices of the roots. No one can see the face for the first time without experiencing a most disagreeable shock. (See Figs. 9, 10, 11, and 12.)

The substitutes are made of vulcanite, the nose being held in place above by the spectacles and below by a small vulcanite hook, which follows the median line across the upper lip and extends into the mouth. The lower prosthetic lip is held in place by two gold hooks, which clamp on the lower canines and hold the piece firmly in position and in apposition with the margins of the living tissues. In this case I feel that the actual improvement is not truthfully reproduced by the camera.

When the substitutes were completed I was sorely disappointed, for the improvements in her appearance did not coincide with my previously conceived mental picture. However, replacing the white glass of the spectacles with amber-colored glass yielded a satisfactorily result, inasmuch as they concealed from view the hideously grotesque eyes.

I was subsequently informed that this woman had confined herself to the house for so many years that on the first attempt to walk the streets for the purpose of attending church, a privilege so long denied her, she had to be supported.

Prosthetic Nose No. 4.

This is a case of a Filipino laborer in Tuguegarao, province of Cagayan; May 1910. In this, as in the others, there is no reliable history. Whatever the cause, the consequences are shown to be serious. The nose is gone, the face is badly cicatrized, the lips are extroverted, and what is the most repulsive of all (not shown without color) is the loss of the eyelashes and the extroversion of the lower lids of the eyes. They are chronically inflamed, excessively red and watery.

In this case I used large smoked

crystals in the spectacles, which concealed all the ugliness of the eyes: the spectacles also hold the nose in place above, while below it is held in place by a hook which passes into the nostrils. Unfortunately, when the case was finished, the copious rains and storms prevented the taking of the pictures, and hence I have been obliged to rely on drawings, which quite fairly reproduce the results attained. (See Figs. 13, 14, 15, and 16.)

Fig. 13.

Fig. 14.

Fig. 15.

Fig. 16.

Prosthetic Nose No. 5.

This is the case of a poor native at Hagan, province of Isabela; May 1910.

Fig. 17.

Fig. 18.

Fig. 19.

Fig. 20.

His face is deeply marked, not unlike smallpox, and the remnant of the nose resembles a strawberry, but is really a warty, ugly substance. The profile resembles an ape. For want of time the photographs were taken while the paint was fresh, and when the brilliancy due to the reflection of the light from the paint has moderated, the improvement will be accentuated. The substitute is made of vulcanite, held in place above by the spectacles and below by a hook

of vulcanite which extends into the nostrils, passing under the wart-like remnant of the nose. (See Figs. 17, 18, 19, and 20.)

Fig. 21.

Fig. 22.

Fig. 23.

Fig. 24.

Prosthetic Nose No. 6.

This is also a poor Filipino, living in Malabon, Rizal province; September 1910. His case, and the next two, present no special features. The nose is held in place by the spectacles and below by a hook which passes into the remnant of the nostrils. Two of the views are from drawings. (See Figs. 21, 22, 23, and 24.)

Prosthetic Nose No. 7.

This is another poor Filipino, a charity case at the Philippine General Hospital, Manila, October 1911, where he had been operated on. (See Figs. 25, 26, 27, and 28.)

Prosthetic Nose No. 8.

This is also a native. He was driving a public vehicle on the streets of Manila. I picked him up and made the piece for him. He is the only one who was in an actively diseased condi-

Fig. 25.

Fig. 26.

Fig. 27.

Fig. 28.

tion at the time of making the prosthetic substitute; November 1913. He has a remarkable protrusion of the lower lip, for which there is no remedy. (See Figs. 29, 30, 31, and 32.)

Fig. 29.

Fig. 30.

Fig. 31.

Fig. 32.

Prosthetic Nose No. 9.

Filipino; Manila, February 1914. This man is a carrier for one of the Spanish dailies. In this as in the other cases, there is no reliable history. His face is exceedingly repulsive, because the cicatrization of the remnant of the nose left it in an irregular wart-like condition. Furthermore, the injury extends to and includes a considerable portion of the upper lip. The cicatri-

zation above the lip is such that he is unable to close the mouth, the upper lip being contracted in a semilunar shape, exposing a gap whence he lost the left central and lateral incisors. At first I extended the vulcanite of which the nose is made, down over the upper lip to fill out the spaces lost from it, but I found that the mobility of the lip in speaking made this impracticable, hence the nose is, as in the other cases, held in place by the spectacles and a hook of vulcanite extending into the nostrils. Fortunately, an exceptionally good color was

Fig. 33.

Fig. 34.

Fig. 35.

Fig. 36.

secured, and the insertion of artificial teeth improved his appearance, because his mouth is perforce always open, exposing now the teeth in place of the former gap.

I made some interesting observations with this man to note to what extent such injury or substitute is observed by people who pass him on the street. I had him walk along ahead of me on the crowded street without the substitute, and watched the faces of those who passed him. Excepting people who were interested in the show windows, engaged in conversation, or otherwise preoccupied, hardly a person passed him who did not take a fleeting notice of his deformity. The faces of many, especially those of the women, had passing over their countenance a momentary expression of pity or revulsion, and they would suddenly turn their faces away.

Then I had him put on the substitute, and I followed him until about an equal number of people had passed him. Not the slightest notice of him was taken by anyone; he moved along in the throng as one of his own people and as one just like them. Then I stopped with him on the sidewalk in such a way that we obstructed the pedestrians, and while some looked at him with an expression of annoyance, I am certain no one took notice of his deformity or its artificial remedy. I take it that this is not due so much to the perfection of the substitute as to the fact that people naturally are not looking for "false" noses, ears, or lips. Sometimes one may be suspicious of a glass eye, or of artificial teeth, because they are more common, and I apprehend that often suspicion may have good foundation when it comes to a substituted complexion or hirsute adornment. (See Figs. 33, 34, 35, and 36.)

In one of the cases described in this paper, after several times calling the attention of an intelligent gentleman to the face of a man who stood in a good light some ten feet away, and whose physiognomy was at the time adorned with a prosthetic nose, the gentleman finally did notice that "There is something strange about that man's nose." But he was unable to decide just what it was, never having heard of such a thing as a "false" nose; and of all places he would not have been looking for one in so far out of a way place as Manila, and certainly not in the case of a man whose appearance denoted him to belong to the lower and poorer strata of the community.

Prosthetic Upper Lip No. 1.

This case is that of a Filipino youth, age eighteen, Policarpo Calderon, residence Echague, province of Isabela; substitute made at Ilagan, same province, June 1910. This is one of the most repulsive cases I have ever seen. It did not occur to me to have profiles made of his features—unfortunately, as the enormous protrusion is not well shown in the full-face view, nor is the improvement made by the substitute as apparent. The division superintendent of schools, an American—who, by the way, suggested the mustache—stated that the photographs do not convey a correct idea of the enormity of the disfigurement, nor justly present the result of the improvement. This is due to the fact that the photographs do not show the receded, raw, and bleeding gums, the oozing saliva, the filthiness of the teeth, the dribbling at the corners of the mouth, and—as might have been shown in a profile view—the extreme protrusion of the teeth. While the photograph of the finished case shows the prosthetic piece as being apparently white in color, it is in fact a pink-brown, corresponding with the color of the skin. The white appearance of the prosthetic lip is, I think, due to the fact that, it being necessary to have the photograph taken while the paint was fresh, it reflects the light, giving it a luster it does not possess when viewed by the eye. Because the photograph was taken shortly after the lower teeth were extracted, the sockets of the teeth, which are located in the lower lip, are also visible. Those who had formerly seen the young man passing along the street did not believe that such a transformation could be made until they were actually convinced.

His story is as follows: When he was six years of age he bought some native candy which, it was subsequently supposed, contained some poison. In any event, within a week after eating the candy a sore appeared on the upper lip, and this continued to spread, involving more and more of the tissues, the lips and mouth becoming enormously swollen. The disease continued for a year, when it subsided, with the result shown. (See Figs. 37 and 38.)

Fig. 37.

Fig. 38.

On examination it will be found that the left ala of the nose is lost, and the lips at the angles of the mouth are cicatrized so that he can open the mouth to so limited an extent that in the region of the first bicuspids the separation of the lower from the upper teeth is possible only to the extent of a quarter of an inch. While his speech is understandable, articulation is indistinct. Above and below the remnants of the lips, the gums and teeth and the maxillary bones and the mandible are as one; so that the appearance is as though the teeth had grown out of the lips, which are of a dirty brown mixed with the original pink color of the lips. In the lower jaw the right lateral incisor contained a dead pulp and was discolored; the right lower central incisor had decayed so that there was only the root left. In the upper jaw the teeth were irregular and exceedingly protruding, unfortunately not well shown in Fig. 37.

At first it was my intention to make an upper and a lower lip, but after extracting the four lower incisors and the lower left canine and first bicuspid the improvement was so marked that I decided to do nothing more about the lower lip, as I was of the opinion that after the usual absorption of the process and the healing of the wounds, the lower lip would be fairly presentable.

In the upper jaw I ground off the prominent portions of the central incisors and of the left canine, thus materially reducing the protrusion. Had there been some other dentist with whom to divide the responsibility I would have removed some of the upper teeth. It must be understood that this case was under my care away up in the interior of the country, among people who are more or less superstitious, and any untoward symptom, such as profuse hemorrhage or some slight fracture of the alveolar process, might have resulted seriously—that is, personally to me—as I shall prove shortly in connection with

the relation of something that happened a few days later at this same place.

The upper lip was made to fit a model from a plaster-of-Paris impression, and is firmly held in position by means of gold caps which fit over the right canine and left first bicuspid, the caps being vulcanized into the rubber. As I have never before made a mustache, the result was not quite satisfactory. In the first place I could not get any black beard hair of a sufficient length in the town, and hence I bought a few curly locks from a Negrito—one of the aborigines of the islands, uncivilized and non-Christian, some of whom happened to be in town. But as they were probably not pure Negritos, the hair was not kinky and stiff, but smooth, wavy, and long. As I could not get enough of this hair, it had to be pieced out with the head hair of the native himself; this was straight and oily, and not easy (for me) to sew on to the gauze, which in turn was sewed to the prosthetic lip. Later I had a mustache made by a wig-maker, with better result, and sent it on. The mustache conceals the margin between the piece and the living tissues.

As some of the photographs preceding and some of those to follow do not represent high skill in the photographic art—and in fact in some instances no photos could be secured at all—with also the difficulty of making Chinese or native photographers understand just what was wanted, I show [see footnote] a photo taken in a case in which the Chinese photographer was requested to photograph only the mouth, and make it "plenty big," so as to show the deposit on the teeth as plainly as possible. He assured me that it would be "velly big"—with the result that not only are the woman and I in it, full size, but considerable of the surrounding scenery as well! As to showing what I actually wanted, its value is almost *nil*.*

However, it will not be out of place to describe what I vainly desired to illustrate. This is the case of a Kalinga woman whom I happened to meet on the street. These people live in the mountains, are partly civilized, and make occasional visits to the near-by towns for the purposes of trade. They resemble the Igorots, Ifugaos, Ibanaos and other similar tribes, which, though differing from each other, have something in common. The Kalingas blacken their teeth with a product made from the bark of a tree. The acidity of the material roughens the teeth as they chew it, and then intensely black, shiny coats, one after another, become deposited, until the teeth are as black and as polished as anthracite coal. In the case of this woman—and I was informed it is common among the women—when the lips are closed and at rest there is a thick, black, rounded line visible from one angle of the mouth to the other, which is considered by them to be *very pretty*. On closer examination I found that there was a heavy deposit, or rather a building up, out of this substance, extending from canine to canine in the upper jaw; it was so uniform and smooth that I felt positive that it could not have been built up with a semi-plastic substance which afterward hardened, but that it must be held in place by a wire, or some fiber of a plant, which was embedded in it.

The Hon. Dean C. Worcester, who is an authority on the non-Christian tribes of the Philippines and who has carefully described the customs of these people, and other persons who have also studied these and other wild tribes, have made no reference to this building-up of the deposit—possibly not observing it as a dentist would do. A Spanish gentleman, who was conversant with their dialect, kindly obtained this information for me: The women first grind the labial surfaces of the upper anterior teeth with a stone, until the teeth are concave, then they carefully build up this deposit, layer by layer, as it hardens, until it assumes the proportions and shape mentioned. Furthermore, they are exceedingly proud when the result is an even line between the lips, and they take good

* [For which reason the picture—No. "39" of Dr. Ottofy's series—is not reproduced in the DENTAL COSMOS.—ED.]

care not to injure it. With a magnifying glass the deposit may be readily seen. Something that seems white in the mouth is a view not of the teeth but of the gums.

For the permission to take the picture, the interpreter told me that she and her party would have to have a drink of gin at my expense, to which I consented—ignorant at the time of the fact that there is a law against giving or selling intoxicants to members of any of the wild tribes. After the gin I induced the interpreter to ask her to permit me to take an impression—with which quite a quantity of this carefully made deposit, in which so much pride was taken, came away with the plaster-of-Paris. It left the deposit rough and irregular, and the "beauty" of her years of care and labor was destroyed! When she made the discovery of the damage there was some warm, indeed hot, Kalinga lingo passing back and forth between her and her five companions, three of whom were men. Remembering that it was not far from where I then was that Professor Jones of the Field Columbian Museum of Chicago, in quest of scientific data, was killed, not so very long before that time, for some indiscretion against these same people, I promptly suggested more gin, had the drinks made of double the quantity, and while it was taking effect I somehow disappeared, and curiously enough my whereabouts was unknown until the wildly gesticulating and threateningly muttering Kalingas had left the town. Next morning I learned that they left under considerable sense of provocation, while the woman had her fingers in her mouth, making digital examination of the damage.

Prosthetic Upper Lip No. 2.

This is the case of a Filipino laborer on the sugar plantation of Welch, Havemeyer & Fairchild, on the estate at San José, island of Mindoro, about which there was some sensational U. S. Congressional investigation in connection with the "Friar lands," some years ago. The man was about twenty-five years of age when this piece was made for him, in August 1913.

Fig. 40.

Like the others, he could give no reliable information. It appears that he had suffered some injury, but of this he

Fig. 41.

knows nothing. His right eye had been wounded, so that it is sightless; the eyeball having never been removed, there

is a constant dribbling of the lacrimal fluid down his cheek beside the nose, where there is also a scar which is continuous from the inner angle of the eye to the upper lip, where it terminates in an inverted V-shaped (∧) loss of the upper lip, exposing the right upper canine and lateral incisor. The ugly appearance of the eye was made less unsightly by the use of amber-colored glasses, while the split in the lip was covered by a vulcanite piece, made much like that in the foregoing case, except that one gold cap fitting over the exposed canine was sufficient to hold the piece firmly in place. As he was a small, wizened fellow, a slight mustache sewed on as in the previous case covered the margin between the prosthetic substitute and the natural tissues. (See Figs. 40 and 41.)

There were two incidents in connection with this case which if not instructive are at least interesting; one of them I will mention here, and the other in connection with the next case. This man received as his wages about 80 centavos (40 cents U. S. currency) per day. While this seems very small, it is ample to feed and clothe himself and to leave a small sum for comforts and luxuries. But, like so many Filipinos—to whom, by the way, gambling is a national curse—he is a gambler, and for that reason, while his ruptured trousers exposed a considerable part of the gluteal region, yet, barely was this improvement of his features made when his first purchase at the general store of the company was—a bottle of perfume!

Prosthetic Upper Lip No. 3.

This is the case of a market woman found at the same place and at the same time as the above. As the pictures show (see Figs. 42 and 43), her eyes and face are perfect except for the loss of a portion of the upper lip on the right side. In fact, the case is merely one of harelip too large to be surgically closed. The loss is not quite so extensive as in the previous case, but sufficient to expose two of the teeth. The substitute was made identically as in the previous case, omitting of course the mustache,

Fig. 42.

but for that reason the margin between the prosthetic and the natural lip is

Fig. 43.

more apparent. Her deformity led her to seek seclusion as much as possible, so that her work lay in the farthest corner

of the market, and was mostly of a nature which caused her back to be turned toward the customers who frequented that stall.

One of the incidents referred to in the previous case is connected with this woman. While I was at San José, as an indication what our rainy season is in sections where it rains much, and where indeed it is needed for the luxurious crops of tropical vegetation, I may say that during the seventeen days I was there the rains continued, or the skies were overcast with clouds, except twice for brief periods—once, before I made the two cases just described, the second time in the afternoon of the day on which I left. Hence it was impossible to get any photographs of these cases. The artist, with the descriptive aid of one who knew and had seen both cases, has given a fair representation of the injury and the improvement, though not of the general appearance of the individuals. I was promised photographs of them as soon as it would be clear enough to make the negatives, but in the meanwhile both left the plantation and married each other! They drifted to some other island, on which, as my informant states, "They are probably living in bliss, planting kiss upon kiss, with loving lips, and yet not lips."

The prosthetic lower lip has been described in connection with prosthetic nose No. 3.

Prosthetic Ear.

This is a very simple case. (September 1910.) Prior to the American occupation, fifteen years ago, there were many cruelties practiced by the natives upon their enemies as well as upon each other in times of disturbance, much as I apprehend is the case in Mexico. Among them was the cutting-off of an ear of one suspected to be a traitor, or one who had shown sympathy with the opposing faction. It was thus that this old man lost his ear. Whether justly mutilated or unjustly I do not know, but he was ashamed of the loss, and usually wore a handkerchief tied around his head.

The ear is made of vulcanite, painted to match his skin, and is held in place by small vulcanite projections which extend into the aural opening. The model

Fig. 44.

Fig. 45.

for the right ear was secured from the impression of the ear of another man whose ears in size and shape corresponded with the left ear of this patient. (See Figs. 44 and 45.)

Prosthetic Eye No. 1, with Surrounding Tissues.

This is the case of a poor Filipino (January 1912), a patient at the Philippine General Hospital eye, nose, and ear clinic in charge of Dr. Rembe. I do not know what the disease was, as shown in Fig. 46, which led to the cleaning-out of the socket of the eye and the removal of portions of the surrounding tissues, as shown in Fig. 47, but the improvement made is apparent from the next illustration, Fig. 48. The piece is made of vulcanite and was very artistically painted by one of the students of the School of Arts. I found within the socket a slight depression in the region of the former lacrimal duct, and also opposite at a point which corresponds

Fig. 46.

Fig. 47.

Fig. 48.

with the outer angle of the eye. The vulcanite extending into these depressions held the piece in place, but as he was obliged to wear a glass on account of some defect of the right eye, the spectacles, by pressure on the piece against the bridge of the nose, and at a point on the temples, aided in keeping the piece firmly in place. The eye is an ordinary glass eye matching the natural one, and is secured in place by means of projections of the vulcanite and silver wire, in the interior of the socket. The lids and the surrounding parts of the eye were carved in the wax, and subsequently reproduced in the vulcanite. The eyebrow and the eyelashes are made of suitable hairs, embedded by means of cement into holes drilled for that purpose in the vulcanite.

Prosthetic Eye No. 2.

This is another charity case sent to me from the Philippine General Hospital, February 1914. It is similar to the previous one, but not so extensive. The piece is held in place by a projection of the vulcanite extending up under the orbital plate of the frontal bone above, and below by a projection of vulcanite into the floor of the orbit, so curved as to retain the piece in place by a slight wedge pressure. The selection from artificial eyes is somewhat limited in this city, and I could find none which was not too large to insert into the limited space left in the rear part of the vulcanite. It occurred to me then to make use of an eye intended by the taxidermist for use with birds and animals. The natural eye of this man is dull, and the white part is of a muddy brown color. It so happened that I fastened the glass eye in the rubber and put it in the vulcanizer, unaware of the fact that the coloring matter used in these eyes is paint or something else. Whatever it is, it was melted by the heat in the vulcanizer and admirably, although by accident, reproduced the muddy and cloudy appearance of the natural eye. (See Figs. 49 and 50.)

Much of the artistic result of these cases depends on the painting of the piece. It is not an easy matter to give

Fig. 49.

a lifelike appearance to so dense a substance as hard vulcanite. In those cases

Fig. 50.

in which I was fortunate enough to have this done by a portrait painter the results were admirable. My own ability

along this line is limited. I have prepared a number of shades suitable for the various tints of the skin of the natives, and made numbered samples of them on a sheet of paper. When the piece is finished, I match the face to one of these samples and do the best I can.

Obturator for Cleft Palate.

While there is nothing unusual about this case, shown in the last four illustrations, it is interesting to note that the little girl for whom this obturator was made, in September 1913, is Ilokano and Igorot mixed blood, and comes from a section of these islands into

Fig. 51.

which white men have but rarely entered until the last fifteen or twenty years. It is no doubt a marvel to her parents and neighbors to find that such improvement can be made.

The illustrations (Figs. 51, 52, 53, and 54) almost explain themselves. Of course she had the two difficulties, as in all cleft cases, of having the food enter the nasal cavity and the impossibility of clear enunciation. The former has been entirely remedied, and the latter considerably so. As will be seen, it is a vulcanite plate extending by ridges into the cleft and by a projection into the fauces to take the place of the uvula. When last seen by me the piece had been worn but a few days, but the improvement in speech was, in the words of others, "simply marvelous." The piece is held in place by the two vulcanite hooks around the molars, and by a gold clasp passing between the bicuspids on the left side. The space where the teeth are

Fig. 52.

missing was too wide for one tooth and too narrow for two, hence there is one porcelain tooth with a gold filling, and adjoining it, where the lateral incisor

Fig. 53.

should be, some white vulcanite which later I have thought may have to be filed to allow the obturator perfect adaptation.

It may not be out of place to state here that the cases here described are purely charity cases. Only for three of them were my actual expenses paid by the Philippine General Hospital. I

have received no other compensation directly or indirectly. All of them are poor people, so poor that in one instance where I had no time to remain, I had to pay the local painter to finish the piece; for another I furnished the carfare, and for another the *banca* (rowboat) fare to cross the river, and for some food and lodging, so that the piece might be made. I do not mention this either boastingly or complainingly, but as affording one instance of the generally altruistic and charitable attitude of Americans toward the natives of these

Fig. 54.

islands. I know of many instances, along other lines of endeavor, more generous than mine.

Many Americans, seeing so many deformities of this character among the natives, especially hare-lip, which seems to be frequent, are of the opinion that the natives are more prone to these afflictions than Americans or Europeans. I am not prepared to state whether that is true or otherwise. I am inclined to think that in the more advanced sections of the United States and Europe, such ravages are not allowed to run their course until the injuries are so pronounced. Thus, hare-lip is usually remedied early in life, while a serious affliction of the face cannot proceed as a rule very far until either some friends or some charitable institution or hospital interferes. Here, especially in the provinces, inadequately supplied with medical men, it seems that such an affliction is likely to run its course until it exhausts itself. While Manila today is provided with ample hospital facilities of the best, they are wofully wanting in other sections of the islands.

In closing, it will not be out of place to mention an experience illustrative of what I have just said: While returning from the Cagayan valley in the northeastern part of the island of Luzon, a few years ago, I was fortunate enough to be on a steamer which was obliged to go out of its direct course to touch at the Batanes Islands and load some cattle. These islands are the most northerly of this group, and lie nearer to the shores of Japan's Formosa than to the island of Luzon of the Philippine Archipelago. The islands have no regular communication with others, on account of the typhoons, which cut them off from the rest of the world for prolonged periods. The natives differ from those living on the other islands of this group. They plant no rice and import none, but live on yams and *camotes* (sweet potatoes), which grow in great abundance. But little sugar-cane is cultivated, and that little is mostly used for fermenting an alcoholic beverage known as *palik*. They eat some meat, fish, and pork, but the principal diet is vegetable. During our short time in port I intended to examine and tabulate the condition of the teeth of the school children, simply because the people differ from those of the other islands, but unfortunately the public schools there had not yet opened. However, the native superintendent of schools happened to be conducting a normal school at which the teachers of the various islands which compose this small group were present, and on his invitation I addressed this class, about twenty-five young people, on dental hygiene.

I found the parochial school in session, and through the courtesy of the priest examined the teeth of about fifty of the boys and girls, but did not consider it necessary to tabulate so small a number. Mentally comparing their condition with the teeth of the Filipinos as I know them to be in Manila, and

other parts of the islands, I would say that in the Batanes Islands they are much better, and come nearer to the condition of the teeth of the Igorots (see DENTAL COSMOS, July 1908), as they are better in structure and I noted less caries, with a generally healthier condition.

Just before the ship's rowboat shoved off the shore, in turning my head and looking shoreward I beheld a sight which for the moment startled me. Apparently a corpse was unloading freight from one of the boats. I was under the impression that I had seen some interesting cases of the loss of parts of the face, but here was a man minus the nose, the entire upper and lower lip, and a part of the face extending on one side almost to the ear and on the other as far as the malar bone, the teeth showing ghastly and repulsive. I was informed that it was entirely out of the question for the man to come to Manila and have the ravages repaired.

On the steamer, returning, I also found a woman, Ambrosia Medraza, age twenty-one, on the way to Manila from the Batanes Islands to enter a hospital for treatment. Her nose was a mass of diseased tissue, and I knew that the entire organ would eventually be lost. She told me that there were a number of other similar cases in these sparsely populated islands. Having in a few hours seen two cases, I presume there may be a number of cases, as these isolated people until recently were almost entirely without any medical aid whatever. In her case the trouble commenced with a small sore on the side of the nose; this continued to spread, and as they lived away from any intelligent help, and ignorant as to what might be done for them, and too poor to do anything anyway, they have allowed the destruction to continue, and became alarmed only when it approached the angle of the eye. It was then that friends contributed toward making the journey. It had then been progressing for eight months. No doubt the loss might have been prevented by timely intervention. I learned subsequently that the case was diagnosed as lupus.

There is a vast opportunity for work and for investigation in these islands along the lines touched upon in this paper. While investigations of ethnological, anthropological, and other scientific character are constantly made by our own insular government, and by commissions and individuals sent here by scientific organizations, yet unfortunately there are no investigations made or provided for from a dental standpoint. This is a most regrettable circumstance, for the progress of civilization will in time obliterate many of the interesting and valuable data which might now be obtained.

TUBE TEETH AND PORCELAIN RODS: THEIR USES AND ADAPTATIONS IN PROSTHETIC DENTISTRY.

By JOHN GIRDWOOD, D.D.S.Univ.Pa., L.D.S.Edin., Edinburgh, Scotland.

(Continued from page 262.)

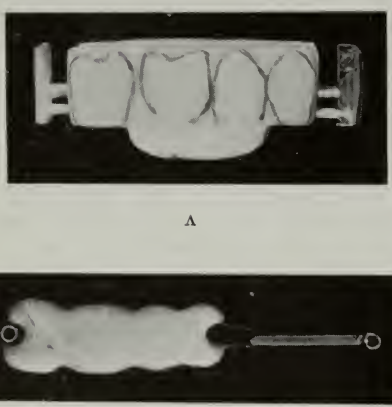
(XII.)

CHAPTER XVI. — Supplementary Suggestions—*Continued.*

The Addition of a Metal Lining to a Porcelain Tube.

In the first chapter dealing with the subject of tube teeth and porcelain rods,

Fig. 188.



A

B

A, Shows length of tube rod No. 27 with teeth outlined for bridge and showing tubed inlays joined to horizontal bars. B, End view, showing vertical groove for tubed inlays. (Fig. 193, A and B, shows finished bridge.)

it was pointed out that no advantage is obtained by the use of a platinum tube to tube teeth, and that the non-platinum tube tooth serves equally well, and has certain advantages over the older forms, which need not be detailed here. While the opinion which was expressed is adhered to, there are circumstances which sometimes call for a modification of it. Almost without exception, however, these are connected with the anchorage of a bridge, particularly a removable one where split posts are employed, and necessarily only in a case where tubed inlays cannot be used in the manner shown in Fig. 188, A, B. The tube in the molar crown should be enlarged by

Fig. 189.

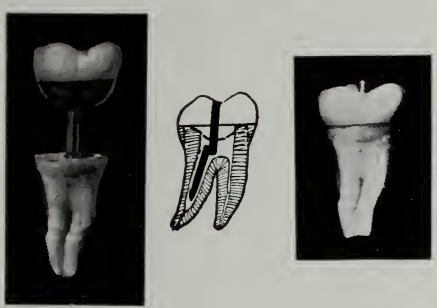
means of a diamond reamer to about No. 10 U. S. gage, the size being determined by the thickness of the split post which it has been decided will afford the necessary strength, and by the thickness of the metal tube. A good average for molars is about size No. 10 U. S. gage for tube, and size No. 11 U. S. gage for split posts. The following method will be found to yield satisfactory results: Cut off a length of thin tubing (Fig. 189), then form a washer or disk of gold from a piece of plate about 20 to 24 gage, and solder it to the base of the tube. Having formed a recess in the base of the porce-

lain into which the gold washer fits, the united tube and washer should be cemented to place; in carrying this out the tube may be left much longer than is necessary, in order to note that the tube is at right angles to the horizontal tubes and exactly parallel to the tube at the opposite end, or to such other form of attachment as may be used for a similar purpose.

Crown Work.

Fig. 190 shows a method of dealing with a case of extensive decay in a molar by means of a partial crown formed from

Fig. 190.



Photographs and sketch illustrating partial tube crown.

a tube tooth or section of a tube rod. Such cases are common, and the usual method of dealing with them is either to build them up with amalgam, by means of a large gold inlay, or to crown them. All of these methods are more or less unsightly, except the last, and the last only is free from this fault when an all-porcelain crown is used, while there may be objections to the employment of an entire crown. It is here that the partial tube crown frequently proves invaluable. The method of forming it is extremely simple, and is as follows: The pulp, if alive, should be devitalized, all decay removed, and the buccal canals filled. The apex of the palatal canal should be sealed after the canal has been reamed out to take a post of suitable size. An additional, though shorter post, may be used in one of the buccal canals. The approximal, buccal, and lingual walls of enamel should then be ground flat across. The posts should then be placed in the canals, and an impression and bite taken in the usual way, the posts being replaced in the impression before it is cast, if they have not come away in it. Before proceeding to fit the tube crown, the post should either be bent so that that portion of it which is to carry the porcelain crown is parallel to the long axis of the tooth, or a separate post should be soldered to the post entering the canal (Fig. 190). An alternative method is to cast an inlay to fit the enlarged pulp chamber, or to swage or burnish a piece of pure gold to fit it, and solder posts and inlay together. The porcelain partial crown should then be shaped up and fitted to the model, and when finished cemented to place.

The Treatment by Crowning of Upper Molars in Which the Palatal Root is Partially Exposed.

These cases are probably more commonly met with in the first than in the second molars, and the difficulties encountered in treating them successfully and of obtaining results commensurate with the amount of time and skill employed has received less attention than the importance of the subject appears to warrant. The method of dealing with those cases is almost invariably by means of an all-gold crown, and there are few cases in which an all-gold crown shows to less advantage. Besides, there is the difficulty of obtaining an accurate fit, and the liability to further recession of the gum. The latter inevitably follows sooner or later, and in consequence these cases are looked upon by the skilled crown worker as among the least successful of his efforts. By means of the tube tooth, however, highly satisfactory results may be readily obtained from the artistic, mechanical, and other points of view. Hitherto, no porcelain crown has been manufactured which will meet the needs of such cases on account of the fact that they lack a sufficient size of base to

cover the roots and extend and supply the lost tooth structure. Even the largest of the special forms of tube teeth or single-tube rods is sometimes too small in the base to permit of sufficient material for the purpose. A section, however, from one of the double-tube rods No. 26, 27, or 28 admirably meets the needs of such cases. Probably No. 28 will, on the whole, be found most useful. In preparing the roots, their surfaces should be ground level with or a little

Fig. 191.

Photograph and sketch showing double-tube crown formed from rod No. 28.

below the gum margin, as long and stout a post as the case will permit of should be fitted to the palatal canal, and a shorter one into one of the buccal canals. The pulp chamber may also be utilized for the purpose of adding to the available anchorage. The enamel should not be removed from the periphery of the roots, as the crown should ordinarily be a bandless one; the cap should be of gold either cast, swaged, or burnished to the surface of the root, and the posts which enter the canals are to be attached to it by soldering. In the case of a cast base, the union of the posts to the base had best be made additionally secure by soldering, unless the posts are of cast metal also, a method to be deprecated. After the base has been adjusted to the model, a section of tube rod should be roughfitted to the surface of the cap and to the form of the crown, and the posts adjusted and soldered in the manner already described. (Fig. 191.)

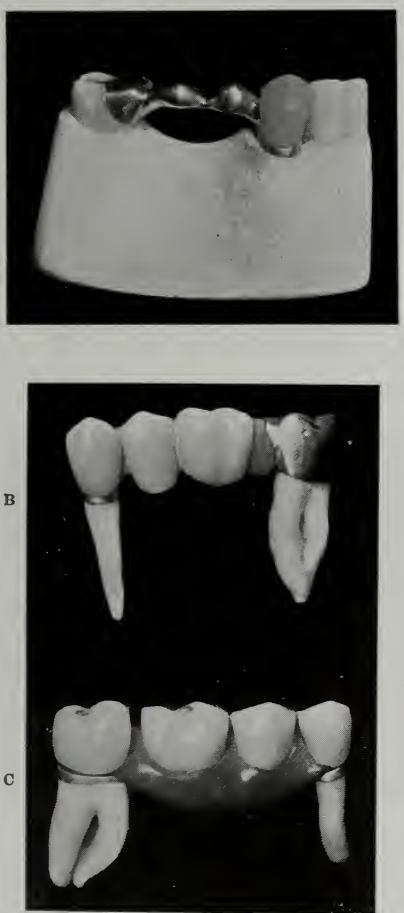
Bridge Work.

Hitherto attention has not been specially directed to the almost limitless use which may be made of the tube principle of attachment in connection with nearly every kind of prosthetic work. Examples have, of course, been given in connection with the tube rods, tube teeth, and gum sections, and more will be provided, but full justice cannot be done to the subject without unduly prolonging these papers, and so it must suffice for the present to point out that any of the cases so far dealt with can be duplicated in gold, either by the ordinary methods, by the casting process, in vulcanite, or any other material ordinarily used, and by following the usual methods of construction. (Fig. 192.)

There are also other points which deserve further attention. For example, the important part played by inlays in connection with tubes, posts, and bars has been abundantly illustrated, but attention has not been directed to the absolute rigidity which the combination of these affords. In the case of double tubes and posts it is so pronounced that any number of pieces may be so united with the result that they possess the rigidity of a solid piece and without the use of a cementing medium, although such a medium is necessary, as a rule, for uniting the pieces after they have been finally assembled. In the case of a single post or bar combined with an inlay, perfect rigidity depends upon the size and shape of the inlay, but it will be apparent that there is more need of a cementing medium to retain the parts together.

In Chapter X it was pointed out that it is not necessary to have the surface of individual roots or teeth exactly parallel to each other—a so-called necessity strongly insisted upon by most writers—but that by the use of tube teeth or rods

Fig. 192.



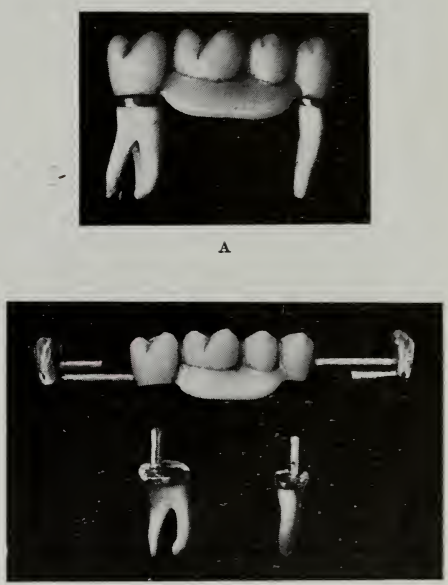
A, Cast gold bridge with tube tooth. B, With porcelain facings. C, Removable vulcanite bridge with tube teeth; anchorage by split posts.

the apparent difficulty may be readily overcome. Several examples were given in proof of this. There was one point, however, which was perhaps not made sufficiently clear, and with the object of remedying this it is necessary to point out that in connection with anchorages formed by tubes and posts, whether or not these are combined with inlays, the tubes or posts, if left sufficiently long to begin with, permit of accurate adjustment being judged by means of the eye alone, or by measuring the distance apart between the posts at their respective ends.

Description of Cases.

No attempt will be made to classify the various types of cases, but a few will

Fig. 193.

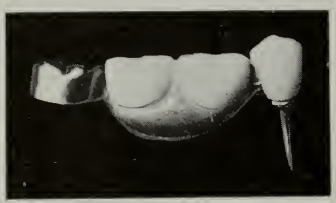


A, Removable bridge with cast tubed inlays. B, Shows details of construction.

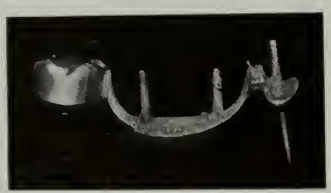
be given which it is hoped will be of sufficient importance to warrant attention being drawn to them. Fig. 193 shows a case where difficulties which might arise in connection with drilling additional tubes for the purpose of obtaining anchorage are done away with, and this is accomplished by cutting a groove in the posterior surface of the second molar extending from the base to the crown of the tooth, and intersecting or passing between the horizontal tubes. The groove,

or recess, thus formed need not, however, extend farther than one-third of the distance between the posterior surface of the crown toward its center. The anterior or bicuspid anchorage should be dealt with in like manner, as shown in Fig. 188, B. Into the groove thus formed,

FIG. 194.



A



B

C

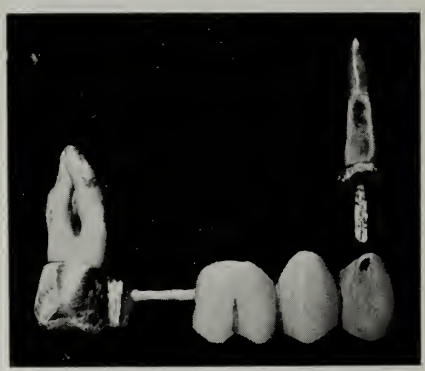
a length of tube should be placed, and the horizontal posts soldered to it, care being taken to have the tubes at right angles to the posts—and this, as already mentioned, is rendered easier by leaving the tubes fairly long to begin with. After they have been soldered to the posts, the tubes can be cut down to the required length. An inlay may now be cast on to the bars and post, as shown in Fig. 193, B, when the bridge may be proceeded with in the same way as if the tubes had been drilled through the porcelain for accommodation of the posts. The addition of inlays to the tube and bars may be dispensed with as far as the necessary amount of strength is concerned, but for other reasons their use is recommended.

FIG. 195.

A



B

A, Upper right bridge shaped up from rod No. 25. B, Shows details of anchorage.

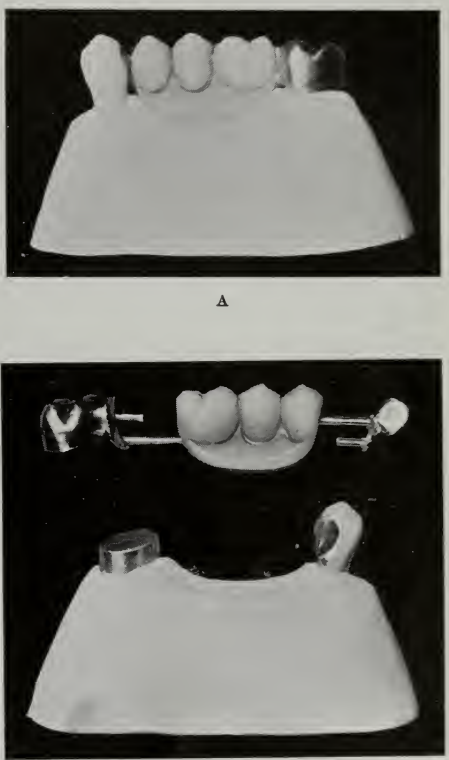
Fig 194 illustrates the use of an old-time gum tube section of two molar teeth, and serves to show how these sections could be utilized in some cases to take the place of fused porcelain, or sections formed from porcelain rods, with advantage in regard to time-saving and doubtless in other ways. The illustrations also show that the bridge is not a

saddle, but a bar, and that the bar is triangular in section with the apex in contact with the surface of the gum. (Fig. 194, c.) The purpose which this is meant to serve is to obtain a surface which can be readily reached by the tooth-brush throughout its whole length. The anterior anchorage, as will be seen, is by means of a capped second lower bicuspid, and a point to be noted in this connection is that provision is made for the employment of a tube tooth instead of a porcelain facing. By means of an extension of the bar on to the top of the bicuspid cap the impact of the bite is transferred to the long axis of the root, and not mainly on to the band. (Fig. 194, B.) This is accomplished without any material sacrifice of strength in the tube tooth, while in the event of fracture the crown can be replaced without the removal of the bridge.

Fig. 195 shows upper right bridge of four teeth, two bicuspids and two molars. The bicuspids and first molar are shaped up from the single-tube rod No. 25, while the second molar—an all-gold crown—has a horizontal bar soldered to its anterior approximal surface, extending as far as the post soldered to the bicuspid cap. The molar thus forms the posterior anchorage for the bridge, while the anterior end is anchored to the first bicuspid by means of a cap and band with the usual post attached, for which a tube has been drilled through the porcelain crown. In order to avoid the difficulties sometimes associated with drilling a special tube in the porcelain rod, the method shown in Fig. 188 may be adopted.

Fig. 196 is the case of a saddle bridge for the right side of the upper jaw, consisting of a porcelain block of three teeth, a molar and two bicuspids, shaped up from rod No. 27, and of an all-gold telescoping crown, which forms the posterior anchorage upon which a gold inlay is formed, carrying the horizontal bars which enter the tubes in the porcelain block. The anterior anchorage consists of a cast inlay and tube combined, the inlay being hollowed out for the purpose of accommodating an inlay and split post, to which the horizontal bars which enter the tubes in the porcelain blocks are attached. The apical end of the tube which forms part of the canine inlay is closed in order to prevent moisture from penetrating through to the interior of the root.

Fig. 196.



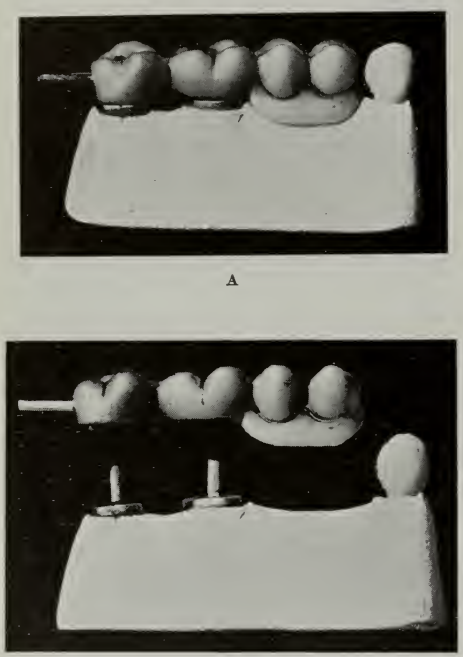
A, Upper right bridge from rod No. 27, showing posterior anchorage, gold telescoping crown; anterior anchorage by inlay and post into inlay and tube in canine. B. Lingual view and details of anchorage.

Fig. 197 is that of an all-porcelain extension bridge for the upper left side, formed from rod No. 27, supplying both bicuspids and the crown of the first and second molars. It will be observed that the absorption of the alveolus due to the loss of the bicuspid roots is made good by the porcelain saddle, which at the

same time affords a sufficient bearing for the anterior end of the bridge. If need be, additional support could be obtained by means of a spur resting on the canine, or by one of the anchorages which has already been described.

The posterior anchorage by means of the split post attached to the molar caps provides a secure and rigid attachment,

Fig. 197.

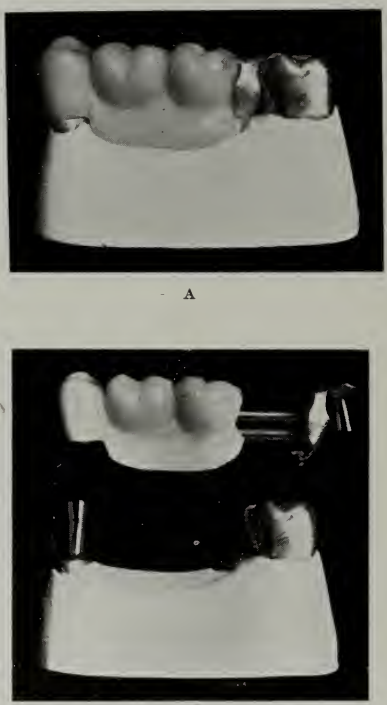


A, Upper extension removable bridge from rod No. 27. B, Shows anchorage by means of split posts.

with at the same time provision for easy removal, and if occasion arises, for readily tightening the piece by slightly opening the split posts. Here the addition of the metal tubes lining the porcelain tubes in the molar crowns may be adopted with advantage. It will be observed that the rod has been used with its broadest section toward the gum, in order to obtain the maximum area of saddle. Had a greater length of tooth or depth of saddle been required, rod No. 39 would have been substituted.

Fig. 198 shows a removable saddle bridge for the left upper jaw, consisting of four teeth, second bicuspid and three molars. The porcelain part of the bridge includes the bicuspid and the two molars, while the third molar is an all-gold

Fig. 198.



A, Lingual view of upper left removable bridge from rod No. 27. B, Shows posterior anchorage by means of inlay and split post, anterior anchorage by means of split post.

crown forming the anchorage for the posterior end of the bridge, the anterior end being anchored on to the root of the second bicuspid.

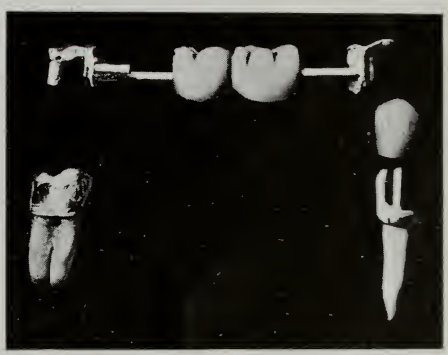
In order to provide for the absorption of the alveolus and shrinkage of the gum, and at the same time to provide additional support for the bridge, the porcelain is shaped to fit the alveolar border. The anchorage for the anterior end of

the bridge is obtained by capping and banding the bicuspid root, and employing a split post which passes through the porcelain block, the tube of which has a metal lining. The all-gold crown which supplies the anchorage for the posterior end of the bridge has a recess formed in it extending from the center of the crown toward its anterior approximal surface, down which it is prolonged to a point a little short of the gum margin. Into the bottom of the recess in the gold crown is soldered a short section of tube to take a No. 13 U. S. gage split post, and the tube carried to the base of the pulp chamber. An inlay formed to fit the recess in the crown has cast or soldered into it the split post which enters the tube. A separate inlay joining the horizontal posts which extend through the porcelain is then soldered to the inlay spur with split post attached, which has been already described. A perfectly secure and strong anchorage is thus obtained, and one which not only permits of easy removal and replacement of the bridge, but if need arise it can readily be tightened at any time by slightly opening the split posts.

Fig. 199 is a removable bridge for the right side of the lower jaw, and consists of the three molars and second bicuspid, the latter and the third molar constituting the abutments. The component parts of the bridge are as follows: The body, consisting of the first and second molars shaped up from the double-tubed rod No. 26 with the parallel tubes horizontal; a tube tooth mounted on the bicuspid root, and an all-gold crown on the third molar. The details of the attachment are as follows: The all-gold crown is constructed in the same manner as described in the previous case (Fig. 198) with inlay and split post; the anterior anchorage is obtained by means of a tube tooth mounted on the capped root in the usual way, but having a groove in its posterior approximal surface extending from the base to the crown and prolonged two-thirds of the way across its surface, for the purpose of lodging and supporting a gold inlay to which a vertical split post, as well as two horizontal bars which enter the porcelain molars, are also attached. In addition to the vertical post carrying the single-tube crown, there is also soldered to the cap of the bicuspid root a tube about three-quarters section, with the opening presenting toward the molar, the tube having an inside diameter to take a No.

Fig. 199.

A



B

A, Removable bridge for right side of lower jaw from rod No. 26. B, Shows details of construction and anchorage.

13 U. S. gage split post attached to the inlay.

Fig. 200 illustrates a type of removable bridge belonging to the class known as "interrupted" bridges, this description being generally applied to those cases in which one or more natural teeth which are not necessary for use as abutments intervene in such a way that they cause an interruption or break in the continuity of the parts of the bridge. It will

be seen that in the case under consideration the bicuspids and first molar are missing, and that the crowns of the central incisors as well as that of the upper right molar require replacing. The following description will doubtless serve to convey a sufficiently clear idea of the procedure followed: The porcelain parts of

Fig. 200.

A

B

A, Removable "interrupted" bridge. B, Shows details.

the bridge consist of the two bicuspids and the first molar shaped up from the double-tube rod No. 27, to fit the alveolar border and the bite, while the two central incisors are shaped up from tube rod No. 30. These are united by means of a narrow gold plate extending on to and covering the capped central incisor roots. An inlay formed in the anterior approximal surface of the bicuspid to which the horizontal bars are attached is soldered to the gold plate. The illustration shows that the roots are capped and banded and have split posts soldered to them as for an ordinary tube crown, and that the anterior anchorage of the bridge is secured by means of tube posts soldered to the plate through which pass the split posts attached to the caps of the central incisors, the tube in the tube

Fig. 201.

A

B

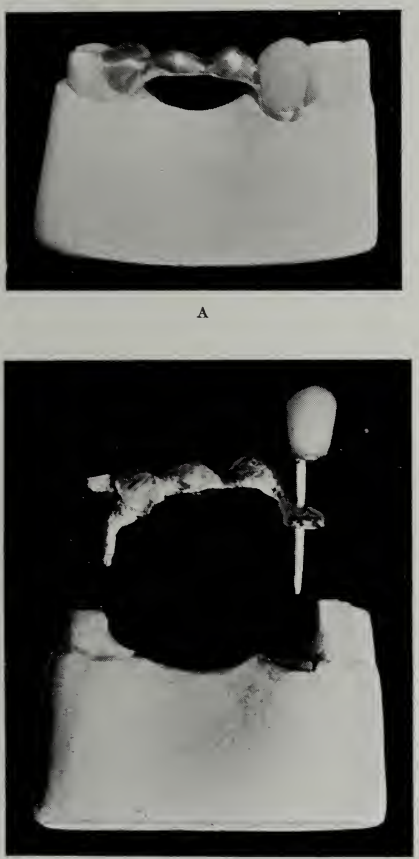
A, Removable bridge for right lower jaw, anchorage by means of split posts. B, Shows anchorage.

porcelain crowns being enlarged for the purpose. The upper right molar forming the posterior attachment is provided with an all-gold crown which has a recess formed in it for the accommodation of an occlusal rest which forms part of the clasp attached to the inlay and horizontal bars.

Fig. 201 shows another example of a removable bridge for the right side of the lower jaw. The anchorages consist of split posts size No. 11 U. S. gage soldered to the capped roots of the sec-

ond bicuspid and second molars; the bridge being shaped up from tube rod No. 26, and shaped to fit the alveolus in the interspace between the molar and bicuspid, and bicuspid and canine, thereby increasing the stability of the piece.

FIG. 202.



A

B

A, Gold bridge and tube tooth with self-cleansing space. B, Shows details.

Fig. 202 shows a small gold bridge with large self-cleansing space, for the right lower jaw, consisting of two bicuspids and a crown. The posterior anchorage is obtained by means of a large gold inlay anchored into the pulp chamber and anterior root of the first molar, and the anterior anchorage by capping and banding the canine root with post attached in the usual way for the purpose of carrying a tube crown. The union of the gold cusps to the canine cap is carried out in the manner shown in the illustration, without interfering materially with the strength of the tube tooth.

THE USE OF GUM TUBE SECTIONS IN BRIDGE WORK.

In the event of a revival in the manufacture of gum tube sections—which it is sincerely to be hoped will take place—a valuable addition would be made to the materials available for the purpose of forming saddle bridges which would be not only stronger than fused porcelain, but would also save much valuable time in building up and fusing. Moreover, these sections could also be modified by the addition of fused porcelain to meet the necessities of individual cases.

TUBE RODS AS A FOUNDATION FOR FUSED PORCELAIN BRIDGE WORK.

In the chapter on Bridge Work it was pointed out that fused porcelain has proved a disappointing material in connection with bridge work except in the hands of the most highly skilled workers. The reasons advanced in proof of this rest mainly on the lack of strength in the material, necessitating a platinum framework strong enough in itself to permit of the strength of the fused porcelain being in most cases disregarded. Manufactured porcelain, on the other hand, is of sufficient strength, unless in cases of close bite, to allow of its use without the necessity for employing a metal framework, although in point of fact tube rods furnish the means of combining a framework and anchorage at the same time, and possess the advantages previously spoken of. There seems every reason, therefore, why tube rods should prove of great use in connection with fused porcelain work, furnishing as they do the necessary strength of porcelain body combined with a ready and efficient means of reinforcement by horizontal and other bars, which, as already

described and illustrated, can be used for the purpose of assisting to furnish any of the methods of anchorage hitherto relied upon, and many others to which tube rods are specially suited.

The details in connection with the formation of a bridge in the manner spoken of need not to be entered into, but it is suggested that the section of porcelain rod should be roughly shaped up to the desired form, both with regard to the body of the piece and outline of the teeth, and that the required additions be made by means of suitable porcelain body.

Partial Plates with Teeth Formed from Porcelain Rods.

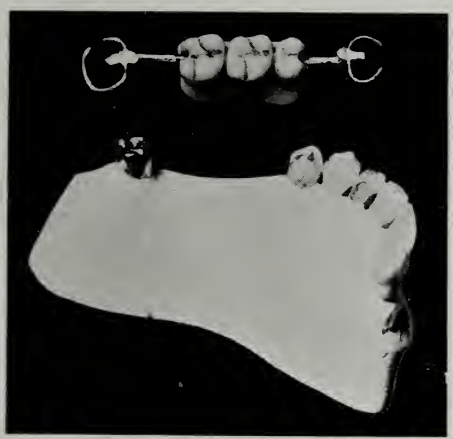
Probably the shaping up and fitting of a partial plate with tube teeth from a porcelain rod will appear to most men to be a somewhat formidable undertaking. In reality it is much simpler than it looks. This statement may be doubted, if not even disbelieved. Nevertheless, it is in accordance with the facts of practical experience, and the reader is advised before coming to what may prove a hasty conclusion, to put the matter to the test. By doing so he will doubtless be able to confirm the foregoing statement. At any rate, an opportunity will thereby be afforded of obtaining an approximate estimate of his manipulative and artistic ability. The problem is much simpler than it doubtless appears; the only point in which it differs from that of an all-porcelain saddle bridge is in the absence of the vertical anchorage posts which form guides for securing the porcelain block's being returned to its exact place on the model while the base is being fitted to it. In the case of a bridge this is provided for in several ways, as has been shown by various examples illustrated and described in these papers. Fortunately, the means of supplying the necessary guides is a simple matter, and the description given on page 387 and shown in Fig. 193 forms a suitable example of the first steps necessary for providing vertical tubes for the accommodation of posts for the purpose. In order to make the matter quite clear, a short description of the procedure followed in shaping up a porcelain plate is here given:

A section of the porcelain rod, usually No. 26, 27, 28, 29, or 39, is cut off, sufficient to fill the space between the abutments. This is then roughly shaped up to the contour of the gum, and the teeth also outlined. A horizontal slot is next made at each end of the block, as in Fig. 188. Into the slot or recess so formed, a vertical tube with horizontal anchorage bars attached to it is temporarily fixed at or in either end of the block, which is thereby transformed into a porcelain block with vertical tubes in addition to the horizontal ones, and is in fact similar for all practical purposes to a porcelain rod which has had tubes drilled through it for the purpose of accommodating the posts and caps of a crowned root or roots, and is in consequence ready to be dealt with in the same way as a porcelain saddle bridge—with this exception, however, that the vertical posts are not yet provided. This is accomplished thus: The roughly shaped block is either held in position with the fingers, or is temporarily secured by means of sticky-wax in a similar manner to that described in determining the position for the post for a tube tooth on a metal plate. The position of the posts having been ascertained by means of a marker, holes should be drilled through the plaster model for the posts with the least possible mutilation of the surface of the model, and these holes should be enlarged from the under side of the model. The vertical posts are then passed through the tubes, care being observed that they are parallel to one another, and the posts, which may be of the base metals, iron, German silver, or brass, are roughened or bent in order that they may be securely held by plaster or other medium. Thus secure guides are provided whereby the block or rod may be fitted by grinding its under surface to adapt it accurately to the surface of the model in the same way as a tube tooth is fitted to a plate, or the end or ends of a bridge to caps on roots. But where a large surface such as a plate is

to be ground to fit, it is sometimes advisable to do the fitting on a separate model, and retain the original one either for final fine-fitting or for reference, and a duplicate model for this purpose, or in point of fact any number of duplicates, can be quickly and easily formed in the following manner:

FIG. 203.

A



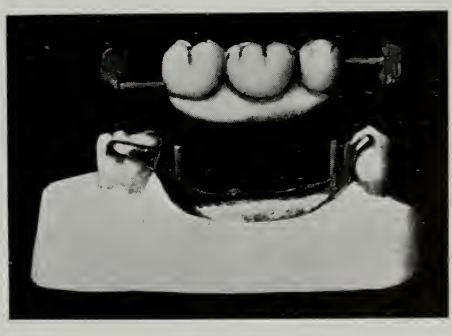
B

A, Upper right partial porcelain plate. B, Shows details of construction.

Over the posts on the original model are placed sections of metal tubes which fit the posts easily but accurately, the tubes being roughened or having tags soldered to them to engage or secure them in the impression of the model, which should now be taken, in one of the many well-known ways whereby models are duplicated. The impression having been taken, posts to fit the tubes are now inserted into them, the projecting ends being left sufficiently long and being at the same time bent or roughened in order to hold them securely. The impression is then cast in the usual way, and when parted the model gives an exact duplicate of the original. Instead of casting the impression in plaster, it may be cast in fusible metal or partly in metal and partly in plaster. If altogether in plaster, the model may be dried and hardened in any of the usual ways. The subsequent steps are, as already mentioned, to grind the base with suitable wheels until it fits the model accurately all over. This is generally facilitated by the use of paint in order to mark the points of contact, but it does not require much experience in order to be able to dispense with the use of paint until near the stage of fine-fitting.

FIG. 204.

A



B

A, Lower right partial plate. B, Shows details of construction.

The shaping up of the teeth with regard to their form and contour, and to the bite, is carried out on the lines already laid down. After this has been accomplished, the piece should be smoothed and polished (see chapter on Polishing Porcelain Teeth), when it is ready for the bands, or such form of anchorage as may be decided upon. The case is now ready for the mouth, after the bands with their anchorage posts have been cemented to place by sulfur or other suitable medium. (Fig. 203.)

The slots or recesses for the accommodation of the vertical tubes are no disadvantage, as they are simply a continuation of the crowns of the teeth at either end of the inlays which would be formed in them for the purpose of joining the bars and bands together, but if it should be considered advisable not to prolong the gold to the crowns of those teeth, this may be done by having the temporary vertical tubes with their attached horizontal bars outside the ends of the porcelain block. This would necessitate cutting away part (perhaps half) of the tooth from either end of the model for the purpose of securing a position for the guiding posts. This, however, would not matter, as the permanent model would remain for the purpose of forming the bands and of adjusting them.

It is needless to enumerate at length the advantages to be derived from an all-porcelain plate, as they are obvious, at all events from the points of view of cleanliness and of the scope such work provides for artistic treatment. The question of the amount of time required will naturally occur to some men, and the comparison this would bear to, say, the time required for making a partial gold plate. Even with a limited amount of practice and with average skill, the time taken should compare favorably with that of a partial gold plate of similar size, and may be put down at from forty-five to ninety minutes for each tooth on the porcelain plate. This does not include the time spent in making the bands and soldering the horizontal posts in them, but for the porcelain plate and teeth alone. These, however, would not occupy much time, and it is to be remembered that there is no slow heating-up and cooling-down of plate and teeth for soldering, and no slow heating-up of investment as when a cast plate is used, neither is there time spent in taking dies and counter-dies for striking up a gold plate.

Fig. 204 shows a partial lower cast plate with gum section of three teeth shaped up from rod No. 27 and with tubed inlays as described on page 387.

SIMPLIFIED SURGICAL TECHNIQUE EMPLOYED IN ROOT RESECTIONS FOR THE RADICAL CURE OF CHRONIC DENTO-ALVEOLAR ABSCESS:

Illustrated Stereoptically, Before and After Operating.

By F. K. REAM, M.D., D.D.S., New York, N. Y.

(Read before the Northeastern Dental Association, at its annual meeting, Boston, Mass., October 15, 1914.)

NO department of oral surgery presents a greater opportunity to the practicing dentist for the arrest of systemic disease and the restoration of health than root resection, amputation, apico-ectomy, or alveolotomy, for the radical cure of chronic dento-alveolar abscess.

HISTORY.

Richard H. Riethmüller, Ph.D., D.D.S., furnishes the following historical sketch concerning root resection:

While the replantation of teeth was one of the early achievements of dentistry before it had attained the dignity of a profession, the practice of root resection is of comparatively recent date.

Smith reports in 1889 that eighteen years before—that is, in 1871—he performed the resection of a root in a case of facial neuralgia. The pain never returned, and the writer subsequently repeated the operation in cases of facial neuralgia.

Farrar in 1880 performed surgical root treatments in chronic alveolar abscess; also Dunn in 1884. (See *British Journal of Dental Science*, vol. xxvii, No. 38.)

Grayston in 1887 (*Journal of the British Dental Association*, January 1887) pronounced anterior teeth, bicuspids, and even molars as being suitable for surgical treatment in cases of chronic alveolar abscess.

In the same year, Claude Martin reported in the Transactions of the International Medical Congress of 1887 that in 1881, in a communication addressed to the Congress of Algiers, he proposed "a new method of treatment of chronic periosteitis of the dental alveolus, consisting in the actual section, *in situ*, of the diseased radicular extremity by the aid of a crown trepan."

M. L. Rhein in 1890 (see *Dental Review* 1890, No. 10) recommended "amputation of tooth-roots" in chronic alveolar abscess, and in roots which had become necrotic from pyorrhea alveolaris. He performed this operation also in molars.

White, in 1893, gave a report before the International Dental Congress held in Chicago concerning the treatment of chronic abscesses. He amputated the root apex, and in molars the entire diseased root. Hern and Woodhouse in 1893 (*Korrespondenz-Blatt für Zahnärzte* 1893, p. 355) described the amputation of the apical root portion of incisors affected with chronic alveolar abscess.

Up to that time, the surgical treatment of roots was practiced only in America, but this method was not based upon scientific reasons or methods until Prof. Dr. C. Partsch, in 1896, in the "Third Report of the Polyclinic for Dental and Oral Diseases of the Dental Institute of the Royal University of Breslau," for the first time established the scientific indications and the surgical technique of root resection.

In Austria, Dr. Rudolf Weiser, in 1900 (Proceedings of the Third International Dental Congress of Paris) advocated and enlarged upon Partsch's method, and since then the chief advocates of this method, which has become routine practice in Germany, have been Kunert, Luniatschek, Mayrhofer, Guido Fischer, Metz, Konrad Cohn, Euler, and Williger.

ROOT RESECTION AS A PREVENTIVE MEASURE.

Dr. Charles H. Mayo sagely remarked that the next step in preventive medicine must be taken by the dental profession, and it is up to us as dental surgeons to make good.

Dr. Victor C. Vaughan, president of the American Medical Association, says—"Whatever the business outlook in commercial matters may be, there has never been a time in the history of the world when the dentist and the physician had so much to do, nor has there been a time when this work was of so much import to mankind. Preventive medicine, a large part of which is dentistry, is proving to be a most potent factor in the uplift and betterment of mankind. The public recognizes this function, and it is not only willing to accept aid from the physicians and dentists, but is demanding help. Dentistry and medicine can grow and increase in helpfulness to mankind only as scientific investigation develops and advances."

Considering the frequency of this malady, as daily witnessed by the practicing dentist, it behooves him to be up and doing, and to master a simplified technique which I hope to outline in this paper. Since the advent of roentgenology, there is no excuse for the operator working in the dark. Foremost in the rank of practice-building stands this opportunity, like a beacon light for every practicing dentist of ordinary skill to develop a broader dentistry.

The saving of time, if nothing more, in the treatment of abscessed and multi-rooted teeth is sufficient incentive for surgical interference, to say nothing of the expenditure of useless hours and energy in repeated treatments, which

lead to failure or extraction in the end, while surgical interference could have brought about an immediate cure.

broader knowledge in the etiology of systemic conditions marks a new era in dentistry.

Fig. 1.

Fig. 2.

Fig. 1 shows a pericemental abscess extending between the roots of two central incisors and well up to the apex of the tooth, but does not involve the apical end.

Fig. 2 shows an alveolar abscess and necrotic area in contradistinction to Fig. 1.

The differential diagnosis is made very clear in these prints made from practical negatives in my routine practice. Note the metal filling in the lingual of the right central incisor made by the dentist, who should have made an X-ray of the case before puncturing the pulp of a normal and vital tooth.

Fig. 3.

Fig. 4.

Figs. 3 and 4 show typical alveolar abscess, the primary source being the lateral incisor. The invasion extended to the central, causing death of the pulp. Both teeth were saved by surgical interference.

Some of these cases gave a history of rheumatic conditions, heart lesions, joint diseases, and general systemic infections, which wonderfully improved almost immediately after pus pockets were drained.

RECOGNITION OF THE SYSTEMIC DANGERS OF DENTO-ALVEOLAR ABSCESS.

The "Macedonian cry" of the medical profession for the assistance of the dentist to combat disease and thus gain a

No physician today dares discharge his patient in a case of confused diagnosis without eliminating the oral cavity as a causative factor in systemic disease.

Gilmer says that 25 per cent. of devi-

talized teeth are affected with alveolar abscess.

The dentist should become cognizant of the general condition of his patients as to systemic tone, and should call at-

the oral surgeon and specialist in extraction, is appalling. In my opinion any dentist who gives up the fight to save teeth in a majority of cases, without a radiogram and the careful study

Fig. 5.

Fig. 6.

Figs. 5 and 6 show typical cases before and after operating for alveolar abscess. The amount of tissue removed in Fig. 6 was determined by the sense of touch and the appearance of the granulation tissue, it being the aim to reach sound surrounding tissue.

Fig. 7.

Fig. 8.

Fig. 7 shows necrotic apical root-ends, imperfectly filled, before resection for the radical cure of chronic dento-alveolar abscess.

Fig. 8 shows the same condition after operating.

These prints are valuable to the dentist, showing clearly the necessity for an X-ray before undertaking these operations. Note that the root-ends are widely separated; separate incisions were made over each root in this case. Without the X-ray the operator might be greatly misled as to the exact location of the field for operation.

tention to foci of infection, and thus the physician and dentist should work together in the cure of disease.

The useless and ruthless extraction of abscessed teeth—which are savable by surgical interference—as witnessed by

of canal and root formations, is derelict in his duty toward the welfare of his patients.

It is true that nothing will more insidiously break down the defensive forces of the body than alveolar abscess,

oftentimes unsuspected by the dentist, and until the last few years seldom if ever observed by the medical practitioner. Chronic endocarditis and myocarditis may be due to streptococcus viridans supplied by the infected blood stream. A vegetative growth on the valves and endocardium takes place; swimming in this oxygen stream it multiplies, and fortifies itself against all methods of treatment. Acute rheumatic fever, arthritis deformans, anemia, neuralgia, cystitis, chronic appendicitis, chorea, cholecystitis, and sinusitis may arise from alveolar or peritonsillar abscesses.

Rosenow and others have transmuted pneumococcus and streptococcus infections from tissues and exudates in these diseases. The blood stream carries infections from the focal point, depositing them in remote parts of the body. Streptococcus viridans, a virulent type of infection found in the blind abscess, corresponds with joint infections.

The practice of treating chronic dento-alveolar abscesses lightly, so prevalent in the dental profession, is entirely too neglectful, and it is the essayist's desire, in a measure, to overcome this practice.

To the present time my operations for the radical cure of these lesions have been largely confined to upper bicuspids and the six upper and lower anterior teeth, although I have frequently completely extirpated anterior or posterior roots of upper and lower molars, also lingual roots of upper molars.

FIG. 9.

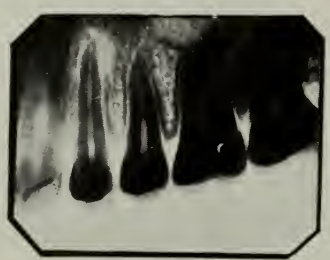


FIG. 10.

FIGS. 9 AND 10—X-rays before and after operating. *Case history:* Female, age thirty-eight, unmarried. General health good except for enlarged joints on each hand. History of constitutional diseases negative. Laboratory tests showed blood and urine normal. X-ray examination of all the teeth, for alveolar abscess or other abnormal conditions, negative, except upper right first bicuspid with blind abscess. Tooth not sore and showed no indications of trouble to percussion or thermal tests. The tooth was single-rooted; the root-canal had previously been treated (?) and a filling inserted. *Treatment:* Operation for root-resection, and culture sent to laboratory. Test showed *streptococcus viridans* so commonly found in joint diseases. Autogenous vaccine; patient immediately improved. Antero-posterior X-ray of head showed maxillary, sphenoid, ethmoid, and frontal sinuses normal.

One peculiar condition about many of the cases that come under the observation of the roentgenologist is that the patients do not complain of pain in the teeth while at the same time they are suffering from systemic infection.

INDICATIONS FOR SURGICAL INTERFERENCE. CLASSIFICATION.

While it may be possible to accomplish much good without the roentgenogram, such purely guesswork practice resembles too much a ship at sea without a rudder. The operator may be greatly misled in his judgment as to the necrosed area, diverging or crooked roots, etc.

Some of the most frequent indications for root resection are (1) imperfect root-canal fillings; (2) perforations through crooked roots; (3) traumatic injuries and fractures; (4) broken

broach ends, and (5) excess of guttapercha or other root-canal filling protruding through the apical foramen. In short, any pathologic condition that involves the apical region in teeth which show sufficient rigidity to withstand surgical treatment is operable.

TECHNIQUE.

After deciding upon operative interference, and finding confirmed by the X-ray the perfect filling of the roots, nerve-blocking (after Riethmüller) with novocain and suprarenin, should be resorted to as the method of choice, under the strictest aseptic precautions. General anesthesia, with but few exceptions, has no place in this work.

INSTRUMENTATION.

But few instruments are required. Those needed are the following: One small obtuse bistoury (Black), four dental burs, a simple retractor made from piano wire, a small curet, and a syringe.

A straight incision in the long axis of the tooth-root, from about 4 to 6 mm. in length, is made. The same small bistoury—I use Black's knives—may be used to release the tissues from their periosteal attachment. A small, spring-point retractor made of piano wire is placed in this opening, and the tissues are drawn taut. Small pointed tissue-scissors are used to clip the resisting fibers of tissue until the opening is of about the size of the diameter of an ordinary lead pencil. The wound should now be irrigated with physiological saline solution, and if annoying hemorrhage occurs, a tampon saturated with adrenalin chlorid applied under pressure for a few moments will control the bleeding. The alveolar plate is now removed with an ordinary rose-head bur, and the root-end is definitely located. The bur is made to completely encircle the apical end, and the opening is extended down the neck of the tooth to sound support or bony tissue.

The end of the root is then plainly visible, and may be excised with a small rose-head or fissure bur. A larger bur or curet is now used to remove any remaining soft or necrotic bone, and the wound is irrigated and packed lightly with a narrow sterile gauze strip dipped in sterile vaselin. Vaselin prevents the breaking-up of granulations and retarded healing. This dressing should remain for from twenty-four to forty-eight hours, according to the subsequent suppurative process.

The dressing is renewed in forty-eight hours, and the wound lightly irrigated. About three dressings applied at such intervals will suffice.

As soon as these little wounds show signs of granulation, they are filled with bismuth paste, and the patient is dismissed.

The accompanying illustrations show several inoperable cases, and operable ones before and after operating, the affixed legends indicating the history, the operative technique, and the after-treatment employed.

DANGER AND ACCIDENTS TO BE AVOIDED.

After opening the alveolar plate and definitely locating the root-end, extreme care should be exercised to avoid injury to adjacent teeth. This possibility will be determined by a radiograph, which will show the proximity of adjoining teeth.

The operator will usually make the opening too high up. It is better even to make the opening a little low and gradually extend the operation to the apex, than to start too high. I have observed some operators make this error of getting too high up on the neck of the tooth-root, or beyond the apex, and during the curetting or burring away of the necrotic tissue, perforate the floor of the nasal cavity. The root-end must be exposed to view perfectly, and adrenalin chlorid employed to obtain a dry and clear field of operation.

Occasionally I have discovered an amputated root-apex which had been left in the wound by an operator who had not taken an X-ray after performing the operation. Healing cannot take place under this condition, and suppuration will invariably follow.

It is absolutely necessary for the operator to search well the area and pocket, after operating, for dislodged fragments. This is usually accomplished by means of a spoon curet. Retarded healing is usually due to such fragments left in the wound, and occasionally in suppurative conditions it may be necessary to reopen these wounds and repack until granulation takes place.

IMPRESSION TAKING BY THE GREEN METHOD.

By D. D. ATKINSON, D.D.S., Brunswick, Ga.

(Read before the union meeting of the Georgia State Dental Society and the Southern Branch of the National Dental Association, Atlanta, Ga., June 4, 1914.)

IT might seem strange that, after all that has been written upon this subject, one should venture to come before representatives of the dental profession with anything claimed to be new upon this subject. It is well known that many of the leading dentists of the country have passed that period when the construction of artificial dentures was attractive to them, and have set aside that important branch of prosthetic dentistry. To these I would say that whatever be their attainments in scientific bridge work, gold or porcelain inlays, or whatever the character of their operations, they do not exceed in scientific requirements those of modern advanced plate work construction, as to both the taking of impressions and the anatomical arrangement of the teeth themselves. To him who is so unfortunate as to have to wear a denture, there is nothing so important as that he should have the best that skill can produce; therefore the dentist who has served his patients up to the time when they are in need of artificial teeth should then feel a just pride in giving them the best possible substitute.

The writer does not claim any authentication for the ideas to be set forth in this paper, but wishes solely to call the attention of the profession to a system of impression taking promulgated as the "Green Brothers' Course in Plate Work."

To those who are not familiar with this system I would say that these operators have given to the profession a system of impression taking that is entirely new, and has never been taught in the dental colleges to any extent; and while the subject is entirely too large to be presented in full in a paper of this kind, I shall endeavor to call attention to a few features, with the hope that my colleagues may be inspired to search further into the possibilities of this system by reading the book written by its originators, which is to my mind the most practical and sensible treatise on this subject that has yet been offered to the profession.

AIM AND ACCESSORIES OF THE GREEN METHOD.

In the edentulous upper jaw of a living subject there is a zone of soft immovable tissue which extends from the frenum labii all the way around behind the tuberosities and across the palate. This zone reaches the line between the hard tissues of the hard palate and the soft movable tissues above and behind. It is at this zone that it is intended, under this new system, that the rim of the plate shall terminate, and rest with valve-like pressure upon the soft immovable tissues, for, if it falls short of reaching this part, the rim of the plate will rest upon the hard tissues

of the alveolar process, where it will be impossible to obtain the valve-like pressure. And if it extends beyond this zone, the movable muscles and tissues will be continually throwing the plate from its position. This theory holds good both in the upper and lower jaws. To accomplish this result, the Green brothers have employed the specific kind of modeling compound known as Kerr Perfection, and have devised impression trays especially for that purpose. These impression trays are made much shallower than the rim of the plate is meant to be, and shorter than is intended for the length of the plate to be.

TAKING THE IMPRESSION FOR A FULL UPPER DENTURE.

For a practical case, a tray is selected which just about fits the jaw, with perhaps an eighth of an inch to spare all around. The tray and impression material being ready for taking a full impression, sufficient of the material is softened in warm water and then placed in the tray and finger-fashioned to conform somewhat to the shape of the jaw. Just before inserting it into the mouth, it is held over a spirit lamp, and the entire surface is softened to a semifluid state, but not hot enough to burn; then it is carried into the mouth, and with a gentle wave-like motion pressed up with about the pressure which the plate is to exert after it is made. The surplus material above the rim all around is pressed up against the outer edges of the alveolar process first on one side and then on the other, and with the index finger around and behind the tuberosities.

MUSCLE TRIMMING.

While the material is still soft, the patient is instructed to work the muscles of the face and of mastication in such a way that they shall cut their own way into the material, and in this way form the height of the impression and likewise of the future plate—but not the *exact* height. This is called muscle trimming. With a cold wet cloth held on the underside of the tray, the modeling compound is soon chilled and removed from the mouth, when it is immediately immersed in cold water. All surplus compound is then cut away, leaving the top of the rim as indicated by the trimming of the muscles, and this trimming is done so that the rim of the impression is not much thicker than the finished plate, whereupon the posterior portion of the impression is cut off to the length of the plate.

DETERMINING THE LENGTH OF THE PLATE.

To find the length of the plate, it will be seen that the movable muscles of the palate have turned the impression down, for it must be borne in mind that the plate must extend posteriorly into the aforesaid zone which intervenes between the hard tissue of the hard palate and the movable tissues of the soft palate. The edges of the rim are then softened, one side at a time, over a little spirit lamp, and placed back in the mouth, with instructions that the patient shall still muscle-trim them, until no further impression can be made by moving the muscles. This, then, is the exact height which the finished plate must have.

If there is any doubt about the length of the plate, this can be determined by warming the posterior edge and directing the patient to swallow. If the plate should be too long, it will be indicated by impression of the movable muscles of the palate, and should be trimmed accordingly. We shall now assume that the muscle trimming has been done on both sides, the next step being to conform the impression all around to the zone of immovable soft tissue already mentioned. This is done by warming the edge of the impression over the hand spirit lamp slightly, just enough to enable it to yield to pressure all the way around behind the tuberosities. This may be done one side at a time, the impression to be carried quickly to the mouth and the rims to be conformed to the soft zone by the

pressure of the fingers and to be held there until the material becomes hard. When this is done properly, there will be a valve-like pressure all around on the outside of the alveolar border, which will not leak, and which will not be thrown down by the muscles of the face, because they have already cut their way into the material when it was soft.

Post-damming. The next step consists in post-damming, which means that the impression at the palate must be warmed and pressed up to conform to the palate itself; this being accomplished, if the work has been properly done the impression will hold fast in the mouth and is called a test impression, and just as this impression fits, so will the plate. I have seen patients try to shake such impressions out of their mouths, or to cough or spit them out, and fail on account of the excellence of the suction.

COMPARISON BETWEEN OLD-TYPE TRAYS AND GREEN TRAYS.

The same principles, with a modification in the details, are to be observed in taking lower impressions. A comparison between the impression trays of the old type and the trays used in the Green system shows that the old-type trays with high rims and long handle will, of necessity, strain all of the muscles of the lips and cheeks out of position, and hold them there while the material is hardening, be it plaster or compound; consequently, when these muscles rebound, there can be but one result; viz, the upper plate must drop or the lower plate jump up. Muscle trimming cannot be done with such trays.

In comparing two impressions, one taken by the old method with the deep tray, the other by the Green muscle-trimming method in the Green tray, the difference is very apparent. The one taken with the old tray cannot be replaced in the mouth with any expectation that it will remain *in situ* without being held, even should it have been taken in plaster. The other impression can be tested in the mouth, and will remain *in situ* comfortably while the patient discusses the whole process with the operator without once throwing it loose.

CONCLUSION.

The results obtained from the Green method are so satisfactory in shallow and all other kinds of mouths that I would prophesy that in time to come no other system of impression taking will be taught.

I should like to state in this connection that I have no interest whatever in the sale of the work called "The Green Brothers' Course in Plate Work," but on account of the impossibility to give more than a scant outline of the great possibilities of this system, I would advise every plate-worker to study this book diligently.

[See also *Discussion,* as reported under "Proceedings of Societies," this issue.]

DEEP MUSCULAR INJECTIONS OF SUCCINIMID OF MERCURY IN PYORRHEA ALVEOLARIS.

By PAUL GARDINER WHITE, D.M.D.,
ACT. ASST. DENTAL SURGEON, U.S.N.

TO be able to check the ravages and afford relief to the sufferer of that most distressing and destructive disease, pyorrhea alveolaris, was in the past indeed a worthy endeavor on the part of the operator who had the patience and persistence and the patient who had the courage and the faith. To be able to cure a majority of cases with the least possible discomfort and pain, and in an incredibly short time, while no more worthy of the operator than in the days of old, is a remarkable stride in the right direction of protecting mankind from the inroads of disease; and in no better way can human maladies be reduced to a minimum than by destroying the disease-makers before they have an opportunity to get beyond the portals.

In the October 1914, number of the U. S. Naval Medical *Bulletin,* the writer published a report of six severe cases of pyorrhea, all of which were completely cured by this new method of treatment. The cure of some sixteen successive cases since then prompts this presentation to the dental profession.

It is not the writer's intention to discuss the various opinions held concerning the etiology of this prevalent disease, but in order that the purport of this report be understood, the following stand is taken: That pyorrhea is due to a local irritation which may be and often is predetermined by general debility and a starved condition of the tissues from lack of nutritive supply.

FIRST EXPERIENCE WITH SUCCINIMID OF MERCURY.

The use of succinimid of mercury in the treatment of this disease was first brought to the writer's attention wholly by chance at the Portsmouth navy yard. Two patients, who had been under local treatment for pyorrhea, presented themselves upon different days with gums swollen and exquisitely tender, and often with free salivation. Being unable to account for such conditions, which occurred at regular intervals, the patients were questioned, and the fact that they were also being treated for other troubles at the same time by Dr. Barton L. Wright, U. S. N., senior surgeon at the yard, was brought to light. Investigations showed that both patients were being given deep muscular injections of mercury at regular intervals, and that the changes in the gum tissues and their hypersensitiveness were usually most pronounced on the second day after injection. The surprisingly quick cessation of the pus flow from the pockets and the corresponding return to normal of the gum tissues led to the introduction of succinimid of mercury in other cases by Dr. Wright and myself.

DOSAGE.

Some twenty or more cases have since been treated by this method, and in every case a cure has been effected inside of four or five weeks. The doses of mercury given at the first injection —these injections being made deeply into gluteal muscles—varied according to the physical condition of the patient, but usually averaged about one grain. For the purpose of tabulation, this was divided into fractional fifths, the first dose usually being gr. 6/5 or gr. 5/5, and at each succeeding injection—at weekly intervals—a reduction of 1/5

gr., as the condition of the case and the patient required.

Dr. Barton L. Wright, surgeon, U. S. N., who had been using succinimid of mercury since 1905 with remarkable results, especially in diseases of vegetable parasitic origin, has demonstrated that "to produce the immediate curative effects, the dosage of the initial injection must be extremely large," and that "small and frequently repeated doses are not productive of rapid results, and when continued uninterruptedly unduly long, render the infecting organisms immune to their chemical affinity."

Quoting further from Dr. Wright—"I now believe that mercury has a dual parasitotropic action: First, primary or direct, in which the mercury by affinity unites with the organisms and without antibody binds complement; or, secondarily or indirect, in which the mercury stimulates the rapid production of specific antibody."

The investigations of Dr. Wright were carried out on the principle of Ehrlich's theory that "For every parasitic organism there is a chemical affinity, which, if found and injected into the infected host, would destroy the infecting organisms and therefore cure the specific disease."

Because of the rapid absorption required in mercurial treatment, Dr. Wright finds that mercuric succinimid, gr. 1.8 = metallic mercury gr. 0.909, is the most efficient of the soluble salts of mercury.

The danger of mercurialism is not very great, it having occurred only once during our investigations, and in that instance having been due to a mistake, the patient being given two injections on successive days. Should such symptoms occur, however, the injections should be at once stopped, and appropriate corrective measures applied. The bowels should be freely moved daily, and surgical asepsis carefully observed in every particular regarding syringe, needles, solution, and skin at the site of injection. While all of our cases have been males, the doses of mercury in females should average from 1/5 gr. to 2/5 gr. less than in males.

LOCAL TREATMENT.

The local treatment, consisting of the thorough removal of calcarious deposits, the extraction of hopeless teeth and roots, and the polishing of the tooth structure, was continued every other day during the course of treatment, Dr. D. D. Smith's prophylactic trimmers and scalers being used entirely. Broken-down tissues and sensitiveness of the necks of the teeth were reduced by a 10 per cent. solution of silver nitrate—which also prevented the discoloration which a higher per cent. solution would produce—and the patient instructed to apply equal parts of aconite, iodin, and chloroform daily as a counter-irritant, and to stimulate absorption.

At the completion of the treatment, prophylactic advice as to the care and use of the teeth was given each patient, and it is hoped that they will profit physically and mentally thereby.

SUMMARY OF CASES TREATED.

A summary of the cases, taken from Dr. Wright's case-book, is given below. It will be noted that in addition to the local action of the mercury in the clearance of the pus flow, an improvement in the general circulation and a systemic regeneration occurred in most cases. In other words, in curing the pyorrhea, nutritive balance, or normal health, is produced.

CASE 1. E. W. C., chief carpenter. The patient came under observation on May 4, 1914, complaining of severe pain, soreness and stiffness of the shoulder joints, and of the feet and ankles. This condition had existed for some years. Treatment at different times had proved of little benefit. For the past few months he had grown much worse, being hardly able to get out of bed or dress himself. He was under treatment for pyorrhea by A. A. Dental Surgeon P. G. White, who considered the case an extensive and bad one. A diagnosis of chronic infectious arthritis was made, the infection probably being due to the condition of the gums.

Injections of mercuric succinimid were given as follows: *May 4th*, gr. 7/5. Slight gingivitis, feels better. *11th*, gr. 5/5. *19th*, gr. 4/5. *23d*, entirely free from all symptoms. Dr. White reports pyorrhea cured. *24th*, gr. 4/5. *June 2d*, complains of pain in both hip joints; injection, gr. 4/5. *7th*, gr. 3/5. *13th*, gr. 4/5. *29th*, feels perfectly well; injection, gr. 3/5. *July 8th*, perfectly well; injection, gr. 3/5. Patient states that a large patch of eczema which has been present on the chest for the past thirty years has also disappeared.

Case 2. W. H. S., sergeant, U. S. M. C. This case was referred to me by Dr. White, with diagnosis of pyorrhea, the gums being soft, spongy, and retracted. Pus was exuding from around every tooth. The patient has a chronic arthritis of the left ankle, which is considered an autogenous infection from the local infection of gums.

Injections were made as follows: *June 29th*, gr. 6/5. *July 6th*, gr. 5/5. Marked improvement. *11th*, gr. 4/5. *17th*, gr. 4/5. All pain and swelling in the left ankle disappeared, gums normal. *21st*, apparently cured. The following two injections were given as a precautionary measure. *July 24th*, gr. 3/5. *31st*, gr. 2/5.

Case 3. C. E. R., chief yeoman. This case was referred to me by Dr. White, who had been treating the patient for about six weeks. There was extensive and severe infection which had shown slight improvement.

Injections of mercuric succinimid were given as follows: *June 29th*, gr. 5/5. *July 6th*, gr. 4/5. *11th*, gr. 3/5. *13th*, apparently cured. Three more injections were administered as a precautionary measure. *17th*, gr. 3/5. *24th*, gr. 2/5. *31st*, gr. 2/5.

Case 4. E. K., G. C. M. P. This case was referred by Dr. White. The patient presents soft spongy gums, which bleed freely, and are extremely tender and sensitive. Pus in large amounts discharges from around every tooth. The patient has a polyarthritis, both knees and botn ankle joints being infected. It is thought that this condition is probably an auto-infection.

Injections of mercuric succinimid were given as follows: *July 28th*, gr. 5/5, followed by marked improvement. *Aug. 3d*, gr. 4/5. By *August 6th* all symptoms had disappeared. *Aug. 18th*, no evidence of pyorrhea was present, but injections of gr. 4/5 were resumed as a precautionary measure. *Aug. 24th*, gr. 4/5. Pyorrhea and arthritis cured.

Case 5. S. K. The patient presented severe and extensive pyorrhea, subacute gonococcic urethritis and gonorrheal arthritis.

Injections of mercuric succinimid were given as follows: *Aug. 16th*, gr. 6/5. *25th*, gr. 4/5. *Sept. 2d*, gr. 4/5. *4th*, pyorrhea cured. *9th*, gr. 3/5. *16th*, gr. 3/5. No discharge from urethra for past ten days; urine free from shreds; arthritis cured.

Case 6. A. W. D. The patient was referred to Dr. White by P. A. Surgeon Wheeler for local treatment of a severe and extensive pyorrhea on August 19th. Dr. Wheeler had on August 18th injected mercuric succinimid gr. 6/5, the patient also having gonorrheal arthritis.

Aug. 19th, gr. 5/5; gingivitis followed. *26th*, gums still slightly tender, but pus has entirely disappeared. *Sept. 2d*, gr. 4/5. Pyorrhea and arthritis cured.

Case 7. J. J. M. The patient presented extensive and severe pyorrhea.

Injections of mercuric succinimid were made as follows: *Aug. 18th*, gr. 5/5; marked improvement followed immediately. *24th*, gr. 4/5. *30th*, cured. *31st*, gr. 4/5, as a precautionary measure.

Case 8. L. P., corporal, marines. The patient presented a moderately severe case of pyorrhea, involving the processes of the upper and lower central teeth.

Injections of mercuric succinimid were given as follows: *Aug. 27th*, gr. 5/5. *Sept. 2d*, gr. 4/5. *4th*, cured; no further treatment.

Case 9. W. C. E. The patient presented a mild case of polyarthritis, involving both knees and ankles.

Injections of mercuric succinimid were administered as follows: *Sept. 14th*, gr. 5/5. *17th*, pyorrhea and arthritis cured.

Case 10. E. S. J. The patient presented a mild case of pyorrhea, involving the processes of all upper teeth.

Injections of mercuric succinimid were given as follows: *Sept. 25th*, gr. 6/5. *28th*, cured.

Case 11. T. J. G., P. M. The patient presented a mild case of pyorrhea, involving the processes of the lower teeth.

Injections of mercuric succinimid were given as follows: *Sept. 25th*, gr. 5/5. *28th*, cured.

Case 12. W. J. S., chief quartermaster. The patient presented a severe case of pyorrhea, involving the processes of all teeth, all of which were loose. He complained of indigestion and very poor appetite.

Injections of mercuric succinimid were made as follows: *Sept. 5th*, gr. 5/5. *12th*, gr. 5/5. *19th*, gr. 3/5. *22d*, cured. The gas-

tric symptoms had disappeared, the patient having an excellent appetite.

Case 13. R. B. C., man-at-arms, 1st cl. The patient presented a severe case of pyorrhea, involving the processes of all teeth, all of them being loose, and with an abscess of the right upper jaw and severe bilateral facial neuralgia. The abscess was incised and drained.

Injections of mercuric succinimid were given as follows: *Sept. 5th*, gr. 5/5. *6th*, neuralgia had disappeared. *12th*, gr. 5/5. *19th*, gr. 3/5. Markedly improved. *26th*, gr. 4/5. *Oct. 2d*, gr. 3/5. Cured.

Case 14. E. B. The patient presented a moderate case of pyorrhea of the upper and lower central teeth, and polyarthritis involving the knees and ankles.

Injections of mercuric succinimid were given as follows: *Oct. 5th*, gr. 5/5. *12th*, gr. 5/5. *19th*, gr. 4/5. *21st*, pyorrhea and arthritis cured.

Case 15. O. S. P. The patient presented a severe case of pyorrhea, involving the processes of all teeth.

Injections of mercuric succinimid were given as follows: *Oct. 8th*, gr. 5/5. *15th*, gr. 4/5. *21st*, cured. *23d*, an injection of gr. 3/5 was given as a precautionary measure.

Case 16. L. A., coxswain. The patient presented a severe case of pyorrhea, the processes of all teeth being involved, the gums exhibiting extreme recession, being soft, spongy, and bleeding.

Injections of mercuric succinimid were given as follows: *Oct. 12th*, gr. 5/5. *19th*, gr. 5/5. *26th*, gr. 5/5. *31st*, cured.

Case 17. J. E. B. The patient presented a mild case of pyorrhea.

Injections of mercuric succinimid were given as follows: *Oct. 20th*, gr. 5/5. *25th*, cured.

Case 18. J. F. W. The patient presented a severe case of pyorrhea, involving the processes of all teeth.

Injections of mercuric succinimid were given as follows: *Oct. 26th*, gr. 5/5. *Nov. 3d*, gr. 5/5. *6th*, cured.

Case 19. F. R. The patient presented a case of pyorrhea, moderate in extent and severity.

Injections of mercuric succinimid were given as follows: *Oct. 31st*, gr. 5/5. *Nov. 7th*, gr. 5/5. *9th*, cured.

Case 20. D. D., P. M. The patient presented a mild case of pyorrhea, the processes of the upper molars and lower central teeth being involved. There was marked recession of the gums.

Injections of mercuric succinimid were given as follows: *Nov. 4th*, gr. 5/5. *11th*, gr. 5/5. *14th*, cured.

Case 21. M. M., F., 1st cl. The patient presented a severe case of pyorrhea, moderately extensive.

Injections of mercuric succinimid were given as follows: *Nov. 3d*, gr. 5/5. *10th*, gr. 5/5. *17th*, gr. 5/5. *20th*, cured.

Case 22. C. O. M., C. man-at-arms. The patient presented a case of pyorrhea, extensive calcarious deposits and gum recession, and a free flow of pus from the upper molars and lower central teeth.

Injections of mercuric succinimid were given as follows: *Nov. 7th*, gr. 5/5. *14th*, gr. 5/5. *19th*, gr. 5/5. *20th*, cured.

Case 23. A. W. O. The patient presented a case of pyorrhea, calcarious deposits and extreme gum recession, also discharge of pus from around every tooth. He stated that he was subject to frequent attacks of laryngitis and tonsillitis.

Injections of mercuric succinimid were given as follows: *Nov. 14th*, gr. 5/5. *20th*, Dr. White reported to me this case as follows: "Wonderful improvement. Pus wholly gone, except around lower anterior teeth, where the flow has diminished one-half."

Case 24. L. P. F. The patient presented a case of pyorrhea, extremely severe, and very extensive calcarious deposits under the gums, which were extremely tender and sensitive, a free flow of pus from around all teeth, and severe arthritis of the knee joints.

Injections of mercuric succinimid were given as follows: *Nov. 2d*, gr. 6/5. *9th*, gr. 5/5. These were followed by an immediate and marked improvement in the arthritis of the knees. By *Nov. 16th*, the joint symptoms had disappeared, and the patient was referred to Dr. White. *Nov. 16th*, gr. 6/5. *20th*, Dr. White reported "Improvement."

There has been no return of pyorrhea or arthritis in any of these cases to date.

THE X-RAY AS AN AID IN DIAGNOSIS.

By GILLESPIE ENLOE, D.D.S., Atlanta, Ga.

(Read before the union meeting of the Georgia State Dental Society and the Southern Branch of the National Dental Association, at Atlanta, Ga., June 4, 1914.)

IN presenting this subject it is my purpose to do so in as simple a manner as possible, leaving out the discussion of all scientific features, but hoping that the hearer will wonder, as I now wonder, how he has practiced dentistry so long without the aid of the radiograph.

In the preparation of the paper I have appropriated the best of all that I could find on this subject, and do not claim originality for all the subject-matter, although it has been my good fortune to radiograph nearly every case described and to observe the features mentioned. Making no attempt to cover the whole field, I simply wish to call attention to cases, such as present daily in an ordinary practice, in which the radiograph will help the operator to a better understanding of his work.

DELAYED ERUPTION.

In cases of delayed eruption the radiograph is employed to determine the presence or absence of unerupted teeth. When there seems to be congenital absence of a tooth from the jaw, it is expedient, to express it mildly, to make an X-ray before making and setting a bridge.

With the exception of the third molars, no teeth are so liable to be delayed in their eruption as the upper canines; for this reason we should be very careful about bridge work here, as one of the most embarrassing experiences for a dentist is the setting of a bridge in this space and having a canine erupt shortly after under his appliance.

PROLONGED RETENTION OF DECIDUOUS TEETH.

In cases where deciduous teeth have been retained, long after they should have been exfoliated, the radiograph will show whether permanent teeth are present.

We frequently have young people between the ages of seventeen and twenty-two apply for treatment or filling, with deciduous teeth still in the mouth and firm in position, and it is up to us to decide whether to extract these teeth or treat and fill them. An X-ray will decide the question accurately, and possibly save the operator a great deal of time, embarrassment, and perhaps loss of the patient.

DEVELOPMENT OF ROOTS OF PERMANENT TEETH.

The radiograph will reveal whether the roots of children's permanent teeth are fully developed. What should the operator do when a child of from six to eight years of age comes into his office with a badly broken down first molar with exposed pulp, causing severe toothache? or, the pulp not being exposed, the removal of all decalcified dentin means an extensive exposure, and therefore devitalization, extirpation, and root-canal filling? Should we practice devitalization in such cases? If the roots are fully developed, Yes.

Often a child meets with some accident which breaks off the angle of a central or lateral incisor, and the resto-

ration of the angle sometimes necessitates the removal of the pulp and the placing of a post in the canal. In such cases the question always is, Is the root fully developed? If it is, we may proceed with the devitalization, but if not we use some temporary restoration and preserve the pulp until it has fulfilled its function of root development. We occasionally find an anterior tooth in a child's mouth so badly broken down that crowning is indicated, and again the same question confronts us: Is the root fully developed? Whether we should keep the tooth temporarily repaired with cement for a year or two, or devitalize and crown it, depends entirely on the answer to these questions given by the radiograph.

IMPACTED TEETH.

In cases of impacted teeth, the radiograph is an invaluable aid to extraction. Careful study of a radiograph will show the dentist the best method of preparation for extraction; just where to cut away overlying or impacted parts, how much bone or process to dissect away before the malposed tooth can be removed, and where to apply force in the extracting operation.

Patients seldom realize that the removal of a tooth is not always a simple operation, and are inclined to blame the operator if the tooth is not quickly removed, instead of crediting him with working dextrously in a difficult operation. They are likewise unwilling to pay a fee proportionate to the difficulty of the operation, as compared with other operations. I frequently tell such patients that the extraction of an impacted third molar is a more difficult operation than the removal of a vermiform appendix. By showing radiographs of such cases, the dentist will gain his patients' earnest, intelligent co-operation; they will know just what is being done for them, and for the first time in their lives they will understand that the extraction of a tooth may be a serious, difficult, and expensive operation.

FILLING OF ROOT-CANALS. PERFORATIONS.

The radiograph further enables the operator to learn if root-canals have been opened and enlarged to the apex before filling, and to observe the root-canal filling after the operation.

In tortuous canals we never know, to a certainty, when our work has been properly done, even though we enlarge the canal with sulfuric acid, being most careful with details; even when this has been well done we sometimes fail to reach the apex with a gutta-percha filling. The use of the X-ray eliminates all guesswork; we know what we are doing.

Lots of perforations would never be made if we would take the trouble to ascertain the direction of the roots before we begin opening them up. If the roots are unusually short, a radiogram will keep us from going through at the apex; and if they are unusually long, we do not stop short of the apex in our work. The patient can be shown the X-ray and informed, as nothing else will tell him, just what the operator is doing for him.

ALVEOLAR ABSCESS.

For locating the tooth responsible for an alveolar abscess the radiograph is indispensable. A patient recently presented himself with a Richmond crown which had been set several years before and was apparently the seat of a chronic abscess, but when an X-ray was taken, the trouble was located on the root of the adjacent tooth. He was a dentist, and it was difficult to persuade him that the other tooth was causing all the trouble, until it was opened up. In chronic abscesses of long standing a radiograph will show the extent of destruction of tissue, both bony and dental. In large abscess areas it can be determined just how many teeth are involved, and at the apices of which teeth do abscesses exist. In crowned teeth the abscessed roots, and in devitalized teeth

improperly filled root-canals are revealed.

It is a common occurrence in practice to have a patient present a pus sinus discharging in the region of the apex of a crowned tooth. If the root has been properly filled we should treat the sinus through the external alveolar plate; if not, the crown should be removed and the treatment effected through the root. The radiograph will determine which course should be pursued.

ROOT AMPUTATION.

The radiograph is a necessity for observing the field of operation before and after root amputation. When a tooth fails to respond to less radical treatment, and it is deemed necessary to amputate a portion of the apex of the root, the question naturally arises. How much shall we cut off? A good radiograph answers the question.

LOCATING FOREIGN BODIES.

For locating foreign bodies, such as a broach, in a root-canal, or a piece of a wooden toothpick in the peridental membrane, the radiograph is a valuable aid. One of the most painful cases which have come under my observation was that of a man who appeared to be suffering from neuralgic pains, none of his teeth being tender to either percussion or pressure, and there being apparently no inflammation. A radiograph showed a shadow against the mesial root of the third molar. Inquiry developed the fact that the patient was accustomed to use wooden toothpicks, and upon extracting the third molar a piece of toothpick was found embedded in the membrane of the molar. After this all pain ceased.

DISCOVERING TOOTH FRAGMENTS AFTER EXTRACTIONS.

The radiograph enables the operator to determine the presence or absence of a small fragment of tooth in the gum after several teeth have been extracted. Patients frequently come in several days after an extraction, complaining of very sore gums, and want to know whether a piece of tooth has been left in the mouth. Unless a radiograph is used, the parts will have to be anesthetized with a local anesthetic, and some of the soft tissues dissected away, to determine whether the inflammation is due to an unremoved fragment of tooth or a small portion of fractured process—all of which would take time and cause the patient annoyance and some pain.

DIAGNOSIS OF ROOT FRACTURE.

For diagnosis of fracture of a root, the radiograph is a most rational expedient, which should be resorted to in all cases of traumatism before treatment is begun. How can we know, without a radiograph, how to treat a case of this description? Suppose a patient presents for treatment after having loosened both upper centrals by a fall, with inflamed gums and pain intolerable on percussion.

Such a case I treated by extirpating both inflamed pulps and filling the root-canals, after which one tooth immediately resumed a normal condition, while the other remained loose and sore. A radiograph was taken, which showed the loose tooth to be fractured near the apex. Upon removing the fractured parts, and smoothing the end of the broken root, this tooth was also restored to normal.

CONTROLLING SIZE AND SHAPE OF ROOTS OF ABUTMENT TEETH IN CROWN AND BRIDGE WORK.

For observing the size and shape of the roots of teeth to be used as abutments in crown and bridge work the radiograph is the most useful accessory. Occasionally we meet with cases of "peg laterals" in the upper jaw, where crowning is indicated, and the usual practice is to place jacket crowns on them. But we all know that this kind of crown is weak at best, is difficult to construct, and very fragile: if the root is long and

strong enough to support some kind of pin crown we may render our patients better service if such a crown is used—and the only sure method of obtaining this information is the use of the X-ray.

ENLARGING ROOT-CANALS FOR POSTS.

When enlarging root-canals for crown posts, the radiograph is a great safeguard. Sometimes when enlarging root-canals we lose the course of the canal, and are at a loss as to whether we are proceeding in the right direction. A wire is placed in the root-canal, and a radiograph made. If there is any danger of a perforation mesially or distally, the radiograph will show it.

EXAMINATION OF INFLAMMATION AROUND BRIDGES.

In examining bridges about which there is inflammation the radiograph is used for determining the inflammatory focus. Fixed bridges are at best none too sanitary, and for this reason we often find intense inflammation about them. Frequently the irritant consists in cement forced into the tissues around a shell-crown abutment, causing an inflamed condition which can only be cured by removal of the cement. Our only means of finding its location is an X-ray.

In observing the field before constructing a bridge, the radiograph will not only disclose the presence of unerupted teeth and unremoved tooth-roots, but will show the operator the size, shape, inclination, and condition of the roots designed for abutments.

FRACTURES.

In cases of fracture of the jaw the X-ray becomes a necessity. Fracture of the mandible is almost always accompanied with so much swelling that digital and ocular examination is very unsatisfactory. The operator who treats a fracture should know just where it is situated, and what kind of fracture he has to deal with, and if there is displacement of the fragments he must know how much and in what direction the displacement has occurred, in order that he may properly readjust the parts. This information can be given by the X-ray only.

TRISMUS.

In cases where the patient cannot open the mouth widely enough for ocular examination—when, for example, an impacted lower third molar is causing a false ankylosis—we may suspect the molar to be the exciting cause, but we cannot be sure of this ourselves nor demonstrate it to others without the use of the X-ray.

RECORDS OF WORK ACCOMPLISHED.

In recording any work done, the X-ray can be put to valuable use. Any kind of record of work done is valuable, and records of extractions, root-fillings, and crowns are at times invaluable to the operator. In cases of trial for malpractice such records would prove conclusively the operator's position, being incontrovertible evidence. Suppose a patient had to go to a hospital after an extraction of a badly impacted lower third molar and should sue the dentist and swear at the trial that he had broken the jaw, would it not be of the greatest value to the defendant if he had taken a radiograph after finishing the operation?

CONCLUSION.

In conclusion, the best argument in favor of the use of the radiograph in dentistry is that it furnishes evidence that none can gainsay or disprove, and that it brings to light hidden conditions which can be revealed in no other way.

THE NATIONAL NARCOTIC (HARRISON) LAW AS IT AFFECTS THE DENTAL PRACTITIONER.

By HERMANN PRINZ, A.M., M.D., D.D.S., Philadelphia, Pa.,
PROFESSOR OF MATERIA MEDICA AND THERAPEUTICS, SCHOOL OF DENTISTRY, UNIVERSITY OF PENNSYLVANIA.

ON March 1, 1915, the National Narcotic (Harrison) Law went into effect. This law has in many respects a direct bearing on the practice of dentistry, as the two basic drugs to which it refers—namely, opium and cocain and their derivatives—are quite frequently employed by the dental practitioner. In the absence of regulations from the bureau of Internal Revenue it is impossible at this moment to lay down specific rules for the dentist. However, a synopsis of the law in its relationship to the dental practitioner is herewith appended:

SYNOPSIS OF THE HARRISON LAW.

(1) The law provides that on and after March 1, 1915, every person, firm, or corporation that imports, manufactures, compounds, deals in, disposes of, sells, distributes, or gives away opium, or coca leaves, or any compound, manufacture, salt, derivative, or preparation thereof, shall register with the Collector of Internal Revenue of the district in which he resides, his name or style and his place of business. At the time of registering, and on or before July 1st annually thereafter, every such person shall pay to the said collector a tax of one dollar.

(2) The specified drugs may be purchased only upon official order blanks issued by the Internal Revenue department, at a cost of one cent each for each original order or duplicate thereof. Whenever the dentist orders any of the above-named drugs he must fill out the official order blank, retaining the duplicate copy thereof for two years and in a manner open to inspection by the proper authorities.

(3) The dispensing or distribution of any of the aforesaid drugs to a patient by a dentist duly registered under the act, in the course of his professional practice only, is not interfered with by this law, nor does the law apply to the sale or disposal in any way of the said drugs by a dealer on the written prescription of a dentist. But such prescriptions must be dated as of the date on which they were signed and must bear the signature of the dentist who issued the same. A duplicate copy thereof should be retained for two years by the prescriber.

(4) The law exempts from its provisions all preparations and remedies which do not contain more than two grains of opium, or more than one-fourth grain of morphin, or more than one-eighth grain of heroin, or more than one grain of codein, or of any salt or derivative of any of them, in one fluid-ounce, or, if a solid or semisolid preparation, in one avoirdupois ounce; all liniments, ointments, and preparations which are prepared for external use only, except liniments, ointments, and other preparations which contain cocain or any of its salts, or alpha or beta eucain, or any of its salts, or any synthetic substitute for them. The exemptions as to the preparations above named apply only when they are sold, distributed, given away, dispensed, or otherwise disposed of as medicines and not for the purpose of evading the provisions of the act.

(5) It is a crime under the act for any person who is not registered and has

not paid the tax to have in his possession or under his control any of the aforesaid drugs, and such possession will be construed as presumptive evidence of a violation of the act. This provision, however, does not apply to any employee of a registered person, or to a nurse under the supervision of a dentist registered under the act, having such possession by virtue of his employment or occupation and not on his own account.

The penalty for violating any of the requirements of the act is a fine of $2000, or imprisonment for not more than five years, or both, in the discretion of the court.

From all appearances, all local anesthetic solutions, tablets, pellets, pastes, etc., containing cocain or opium, or any of their derivatives, are amenable to this law.

According to a ruling of the Treasury department dated February 26, 1915, the following statement concerning the substitutes of cocain has been issued:

> The question as to whether novocain and similar preparations come under the provisions of the Harrison Narcotic Law as synthetic substitutes for cocain is now under consideration. Until this question is fully determined, novocain and similar preparations the exact character of which has not been fully established will not be held as coming within the scope of this law.

Tropacocain is a synthetic product of cocain, consequently its sale will be governed by the law, while chloretone, *i.e.* acetone-chloroform, and quinin and urea hydrochlorid are not affected by it.

The practitioner who purchases ready-made solutions, tablets or other pharmaceutical compounds should carefully read the attached labels so as to familiarize himself with the components of the respective preparations. Aside from the before-mentioned drugs there are a number of pharmaceutical preparations employed by the dental practitioner upon which the new law has a direct bearing. The most important compounds are herewith enumerated: Fluid extracts, tinctures, and elixirs, powders, pills, tablets (compressed and hypodermic), and pastes containing opium, coca, or their derivatives, such preparations including the following compounds: Warburg's tincture, Dover's powders; paregoric, ipecac, and opium pills, Brown's chlorodyne, brown troches, Tully's powder, opium and lead wash, some of the anti-neuralgic liniments, most of the pulp devitalizing compounds, and such local styptics as stypticin (cotarnin hydrochlorid) or styptol (cotarnin phthalate), and the occasionally internally employed hemostatic—the camphor, opium, and lead-acetate pill. Many of the anodyne compounds which are administered by the dentist as pain-relievers contain opium or its derivatives, *i.e.* codein, heroin, morphin, etc. Incidentally this is equally true of most cholera drops and cough mixtures. Preparations for the mouth and teeth in the form of washes, powders, pastes, and soaps are usually free from opium or cocain admixtures, while a number of other pharmaceutical compounds used by the dentist contain these drugs. Merely to enumerate a few, the following preparations may serve as examples: A widely advertised abscess cure contains morphin: mummifying pastes are known to contain cocain. This is equally true of certain antiseptic and anesthetic pastes employed for polishing teeth and massaging the gums. It may seem ridiculous, but nevertheless it is true that even some root-filling compounds are known to contain morphin.

THE CHEMISTRY OF DENTAL AMALGAM ALLOYS, WITH SOME CONSIDERATIONS CONCERNING THEIR PHYSICAL PROPERTIES.

By WM. W. ATKINSON, Philadelphia, Pa.

(Read before the Clinical Club, Newark, N. J., October 28, 1914.)

ROBERTS-AUSTEN, in speaking of the work of the modern metallurgist,* says: "The chief point proved by these researches is that all of the properties of the alloys, and therefore their industrial value, depend directly upon two factors: (I) Their *chemical* constitution; that is to say, the relative properties of (*a*) the component metals, (*b*) the chemical compounds formed by these metals, (*c*) the isomorphous mixtures, or (*d*) the various allotropic modifications of the constituents. (II) Their *physical* constitution or structure; that is, the shape and dimensions of the crystals of the elementary constituents which, by their juxtaposition, constitute the metallic mass. The first aim of a systematic study of alloys must be to ascertain their chemical constitution or structure, and its final aim must be the study of the relation existing between these ascertained factors and their useful properties."

Such a consideration of the subject of dental amalgam alloy must dispel the uncertainty that has ever obtained regarding that important material. Dental metallurgists, after many years of more or less empirical experimentation, have established the metals best suited for the purpose, as well as the physical requirements for an amalgam filling. Silver-tin has been proved to be the basic alloy, and after it was ascertained that gold, zinc, and other metals failed to confer desirable qualities, copper has been found by the majority of investigators to be the only metal of value as a modifier of that base.

The requirements that have been established are, that there should be a slight expansion to prevent the ingress of bacteria, but not so pronounced as to break frail cavity walls or to interfere with the articulation of the opposing teeth; the final stage of setting should be quickly attained, and there should be no after-changes in form; there should be also rigidity, strength, and resistance to corrosion. By empirical work, however, no scientific formula has been deduced nor any manufacturing process evolved whereby these requirements could all be met. We must turn, therefore, to the scientific study of alloys as outlined by Roberts-Austen, the method for which is afforded by metallography—a study of the inner constitution and structure of the metals and their alloys. In this work are applied all of the resources of physical chemistry, of which it is a most important branch. By means of charts plotted in values denoted by curves, it visualizes its results, so that the narrower definition which we sometimes meet, of the mere microscopic investigation of the internal structure and constitution of alloys, does not obtain—for it is an all-inclusive science which searches by any or every means at its command the reasons for all of the phenomena of metals and alloys of metals, and the relationship of these phenomena to their physico-chemical properties.

* "An Introduction to the Study of Metallurgy," page 211.

Percentages dealt with are, as a rule, atomic percentages, and the various combinations of these in alloys are termed "concentrations" of given metals. Numerically these concentrations are regarded as "systems," thus any two metals in any concentration are in the "binary" system, three metals are in the "ternary system," four metals in the "quaternary system," etc. Those concentrations that fall under a system are termed a "series." For example, in the three metals with which we are to deal (silver, tin and copper) there are two "systems" and four "series" involved. In them we find the silver-tin, the silver-copper, and the copper-tin series of the binary systems, and the silver-tin-copper series of the ternary system.

The liquid or melted state of a metal or of an alloy of metals is known as the "liquidus phase," and the solid or frozen state as the "solidus phase." These phases can be coexistent—as, for example, where either chemical compounds or crystals of pure metals freeze out from a cooling mass of melted alloy. As cooling progresses, the "liquidus" state disappears, and the mass freezes completely, and is then in the "solidus" phase. In such a case the first portions to freeze out are called "solutes," and the last portion is the "solvent" or "mother lye." There is also the gaseous or vapor phase, but in practical metallurgical work this is a negligible quantity.

Classification of Alloys.

Alloys are classified in accordance with their constitution, and we shall treat of several of the divisions in the order of their importance to dental amalgams.

I. Chemical compounds of metals with metals form a highly interesting and important division. They form a large group of alloys in which the atoms of the metals are built up, by the force of chemical affinity, into chemical molecules, with the components in the ratios of their atomic weights. These compounds form during the cooling of a melted alloy, just as salts form under like conditions; the analogy is complete, for in each case there is first absorption of thermal energy which frees the atoms, and then a loss of thermal energy which permits the operation of chemical energy and the formation of the true chemical molecules.

We speak of the salts of the halogens as "halides," and we may, with equal force, speak of the chemical compounds of metals as "metalides." These form within an excess of one or more of their constituent metals, in which case they are termed "inter-metallic" compounds; or they may be formed by correctly melting together the required metals in the ratios of their atomic weights, then pouring the melted mass, at a temperature slightly above the heat of formation, into a well-chilled ingot mold. All chemical compounds of metals are homogeneous, but their valencies, that is their numerical combining values, do not conform necessarily to their known valencies in relation to the other elements; yet the metals are subject to the operation of the periodic law to the extent that when they fall in a vertical column of the periodic table we do not expect them to form compounds with each other, yet compounds are formed between many of the metals on the horizontal lines. Thus in the vertical column I of the periodic table, we find the metals Ag, Cu, which form no compounds with each other, yet copper combines chemically with tin to form the compound Cu_3Sn, which compound forms the basis of the bronzes, and is the hard constituent of dental amalgam alloys. Copper also combines chemically with zinc, forming the compounds Cu_2Zn and Cu_2Zn_3, these being the bases of the brasses. Silver combines chemically with tin, forming the compound Ag_3Sn, the basis of all dental amalgam alloys, which compound, so far as the writer knows, is of no other practical use. There is a hypothetical compound of silver and mercury, Ag_3Hg_4. This is supposed, by some writers, to contribute the property of "setting" to dental amalgams. The appendix to "Metallography," by C. H. Desch, 1913, con-

tains a list of one-hundred-and-nine chemical compounds, which number, the author says, is certain to be very greatly increased during the next few years.

It is in chemical compounds that all of the physical properties of the constituent metals undergo the most profound changes. These properties are never the mean of the properties of the component metals—that is, they are never the sum nor the accumulation of those properties. Thus, most chemical compounds of metals are harder, less ductile, of greater compressive strength, of markedly different specific weight, of lower electrical conductivity, different color, and possess greater resistance to corrosion than any other types of alloys. These differences are well marked in the compounds Ag_3Sn and Cu_3Sn.

If we follow the question of chemical affinity into the realm of scientific conjecture known as the electronic theory, we find that the atom, which was formerly supposed to be the ultimate division of matter, is divided into corpuscles intermingled with negative and positive electrons, and to this theory we must look for an explanation of valency. Samuel Smiles, in "The Relations Between Chemical Constitution and Some Physical Properties," 1910, says: "The chief line of advance has been made through the corpuscular theory of matter introduced by J. J. Thomson. According to this theory, valency must be regarded as an electrical phenomenon. The affinity of the atom is occasioned by the instability of the system of corpuscles composing the atom. In order to attain a condition of stable equilibrium, one or more 'electrons' must be expelled from the system, and the number of electrons (or groups of electrons) which are thus rendered mobile determines the valency of the element." On page 545 he says: "This problem of the nature of valency is undoubtedly the most important of those awaiting solution from the chemist. The opinion of the chemists seems divided as to whether the electronic theory can be accepted or not. Against its adoption it is urged that the electron is nothing but a figment of the physicist's imagination, and that chemists can derive no real benefit from it. But it may be pertinently asked whether the atom is not equally the figment of the chemist's imagination, and are we to reject this also? At present, however, the electronic theory seems to be the only means by which there is any prospect of attaining further knowledge of the nature of valency, and this circumstance alone should be sufficient recommendation for a thorough trial. At any rate, if we reject it, we have nothing else to offer as an adequate substitute. Moreover, the electronic theory offers some mechanical conception of the process of chemical union, and, although mechanical ideas are apt to mislead if followed too far, it should be remembered that the chemist has always found them to be peculiarly adapted to his needs."

"The Theory of Valency," by J. Newton Friend, 1909, contains a history of the electro-chemical theories from that of Sir Humphry Davy, 1806, to the present day.

II. Solid solutions. Metallurgists generally had, until metallographic research established the individuality of different mixtures of metals, and so classified them into groups according to their physico-chemical characteristics, regarded most alloys as "solid cold solutions," whereas it is now known that this is but one of their several divisions. Under chemical compounds of metals with metals we have dealt with atomic combinations—that is, with alloys in which the structure is that of chemical molecules composed of two or more atoms of two or more metals that have chemical affinity for each other.

In solid solutions, however, we have to deal with alloys in which the structure is that of crystals in which two or more metals are dissolved. Here some of the forces of chemical affinity are not in evidence, and it is fair to assume that the constitution is molecular in character. These molecules are not chemical combinations of atoms of different metals, but each molecule consists of the atoms of a single metal in intimate as-

sociation or solution with like molecules of other metals, in the crystals. This gives rise to the term "mixed crystals," by which term solid solutions are sometimes classified. Solid solutions, then, are physical mixtures of the molecules of pure metals built up into isomorphous crystals, the shape of which is determined by that metal which is in excess. Solid solutions, when in a state of thorough diffusion, are homogeneous. Their physical properties are changed, but not to such a degree as are those of chemical compounds; in fact, there are additive properties. Examples of alloys which are solid solutions are gold-silver, copper-gold, and copper-platinum. These form solid solutions throughout. In dental amalgam alloys, however, the solid solution must be conceived of as an unappropriated portion, the formation of which depends mainly upon considerations of temperature and concentrations. The subject of solid solutions is comprehensively treated in Desch's "Metallography."

III. Eutectics. A eutectic is defined as that concentration of any series which has a lower melting-point than any other concentration in the series. Thus, through the intimate association of two or more metals, by the operation of melting, we sometimes find that there has been a mutual depression of their melting-points, so that the resultant alloy melts at a considerably lower temperature than that of the mean of the constituent metals. A eutectic is always a mechanical mixture of metals, that is, its metals are only in physical juxtaposition, and are not dissolved in each other. The structure is that of intimately mixed microscopic portions of pure metals, which exist either as leaves, globules, or crystallites, or of a mixture of two or more inter-metallic compounds. In several of the writings of dental metallurgists we encounter the term "eutectic" applied to the phenomenon of the liquefying of a portion of an ingot of alloy upon its being remelted, this taking place at a lower temperature than that required for the melting of the entire mass of alloy, and manifesting itself as globules distributed over the surface of the ingot like those which appear on the surface of a button of copper amalgam when the dentist heats it in preparation for a filling.

It is the eutectic, but these writers often attribute this phenomenon to poor melting, and assume that certain of the contained metals had, as a result of such error, not gone into "solution," and that this could be corrected by remelting the ingot and carrying it to a higher temperature than had previously been done. This phenomenon, however, is considered by metallographists to be one of the phases of a heterogeneous alloy. To illustrate this, using an ordinary dental amalgam alloy, we have therein various combinations, according to the desire of the manufacturer, of silver, tin, copper, zinc, gold, platinum, etc. Between these metals is possible a long series of chemical compounds, solid solutions, and eutectics. The cooling of the alloy gives rise to the formation of several of these series, and the first to solidify is that chemical compound or solid solution which has the highest melting-point, this being followed successively by those concentrations which have lower melting-points; so that the last portion to freeze out is the last "liquidus" phase existing in the alloy outside the first-formed crystals. Further cooling results in the solidification of the whole mass, when two or more separate "solidus" phases are coexistent, each with a different melting-point. When the alloy is again heated, we find the "eutectic" to melt first and to show as globules over the surface of the ingot, and the alloy to be resolved into the liquidus and solidus phases. The liquidus phase may be a low-melting chemical compound of metals, or what is more often the case, a solid solution of excess metals, or a conglomerate, according to whether the excess is of high or low melting-point, this depending upon considerations of chemical affinity of greater or less degree. Eutectics of importance to our subject are Hg-Zn, formed at 1 atomic per cent. Zn, with a freezing-point of —42.5°C.; Hg-Sn, formed at nearly 100 atomic per cent.;

Hg, freezing-point not established; and Ag-Cu, formed at 60 atomic per cent. Ag, freezing-point 778°C. (Desch.) It will be seen that, in an amalgam filling of the ordinary type, two eutectics are possible which would have an effect upon the freezing-point which we term "setting." Also there is possible the last-named eutectic of Ag-Cu, which forms at 60 atomic per cent. Ag. at a temperature of 778°C. This eutectic is known as Levol's alloy, and was erroneously announced by its discoverer, A. Levol, as a chemical compound having the formula Ag_3Cu_2, in the (French) *Journal of Pharmaceutical Chemistry*, 1850, but through the researches of Guthrie, Roberts-Austen, Haycock and Neville, and others, it was long ago proved that it is not a chemical compound, but a physical mixture of copper-silver, the true eutectic of the series.

A eutectic widely used in dentistry is that of Bi-Sn. It is known as fusible metal, and is used for casting lower plates and inlays.

Eutectic alloys possess qualities that are in a degree additive. Thus their electrical and thermal conductivity are said to be sometimes a linear function of their composition, and their color is sometimes a blend of the colors of the component metals. Eutectics, as a rule, are more brittle, less malleable, and of lower tensile and compressive strength than any of their constituents. They are also more easily corroded than are other types of alloys.

General Considerations.

We have so far dealt with the constitutions of alloys, and we shall now take into consideration the properties that result therefrom. Dental or other alloys rarely conform to any one of the main divisions which we have noted, but are more often conglomerates of two or more of them. Thus there may coexist in an ingot of alloy several phases in the solidus of compounds, solid solutions, and eutectics, and the alloy would be entirely out of such physical equilibrium as is required for dental purposes.

These questions as to constitution must be determined by methods of metallography—which are, first, the plotting of a cooling curve by pyrometric tests, which are checked by microscopic study of the sections of the ingot in order that the structure so revealed shall confirm the findings of the pyrometer. It is unnecessary now to enter into details of this work, as works on the subject of metallography contain treatises upon these methods of investigation.

Corrosion.

Corrosion, usually termed discoloration in dentistry, arises from the fact that any two metals in juxtaposition form, in the presence of a fluid solvent termed an electrolyte, a galvanic pair, the members of which are positive and negative to each other, and are called respectively anode and cathode. In such pairs the positive member or anode is dissolved in proportion to its degree of solubility in the particular electrolyte in which it is immersed. Industrial application of this principle is found in electro-plating various objects with gold, silver, nickel, copper, and brass, also in the electrolytic refining of many metals —such as gold, silver, copper, and tin. Alloys may be resolved by electrolysis into their several constituent metals, but there is an order of solubility dependent upon the factors of physical and chemical constitution and the activity of the electrolyte upon the metals in any given combination. In these industrial operations the electrical impulse is given from without, either by a battery of generating cells or by an electric dynamo, but the principle in all cases is the same. The conglomerates are the alloys most susceptible to electrolytic action, and are followed in the given order by eutectics, solid solutions, and chemical compounds. Thus it is seen that of all alloys, chemical compounds best resist corrosion. Zinc is positive to every other metal that is used in dental amalgam alloys, and as a result of this it is the first to dissolve by electrolytic action in the mouth. This causes the filling which contains it

to become porous, and the zinc as well as the other metals are exposed to the action of the sulfids and chlorids in the saliva, which causes the blackening of the filling and the staining of the tooth. Zinc has been advocated for the whiteness which it is supposed to confer upon amalgam fillings, but it can be seen that this whiteness is transitory. Desch's "Metallography" contains a chapter on corrosion which thoroughly sustains these conclusions as to corrosion.

VOLUME CHANGE.

It is known that certain alloys undergo condensation in freezing, that certain other alloys undergo expansion in freezing, and that others retain the ideal volume of the average of their component metals, and are then considered to be in volume equilibrium. Thus the copper-tin series show marked contractions over a considerable range of concentrations; the copper-silver series show expansion for that range of concentrations lying between 5 and 45 per cent. copper. In the mercury-zinc series there is volume equilibrium, that is, over the entire range the volume corresponds to that of the average of the components. In other alloys there are all three states according to the ratios in which their component metals are present. Volume determinations are surrounded by every precaution of scientific control to insure accurate results. The metals must be of the greatest purity, and each metal must have its specific volume determined under the exact conditions that obtain in the volume determination of the alloys. If, for instance, we wish to ascertain the volume of a silver-tin-copper alloy, each metal to be used in the alloy must be first brought to its full melting-heat, being protected during this operation from oxidation or other chemical changes, then allowed to cool down slowly to room temperature. Sections are carefully made from the ingots, and their specific weight is ascertained. This is done by weighing a section in air, then in water at 4°C., then subtracting the weight in water from the weight in air. The weight in air is then divided by the difference, and the quotient represents the specific weight, this being the ratio of the weight of the section to that of the water which it displaces. Thus, if a solid object has an actual weight in air of 10 grams, and its weight in water is 4 grams, the difference is 6 grams; and 10 divided by 6 equals 1.666+, or the specific weight of the object. Water at 4°C. is recognized as the unit of volume for substances heavier than itself, and as unity is 1 it is obvious that 1 divided by the specific weight must equal the specific volume; therefore we divide 1 by the specific weight which we have ascertained for each metal, and so obtain its specific volume. We are now ready to proceed with the volume determinations for an alloy of the metals used in the experiments. We melt them together in such ratios as required, and when they are thoroughly diffused, that is in perfect distribution, having been protected from oxidation, the alloy is allowed to cool slowly to room temperature. The ingot should not exceed two grams in weight. We now determine the specific weight and specific volume of the entire ingot, in order that the factors of error may be reduced to a minimum. The ingot is now analyzed. The ascertained specific volume of each metal we multiply by the percentage in which it is present in the alloy, add the results, and divide by 100. This gives us the ideal specific volume, which, compared with the actual volume that has been determined for the alloy, shows whether the alloy has expanded or condensed or is in volume equilibrium. There are factors of error in the weighing and analyzing, and slight differences in the rate of cooling, but these should not exceed two or three hundredths of one per cent. if the work has been carefully conducted, and may be disregarded for practical purposes.

What is termed shrinkage and expansion in an amalgam filling are phenomena of a quite different order from the volume changes that take place in the actual alloying of metals. The amalgam filling is never in the perfectly melted

state that is necessary to insure correctness of the determination of its specific volume. So we must look to its constitution and to thermal, mechanical, and manipulative treatment which it has undergone, in order to get a clear understanding of its volume changes.

As to physical constitution, amalgam alloys may be divided into two classes, those which contain a large percentage of tin, recognized by their characteristics of rapid amalgamation, great plasticity, and slow crystallization; and those which have a small percentage of tin, which have directly the opposite characteristics, that is, slow amalgamation, reduced plasticity, and rapid crystallization. The first class contains alloys that appeal to those who wish their amalgams to "work easily." This desire is an error which has resulted in the loss of a countless number of teeth which might otherwise have been saved; for such alloys, after amalgamation, change form in such a manner that the fillings draw away from the edges of the cavity walls, this phenomenon often being referred to as "shrinkage" or "contraction," whereas, as a matter of fact, the filling may have actually undergone an increase over its ideal specific volume. This drawing away of the filling is due to the fluidity of such soft alloys, and the tendency of a fluid body to assume a spheroidal form. It is not true volume change, but rests in the physical constitution of the amalgams in which it occurs. In them there is first a chemical reaction between part of the Hg and all of the Ag_3Sn constituent, then the remainder of the Hg forms a solid solution with the excess Sn which, as a soft matrix, envelops the chemical crystals. It is the softness and low melting-point of this matrix of HgSn that permits the operation of the law which governs the shape of fluid or partly fluid masses.

In the alloys of low tin content we encounter apparently contradictory properties, for with a given formula we may in an amalgam filling have either shrinkage or expansion, or shrinkage followed by expansion. In the case of shrinkage or expansion of the amalgam, we have to deal not only with constitution, but also with thermal considerations as well as manipulative processes. Thus, if such an alloy, thoroughly melted, is cast into a very cold ingot mold, it suffers a correspondingly rapid loss of thermal energy, and will be found to be in a state of condensation, and if this ingot be slowly reduced, by means of filing or turning, to fine powder or shavings, the ingot and the cutting tool being frequently chilled during the operation, the filings or turnings will still be almost in the same state of condensation as was the ingot from which they were obtained. As this condensation is really a state of strain, which must be relieved before there can be a return to normal volume, we may expect an alloy in this state to return to its normal volume when amalgamated. Thus we have the phenomenon of excessive expansion of the filling, due to the release of the strain of condensation.

Such a strain is relieved by annealing, termed "aging," or automatically in the course of time. Conversely, had the melted alloy been cast into a hot ingot mold, then allowed to cool slowly, after that being cut down without cooling the ingot or cutting tools, this being followed by annealing the cuttings over too long a period of time or at too high a temperature, the alloy would be in an over-relaxed state, and, in crystallizing after amalgamation, it would shrink, but not necessarily "condense" in the scientific meaning of the word as regards the ideal volume of its components. In the case of an alloy which both shrinks and expands, we have to do with both thermal treatment and chemical constitution, for if an alloy has not been thoroughly melted there will be crystals of free metals which must, by slow diffusion of the mercury, be brought into a state of comparative solution before the amalgam can be in a state of rest. During this operation the filling may, through internal motion, change its form, *i.e.* first draw away from parts of the cavity walls and then expand. Manipulation has an important bearing on these properties in an alloy

which both shrinks and expands, for if through errors in manufacturing processes it shows a tendency toward excessive expansion, it may in part be controlled by thorough trituration with an excess of mercury, the release of the strain of condensation taking place during the operation of mulling, through the solvent action of the mercury and the mechanical disintegration of the crystal. On the other hand, if errors of manufacture have resulted in shrinkage, it may in part be controlled by employing less mercury, less trituration, and then strongly compressing the amalgam when it is introduced into the tooth cavity.

In this connection, it should be strongly emphasized that "shrinkage" may develop as a result of the over-trituration of any amalgam alloy, it matters not how scientifically it may have been originally adjusted to a correct expansion point, for, as has been shown, the condensation of an alloy may thus be over-relaxed, and consequently produce bad margins and leaky fillings. This error must therefore be carefully guarded against.

THE EFFECT OF CORROSION UPON CHANGE OF FORM.

When speaking of "corrosion" it was shown that zinc is soluble in amalgam fillings under the conditions by which it is surrounded in the mouth. Such a solution gives rise to new combinations of the zinc with other elements that are present in the saliva. These combinations are obviously of greater volume than the metal which forms their base; for each element, whether it be sulfur, chlorin, or oxygen, has its individual volume, which cannot be destroyed. This volume is added to the volume of the zinc which forms the base of any of the combinations. This naturally results in an increase in the bulk of the filling—that is, its "bulging" from the cavity. As this corrosion of zinc progresses in the amalgam filling, the other metals are taken up in the order of their solubility and in the same manner, until the filling has been fairly forced out of the tooth cavity by the accumulation of the by-products of solution and re-combination. This may be looked for in amalgam fillings which contain zinc, whether the tin content of the alloy be high or low, in proportion to the ratio in which the zinc is present.

SOLUTION.

In the melting of an alloy it is highly important that its metals should be brought into a state of complete solution in order that the alloy may be homogeneous. The possibility of such a state depends, first, upon the mutual solubility of the metals that are used, then upon factors of temperature, time, and diffusion. This latter function depends upon osmotic pressure, defined as the driving force in solutions. (See Walker's "Introduction to Physical Chemistry," 3d ed., page 171.) It produces molecular movement in solids, liquids and gases and so causes the intimate admixture of substances that are mutually soluble. Diffusion progresses in alloys at quite low temperatures, even though the alloys are in the solid state. This is demonstrated by Roberts-Austen's famous experiment with superimposed cubes of gold and lead, in which the gold rose by diffusion, against gravity, quite to the top of the upper cube of lead. The cubes, in perfect contact, had been maintained at a temperature of about 18°C. for four years, after which analyses were made of successive cross sections of the lead taken from the top to the bottom of the lead cube, and the ratio of diffusion of the gold into the lead was thus established. Desch gives instances of diffusion in solids, and illustrates with photo-micrographs the diffusion of zinc into copper.

In order that diffusion may be thorough, in an alloy for dental amalgams, it will be seen that the operation of melting an amalgam alloy must be properly conducted, or the product will be impaired. The alloy must be of correct formula in order that the affinities of the various metals shall be such that they are chemically soluble in each other.

They must be melted together at the correct temperatures and over a sufficient period of time, during which the melted alloy must be protected from oxidation (or other chemical changes) so that by-products of combustion shall not mechanically interfere with the progress of diffusion.

Diffusion operates at mouth temperature, so that a seemingly inert amalgam filling may nevertheless be in a state of slow internal motion, this being particularly true of fillings made from heterogeneous alloys.

Conclusions.

We have considered the matter of dental amalgam alloys, first, from the standpoint of the metals that have been established as those best suited for the purpose of dental investigators as well as by the dentist himself; second, the physical properties demanded as the requirements of such alloys; third, the structure and constitution of dental amalgam alloys as determined by the methods of metallography; fourth, the phenomena that develop incidentally to their use as amalgams; fifth, the effects of errors in manufacturing processes and manipulation; and it now seems timely to consider the relationship of all of these factors to the problem of how best to utilize the metals silver, tin, and copper in the production of a satisfactory amalgam alloy for dental use. Thus we shall follow, as best we can, the aim postulated by Roberts-Austen, that of applying the results of our studies to the development of "the relation existing between these ascertained factors and their useful properties."

Several facts have developed, the first of which is that in order to secure the property of expansion when it is amalgamated, we must produce an alloy of condensed volume. This condensation must be accentuated by quenching in a cold ingot mold during the casting of the melted alloy, and the filings made from the ingot must be tempered by annealing in order that the subsequent expansion of the amalgam shall not be in excess of the requirements. Heterogeneous alloys, being in their nature conglomerates, we may expect to fail in respect to this requirement, and eutectics are also to be rejected—for they, as a rule, expand in cooling. Chemical compounds, then, by reason of their close organization and the consequent condensation in cooling and the fact that they are, if correctly melted, homogeneous, are the alloys best adapted for the development of this property.

The requirement of prompt "setting" is best met by a chemical compound of metals, for chemical reactions are invariably more rapid and certain than those of merely physical combination.

The requirements of rigidity and strength are best met by a chemical compound—for such compounds, as a rule, are harder than any of their constituents, and they possess greater compressive strength, the latter property being of the highest importance in an amalgam filling. The requirement of resistance to corrosion is best met by a chemical compound of metals, for, as has been shown, such compounds are more resistant to electrolytic decomposition than are either solid solutions, eutectics, or heterogeneous alloys.

The quality of uniformity—that is, the continuous reproduction of given properties—is best met by a chemical compound of metals, for, as a result of the fixed proportions of their components, their properties are constant.

THE PROBLEM OF DENTAL EDUCATION.

By EUGENE S. TALBOT, M.S., D.D.S., M.D., LL.D., Chicago, Ill.

THE dental schools of this country up to the present time have been passing through a period of incubation which has extended from the earliest beginnings of the filling and extraction of teeth, as well as the inserting of artificial substitutes. The technique was purely mechanical and confined entirely to the teeth, whereas the general welfare of the patient was not considered, except so far as mastication is concerned. Even as late as 1839, when the first dental school was established, the earmarks of what constituted dentistry then were set forth in no unmistakable terms by conferring upon graduates the degree of Doctor of Dental Surgery, which expressed in exact terms what constituted dentistry to the recipient and to the community. The graduate was thenceforth considered qualified to treat the teeth. This badge of qualification to practice is still in existence, and is granted or issued not only by dental departments of universities, but by the schools owned by private individuals. It is true that dental schools have always had chairs on anatomy, physiology, chemistry, histology, bacteriology, etc., and that in some of them the students are taught these subjects by the same teachers and in the same classes with medical students. The active tendency, even at the present time, in all the schools, unlike those abroad, is to concentrate the energy of the student on the study of the mechanics of dentistry rather than on the general welfare of the patient, as is shown by the fact that during the major part of the term the mind of the student is centered on the clinic and laboratory. It is also true that the university will not give credit toward a medical course in the general branches of medicine already taken by the student and passed upon by the chairs. Nowhere in this country can the graduate of dental surgery obtain credit in any medical school for his three or possibly four years of study. This demonstrates clearly that his dental course of study has been superficial, so far as medical branches are concerned. It is a foregone conclusion that the graduate of dentistry is not prepared to, nor is it intended that he should understand the diseases of the body in their relation to the teeth, much less treat them. The teachers have shaped the course of studies in the dental schools and have placed the standard of requirements purely on a basis of the mechanics of dentistry, in accordance with the nature of the degree to be conferred.

REQUIREMENTS FOR ADMISSION.

Although the students are required by most dental schools to possess a high-school certificate or its equivalent for admission, many of them fall far short of the standard of a four years' high-school education. The student, therefore, after a three years' course, is found not up to the professional standard he should be when he enters practice. The result is that those who practice dentistry do not possess the standing that is exacted of those practicing the other specialties of medicine.

Whenever the subject of dental education has been discussed in our societies, the teachers have always offered the same excuses which have been handed down for many years, and have become *ad nauseam* to the older members of the profession. Since my

articles on "Swan Songs"* were published a few years ago, the older excuses for the want of advancement of dental education have been to a certain extent abandoned. Three new "swan songs" have lately been introduced as excuses for not increasing the number of years of study for dental students. One is that there are too few dentists to supply the demand; hence it is natural to suppose that the students must be rushed through the dental college mills as cheaply and quickly as possible to supply the demand. It is not necessary to comment further on this phase of the subject at this time.

Another excuse is that the state board laws are such that they do not require or demand a higher standard for practice, and that these laws must be changed before any advancement can be made in the dental schools. In reply to this excuse, I have only to refer the teachers to what has been and is being accomplished in the practice of medicine in this country in the past few years.

MEDICAL COLLEGES AND STATE LICENSING BOARDS.

Ten years ago there were 166 medical schools in this country, while now there are only 101. Of this number this fall, 37 for the first time are requiring for admission one year of collegiate work, in addition to a four years' high school education; add to this number 47 which had already adopted this standard, making in all 84 colleges. Only 22 of the 49 state licensing boards require this standard. In addition to this, 34 of the 84 colleges and 7 of the state licensing boards have gone farther, and adopted the requirement of two years of collegiate work as the minimum preliminary standard. Many of the state medical licensing boards, like that of Illinois for an illustration, require only a high-school certificate as a minimum for entering a medical school, and yet there are three schools in Chicago that require two years' academic training, six or eight others requiring one year. And there are other schools which require as a minimum amount, only a high-school certificate for entrance. The same pertains to other states. It will be seen, therefore, that the state medical licensing boards have had very little, if anything, to do in formulating and fixing the standard of medical education. It will be observed that the state boards have not all kept pace with the requirements of advanced medical education. The medical schools, however, are still raising their standard in advance of state licensing board requirements. Since both the medical and dental schools always have and probably always will set the standard for teaching, the state licensing board will be obliged to conform to the dental curriculum, just as the medical boards have conformed to the medical curriculum. The tendency is to blame the dental profession for the standards of the dental colleges and the state boards. The teachers forget that they regulate the school educational standards for the dental profession, and most dentists, when they graduate, are contented to abide by those standards. While most of the members of the state boards of dental examiners possess the ability of the average general practitioners, many of them are far below that standard, since they are unable to prepare lists of questions for their yearly examinations, and are obliged to go to the college teachers for instruction and assistance along this line. Can water rise higher than its source? Who, then, is to raise the standards of the state boards? Let the teachers educate the students to the standard required by the public, for which they have been paid; then the profession will bring the state laws up to that standard. The teachers who are continually offering excuses for their shortcomings are not calculated to make a success in life. If the dental schools would raise their standards, the state boards would soon follow, just as is being done by the medical licensing boards.

* See DENTAL COSMOS, March 1908, vol. l, p. 232.

The third excuse is that if dentists be graduated in medicine, they will practice medicine rather than dentistry. The excuse is not tenable, from the fact that the medical profession is now greatly overcrowded.

From an editorial, "No Danger of a Scarcity of Physicians,"* I quote: "The normal proportion of physicians to the population in the leading nations of Europe is one to every 1500 to 2500 people; this country has one physician to every 600 to 650. The figures given for this country do not include the osteopaths, Eddyites, and other so-called drugless practitioners, which are scarcely found in other countries. The annual loss of physicians by death in this country is approximately 2000, while the annual report of physicians from medical colleges for several years exceeded 5000."

It requires at the present time an exceptionally well-educated man to compete with those engaged in active medical practice. If, therefore, a student who has been graduated in dentistry thinks he can achieve greater success in the practice of medicine, he should be encouraged to do so. The outlook for the stomatologists is brighter, however, since the field is larger, and quicker remunerative returns are assured.

STANDING OF THE DENTIST.

The standing of the dentist and the dental profession depends upon the product of the dental schools. The dental teachers specify what the standing of those who enter shall be, and supervise the instruction for the finished product. If the medical colleges and the state boards are a criterion to go by, it behooves the dental college faculties to get busy, and advance their standards along lines of one or two years' more study. Shall the extra year be added to the dental course, or shall it be a year of academic training? There are some teachers who believe that one year of academic training along the lines of a preliminary medical school curriculum, together with a four years' high-school course, would place the student on an equal footing with the medical student; that it would save much time in the dental course. The student would be better prepared to take up and understand medicine and dental subjects. Much of the preliminary work in the dental schools could be dispensed with.

Other teachers would prefer to add a year to the regular dental course, since it would increase the income of the school. How it is possible to fill in another year teaching dentistry is a problem to the author. At the present time, in some of the schools, the students are sitting about doing nothing a considerable part of the day. Much time could be saved by eliminating unnecessary lectures. By keeping the students busy every hour in the day, and reconstructing the lecture course, much time could be conserved for better purposes. After foundation principles have been taught, I know of no specialty in medicine that cannot be acquired by the student in two years' time.

DENTISTRY AND DISEASE.

Lately it has dawned upon some members of the dental profession that certain pathological conditions of the teeth play an important rôle in producing diseases of the human body, and that a knowledge of general medicine is necessary to practice dentistry successfully. It is only within the past few years that physicians, like Billings and Rosenow, have actually demonstrated a part of this relationship. Dr. Charles H. Mayo asks, "What will the dentists do about it?" A certain number of the dental profession realized this connection between diseases of the mouth and diseases of the body. There are still a certain number of teachers who do not or will not believe that this relationship exists; they maintain that the teeth are like so much cord-wood, to be cut and sawed without the least regard for the patient's welfare. This statement is evidenced

* *Journal of the American Medical Association*, August 22, 1914, p. 692.

by the fact that they advocate adding a fourth year to the dental course, which, in reality, would narrow rather than broaden the scope of the student. The fact still remains that there is a field between medicine and dentistry which can only be filled by broad, medically educated men. They are the men who will be the successful practitioners of the future. The men who have already grasped the situation and are working in harmony with the general practitioners of medicine are those dentists who are medically educated. That there is a demand for a larger number of dentists is true, but they should be able to grasp any situation, and be equal to any emergency that may arise in relation to general diseases and mouth lesions. Hardly a day passes but that the better educated men, in our large cities, receive patients from different parts of the country suffering from complications that are not understood by the average dentist.

The period of incubation in our schools has now passed, and we are in the dawn of a future higher development. The question has already been asked, Will the profession rise to the situation? That will depend upon the influence brought to bear upon teachers to so reconstruct their methods of teaching that the future graduate will be competent to take up the work and carry it forward to a higher development. We have passed the line marked out sixty-five years ago as dental surgery, and have entered the field of stomatology. If we are to be successful in the practice of this branch of the healing art in the future, students must have a thorough preliminary training before they enter the dental school, and also a general medical education before they are graduated. We have come to realize that our specialty is as intimately connected with the welfare of the human body as are other specialties of medicine. Why, then, should we not strive to make as rapid progress in the advancement of teaching as the medical schools?

TWO CAMPS IN THE FIELD.

At the present time, the profession is divided into two camps. One advocates that the degree of D.D.S. is all-sufficient for practice, while the other contends that the M.D. degree is necessary. The author, as is well known, has devoted his energies to the latter camp-followers for the last forty years. He has watched the progress of both medicine and dentistry from year to year. His associations with medical colleges and societies have brought him in intimate relations with the progress of medicine as well as dentistry. He has always been a strong advocate of a thorough medical education for the practice of our specialty, and believes that those who can pursue the regular course of medicine in connection with dentistry will feel more than repaid for the extra time and money spent. Such men will have the respect and influence of the medical profession. The time has arrived when physicians must consult with the dental practitioner, as has already occurred in the larger cities. Physicians are seeking in their consultation work the aid of those specialists who are medically educated graduates.

There is, however, a class of teachers and practitioners who are satisfied with the dental degree. There is no question but that there are plenty of teeth to be doctored. The mechanics of dentistry have always been required and always will be. How, then, can the courses of study be arranged so that the granting of both degrees may be made possible, harmonizing all the difficulties mentioned (and many others not mentioned), and wasting no time or money in the effort?

A RATIONAL SCHEME FOR THE PROBLEM OF DENTAL EDUCATION.

Both medical and dental schools now require the candidate to be a graduate of an accredited high school, or to possess a certificate from the state superintendent of public instruction showing that the applicant has an education

equal to that obtained in an accredited high school. The candidate should now enter the university or college for at least one year. In this year the student should take up biology, physics, chemistry, and modern languages. The same studies are required of the medical student. He is now prepared to enter the medical or the dental department, as the case may be. All dental schools should be actual departments of universities, preferably state universities. The first year should be devoted to the fundamental branches of medicine, and due credit should be given for the same toward a future medical course. The student may now enter the dental school for two years and graduate with the degree of D.D.S. If he is desirous of continuing his studies in medicine and to become a stomatologist, he may now enter the medical school and finish his studies in this department, obtaining the M.D. degree. The course may be reversed; he may enter the medical school, graduate, and finish with the dental course.

In a general way, I have mapped out a course which covers most if not all of the objections, and which may easily be acquired. The details can be worked out by the dental faculties to conform to individual cases. By the first method the graduate of dentistry will be on equal footing with the medical graduate, so far as he has progressed, and the stomatologist has lost no time or money in acquiring the knowledge and position he is so desirous to obtain. The dentist, on the other hand, is so situated that, should he change his mind and desire to continue his studies and become a medical graduate, the time and money spent in the dental school have not been lost.

Such rapid progress has been made in the past few years in the medical schools, and so little has been accomplished in the dental schools, that the contrast is appalling. Let me inform the teachers that there is no way to shift the responsibility for a more complete education of the students. They matriculate in our colleges, and are utterly innocent as to what is required of them as practitioners. The standing of our specialty in the community, as a whole, practitioners, or members of state licensing boards, as well as our state laws, depends entirely upon the qualifications of our graduates. Let us hope that the teachers will cease formulating childish excuses, and instead get together, and all agree on some course of procedure which will eliminate all the incongruities of the past and place our speciality in the line of progress on a par with that of the medical profession.

THE RECOGNITION OF SYSTEMIC DISTURBANCE IN THE TREATMENT OF ORAL LESIONS.

By B. H. TEAGUE, D.D.S., Aiken, S. C.

(Read before the South Carolina State Dental Society, at its annual meeting, Greenville, S. C., June 17, 1914.)

"THE practice of dentistry is the exercise of dental art, and embraces all that pertains to the knowledge, prevention, and cure of the diseases which the dentist is called on to treat"—to paraphrase the introductory assertion of the author of a medical work. "Disease may be defined as any departure from the normal standards of structure or function of an organ or tissue, or both combined." (Hughes.)

The diseases that dentists are called

on to treat are oral lesions, and are generally of toxic origin, either local or systemic, and the treatment given them is usually solely topical. Nature, in great part through *vis vitæ* and patience, accomplishes a cure, when adjuvant systemic treatment would have accelerated her strenuous efforts toward that end.

ALVEOLAR ABSCESS: ADJUVANT SYSTEMIC TREATMENT.

Alveolar abscess, the most frequent of the oral lesions that require attention, in its incipient stage—viz, that of peridental inflammation—is most readily aborted by opening the septically surcharged tooth which is the focus, irrigating it with a germicidal wash, cleansing it of bacterial matter, and filling the roots and crown with antiseptic material, either temporarily or permanently as the case demands, and then by applying counter-irritants to the adjacent gums. If the patient's system, however, is in a bilious condition, the heroic method of surgical perforation of the alveolar plate, reaching the inflamed point, and bloodletting, is absolutely necessary for quick relief. This systemic condition should always be diagnosed, and when it is confirmed, the patient should be put upon a course of systemic medication conjointly with the topical treatment. If neurasthenia exists, and the patient's vital force is low, it will be found that the case will not readily yield to alleviatory measures. The general nervous system then should be attended to and toned up. A cure is especially difficult when the patient is affected with disease of the kidneys. In chronic diabetes, particularly, the family physician should be called to consult with the dentist. In this dyscrasia the capillaries are sluggish and inert in disposing of the effete blood at the focal point; congestion takes place, and pus rapidly forms. The system is so charged with toxins uneliminated by the weakened kidneys that the offending tooth acts as "a splinter in the flesh," and in spite of all remedial efforts, extraction in the majority of instances is to be resorted to, to prevent toxemia.

OTHER ORAL CONDITIONS REQUIRING PRELIMINARY SYSTEMIC TREATMENT.

It is in this condition of dyscrasia that a blind abscess evolves into the active stage. In this condition, moreover, local as well as reflex neuralgia occurs, severely at times, in the treatment of septic roots of teeth, in the extraction of semi-devitalized pulps from tooth-roots, and in the insertion of pivot teeth. The slightest impingement on or disturbance of the end of the connecting nerve to a tooth, or those in the tissues adjacent to the end of the root, is sufficient to cause nervous derangement. This condition of the system should be recognized in the treatment of such forms of stomatitis as the aphthous, catarrhal (salivation), gangrenous (cancrum oris), and ulcerative; particularly in pyorrhea alveolaris, hypertrophy of the gums, inflammation from the eruption of third molars, and irritation of the mucous membrane under artificial dentures; when hemophilia is suspected, when the gums are to be lanced or excised, and teeth are to be extracted. An alterative and tonic systemic course of treatment is here indicated before operations are performed, and a sedative course should be given in cases of excessive nervousness prior to sittings for the excavation of sensitive dentin, since it will be found that topical applications of anesthetics for the prevention of sensitiveness will be more effective, and the patient will also submit to strain better when previously prepared for it.

SYPHILIS.

That terrible, blighting scourge of humanity, syphilis, should be reckoned with more appreciatively by dentists than is generally the case. The symptoms of its three stages should be known, especially those of its secondary manifestation, for in this stage the danger of infection is greatest to the operator, and through him to his patients. The

markedly pitted and ill-shaped teeth of inherited syphilis are generally well known. In the treatment of pyorrhea alveolaris, systemic disorders must be considered most carefully. Dr. Baldwin and Dr. Larned in their brochure, "Syphilis in Dentistry," have this to say: "It was then that a more careful examination of the teeth of syphilitics was entered into, and the result was the finding of a comparatively large number of cases of pyorrhea alveolaris. Upon request, a number of dentists submitted cases. These were carefully questioned, and about two-thirds gave a history of syphilis. A sufficient number existed to classify them as cases of syphilis *ignorée*, or as old cases of tertiary syphilis in which there was only the bone symptom to be observed. However this may be, the subsequent treatment showed that the etiology had been correctly established." "The few observations made have shown a greater or lesser interdependence between syphilis and pyorrhea alveolaris."

SYSTEMIC DISEASES ASSOCIATED WITH PYORRHEA ALVEOLARIS.

"Is it not a curious coincidence that Riggs' disease should be observed in so many cases of secondary syphilis as well as the late form of this period? It must also be remarked that pyorrhea alveolaris occurs as a parasyphilitic phenomenon. When we take into consideration that the teeth are observed to be sound before syphilitic infection, and that after the disease has manifested itself it shows its presence; and, further, when systemic as well as local treatment directed to the syphilis causes both to disappear, we are justified in concluding that lues is a factor in the production of Riggs' disease."

Other dyscrasias must be thought of in the treatment of this malady. Tuberculosis, malaria, fevers, liver trouble, diabetes, gout, and rheumatism are to be considered as potent basic factors in the stubborn resistance to cure in spite of skilful instrumentation and intelligent application of topical medicaments.

Without doubt, many of the failures of successful treatment of pyorrhea alveolaris, assiduously attended to locally, are caused by neglect of the consideration of systemic conditions.

Hypertrophy of gum tissue, at times almost overreaching the grinding surfaces of the teeth in its severity, is best treated by diagnosing the etiology of the disorder, and employing such general therapy as will accelerate the topical.

Irritation and inflammation are the characteristics of oral lesions that dentists have to treat, and in the main are reflexes and local manifestations of general systemic disturbances. In the practice of orthodontia it is well to recognize the importance of keeping the general system in such healthy condition as to preclude nervous strain and shock. The same is to be said in the treatment of traumatic injuries of the jaws, fractures of the mandible, etc.

A PLEA FOR SYSTEMIC MEDICATION.

It may be argued that the busy dentist cannot undertake the systemic treatment of his patients, and especially in chronic cases. This may be true as far as the majority of the profession is concerned, but to those who practice according to the full scientific light of the calling it is only true in part. The dentist should be familiar with pathological conditions of the general system, and know when to advise general medical treatment to his patients, at the hands of the physician, when he is confronted with a severe local lesion of a deranged system which is stubborn to cure. His should be the province to prescribe for simple derangements of the system such as biliousness, nervousness, and other temporary ailments.

We plead for more scientific study along these lines, and though we would not seek to minimize the artistic and technical phase in the practice of dentistry, yet dentistry being the connecting link between medicine and mechanics, this link should be made strong and perfect in all its parts.

PROCEEDINGS OF SOCIETIES.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held December 22, 1914.

THE regular monthly meeting of the Academy of Stomatology was held at the Aldine Hotel, Philadelphia, Tuesday evening, December 22d, at 8 P.M., Dr. J. V. Mershon in the chair.

The first order of business was the reading of the minutes of the previous meeting, which were approved as read.

The Council reported the following officers elected for the ensuing year:

President—Dr. J. C. Curry.
Vice-president—Dr. A. P. Lee.
Secretary—Dr. Dudley Guilford.
Treasurer—Dr. A. E. Bassett.
Member of Council—Dr. J. C. Salvas.

Dr. Curry was duly installed as the new president, and presided during the evening.

INCIDENTS OF OFFICE PRACTICE.

The next order of business as announced by the Chair was the reading of the following five-minute papers on incidents of office practice, which were discussed together:

Intermittent Pain in the Superior Dental Nerve Due to Obscure Dental Causes.

By Dr. J. CLARENCE SALVAS, Philadelphia.

The following case is reported for two reasons: First, because in the experience of the general practitioner it is rare, and second, because it is a forcible reminder of the responsibility of the dentist, impressing upon us not only the importance of following up every possible clue that may lead to the determination of the cause of obscure troubles, but also the necessity of being familiar with all conditions wherein this cause may exist. By reason of the fact that we work in a comparatively small field, and are thoroughly familiar with the causes and symptoms as expressed in pathologic conditions, we are apt to work more or less perfunctorily. Our diagnoses are necessarily made quickly, in fact, frequently before an examination is made. Pulpitis, for instance, will cause pain which has certain characteristics differentiating it from periapical disturbances. When a patient comes to us suffering with neuralgia or pain in the face, we look for some one of the familiar conditions with which we are meeting daily, but when there are none of these conditions to which we can attribute the trouble, we generally pass the case on to the physician. This had been done by two practitioners in the case under discussion. The patient was a sort of football between the physician and the dentist. The dentist being unable to locate the trouble, she was turned over to the physician, who, as he said, exhausted the pharmacopeia in treating her for everything from facial neuralgia to tic douloureux. The patient was then sent back to the dentist, but without any results. Her husband, being a physician of intelligence, felt that he had exhausted every possible means excepting a surgical operation for relieving his wife of the agony she was suffering, and it was with reluctance that he consulted a surgeon. The surgeon urged a consultation of

dentists and advised that if they could not locate the trouble the patient should have alcoholic injections; if these failed, an operation was to be performed. This, in short, is the history of the case up to the time when it came into my hands.

The patient, fifty-three years of age, in good health, had been suffering for from three to four weeks from pain in the upper right side of the face. The pain was intermittent, appearing sometimes in the mornings, sometimes in the afternoon, and frequently at night. The teeth had been well cared for. On the right side, the first and second molars and the second bicuspid were present; the first bicuspid had been extracted, also the third molar. She was wearing a small gold plate. With the exception of a pyorrheal pocket, the canine was in good condition. The second bicuspid was perfect. The first molar had a small gold filling in the buccal surface, and the second molar a cast gold filling. These fillings were removed to note the condition of the pulp, and a thorough examination was made of the adjacent teeth. Finding nothing of a pathologic nature, I ordered an X-ray to be taken. This was done at once, and the operator reported the sinuses clear and no indications of any trouble about the roots of the teeth. When the husband of the patient brought the X-ray plate to me, I found that, from the dental point of view, it was not clear enough, and urged him to have another exposure made. He consulted Dr. Pfaehler, who reported, after the plate was finished, that it disclosed nothing that would indicate a pathologic condition. I found on examining this plate that the root of the bicuspid had penetrated the antrum, though there was nothing that would indicate any trouble. My working on this tooth seemed to have a psychic effect, as the next morning the patient appeared with her husband saying the trouble had localized in the tooth, and that the pain during the night was in that tooth and not in the face where it had been. After careful consideration I removed the pulp under pressure anesthesia, leaving a dressing of camphophénique in the canal. The following morning the patient's husband called me up and said that his wife had spent the most comfortable night she had had for several weeks, being absolutely free from pain. I felt certain, however, that the relief was but temporary, as the pulp of the tooth had been normal. I sent the X-ray plate to two other experts in the reading of radiographs, but they reported nothing wrong. In the evening of the fourth day following the removal of the pulp, the patient had a return of the pain, which during the night became more severe and more intense than ever. The husband was now determined to discontinue the dental treatment, and try alcoholic injections, but I persuaded him to consult Dr. Cryer first. Dr. Cryer made a careful examination, secured another radiograph, and decided after studying it that the trouble was due to the roots of the molar and bicuspid impinging on the superior dental nerve. He advised the immediate extraction of the two teeth, and subsequent to this operation the trouble disappeared definitely.

A Method for Preventing Caries in Children's Teeth.

By Dr. E. Carlton Palmer, Philadelphia.

The method to be described may have been used by many practitioners before, but it may offer to others a way for the satisfactory solution of what has heretofore proved a vexatious problem.

Initial caries in first and second molars and bicuspids, which often appears almost as soon as these teeth begin to erupt, seems almost impossible to prevent without cutting out the groove or grooves and inserting some filling, but this procedure has always seemed unsatisfactory to me.

In caring for the teeth of my daughter, who is twelve years of age, I observed the well-known deep sulci, especially in the first and second molars, where the enamel has failed to unite completely, leaving defects which it is impossible to keep clean by everyday oral hygiene. Despite a careful clean-

ing on my part, I was afraid that there still remained caries-producing material in these sulci, and I was driven to seek some remedy to prevent the formation of cavities.

When the teeth first appear through the gum, the rubber dam is applied and the tooth isolated, washed thoroughly with an alcoholic solution of iodin and polished with a stick and pumice and with stiff brush wheels in the engine handpiece. Then the tooth is washed carefully with 95 per cent. alcohol and dried carefully.. With the finest explorers, as much of the foreign material as possible is picked and scraped out of the sulci, using an excavator only where absolutely necessary, the reason being that we do not wish to cut the surface of the enamel if it can be avoided. It is surprising how many teeth, after having been washed, cleaned, and dried in this way, show well-defined cavities that need the regular cavity preparation and filling.

After all the fine grooves and pits have been cleansed mechanically, they are washed with a 1:1000 solution mercury bichlorid, dried, and washed again with alcohol, and again dried finally. *Black* copper cement is then mixed to the same consistence as for setting a crown or bridge, and smeared all over the crown of the tooth, filling all the depressions. With fine explorer points this cement is worked into the pits and sulci; then, while the cement is still soft a piece of unvulcanized rubber of about the size of a small marble is placed over the cement, and with a finger is pressed hard to the tooth and held there until the material is quite hard enough not to be disturbed when the pressure is released. Plenty of time is allowed for the cement to become well set before it is trimmed. When the material is well hardened, the excess is carefully scraped and burred from the surface so that it will in no way interfere with mastication, else there will be danger of drawing the cement out of the grooves when it breaks off, which it will do in a few days, leaving a hairlike line of the black material, which penetrates to the very bottom of the defect, and presents such a small surface to the action of the saliva that it washes out very slowly.

I have tried other cements, at various times, but nothing seems to give as good results as black copper cement. Its extreme stickiness renders it specially suitable in these cases, its objectionable color being not nearly so much of a blemish as one would at first suppose. Furthermore, owing to the great contrast between the color of the tooth and that of the cement, the coming-out of any part of the material is at once detected.

Since this treatment of my daughter's teeth I have found no indications of caries, the cement holding perfectly. Her teeth have been treated in this way now for a period of three years. I have also been following this method in other children's mouths with equally satisfactory results.

Advisability of the Use of Vaccines in the Treatment of Pyorrhea.

By Dr. W. Sterling Hewitt, Philadelphia.

About two years ago I became convinced that the treatment of pyorrhea by the use of a vaccine was a scientific and practical method. I have now treated a sufficient number of cases to be able to report to this society upon its success and failure, and the probable cause of either. I started with the assumption that all cases of pyorrhea were the result of infection by various forms of bacteria, and therefore curable by means of a vaccine or bacterin. The first few cases I undertook were so successful that I was dazzled, and saw a sudden end to our greatest difficulty.

I then undertook the treatment of a case which apparently presented the same conditions as the preceding ones, and failed hopelessly, even aggravating the symptoms. This caused me much embarrassment, for I had promised too much. Since that time I have had successes and failures, either curing absolutely or failing miserably. I will say in passing that all cases were preceded by careful local treatment, using the

bacterin only as a last resort. These results are most remarkable when we consider recent announcements and discoveries as to the cause and cure of pyorrhea. If all cases are caused by an amœba, how came I to cure any one case with bacterins? If all cases are caused by bacteria, why did I not cure all with autogenous vaccines or bacterins? If all cases are caused by constitutional conditions, how can any case be cured by any method directed toward local conditions?

In view of the above, I am convinced that so-called pyorrhea, instead of being one disease, is a group of diseases having a similar final result. By even the most casual examination of a number of cases, differences of the most marked character will be observed. I am afraid that we are as unscientific as the ophthalmologist would be, if he looked upon all diseases causing blindness as one disease and treated them accordingly.

We should cease trying to find one great and only cure, and direct our energies toward isolating and classifying these different lesions, and assigning to each its appropriate treatment. Until we do this I am afraid we can regard ourselves as little better than charlatans. I therefore advocate the use of an autogenous vaccine most heartily when it can be proved that bacteria are the actual cause of the disease. In those cases where some of the protozoa, or constitutional conditions, are proved to be the primal cause and the bacteria are only associated, a vaccine is manifestly useless.

Repair of Split Roots: A Case of Replantation.

By Dr. H. E. Roberts, Philadelphia.

On July 13, 1907, a gentleman split his upper first bicuspid, which had prominent cusps, deep sulci, and contained a large filling in the occlusal surface. The tooth was ligated with seagrass, which was allowed to shrink so as to render it very tight and firm. A hole was drilled through the tooth from the buccal to the lingual surface. A piece of platinized gold wire of No. 18 gage was threaded at one end, the measure of the width of the tooth taken, and the other end of the wire headed. The hole through the tooth was countersunk on both sides, and the inside of the hole through the tooth was slightly roughened. The wire was then placed in the tooth, and cement worked into the thread and allowed to harden. The ligatures were then taken off, the wire riveted with an automatic mallet, and the surfaces polished. Afterward the posterior surface of the tooth was filled with cement-amalgam, and the filling contoured. The tooth is apparently as perfect now as it was when I first inserted the wire seven years ago, and there has been no irritation or inflammation, although this tooth was split through the bifurcations of the root.

In March 1908, a lower first molar which was in bad condition also was split longitudinally. I did not care to drill a hole through the molar, so a platinum band was adapted and cemented to the tooth. That tooth is still in as good condition as could be expected. It is, however, a diseased tooth, and always will remain such, but it is in better condition now than before the band was put on.

In March 1909, the same patient split the upper first molar on the same side, and that tooth was treated in the same way as the bicuspid. It also is in perfect condition at the present time. This simply shows that split teeth need not necessarily be extracted.

Some two months ago a patient came into the office holding a black tooth in his hand, which had been knocked out the night before in playing basket-ball. The patient had been carrying the tooth around in his vest pocket and happened to show it to my son, asking him what he should do with it, and he was told that he had better have it replanted. I opened the badly discolored tooth, removed the pulp, resected the apex, and sterilized the tooth in a weak solution of formalin. The tooth socket was then cleaned out, and the tooth forced into proper position. An impression was

taken, and a silver plate swaged to fit over the masticating surfaces of the canines and the incisal edges of the incisors, and cemented into position the next day. Two weeks later there was no irritation or inflammation, and the tooth was practically free from soreness. I am now watching the result of this implantation of a tooth which had been carried around in a vest pocket.

Technique of Making a Carmichael Attachment by the Casting Process.

By Dr. Dudley Guilford, Philadelphia.

When Dr. Taggart gave his first demonstration of the casting process in Philadelphia, I was impressed with its possibilities in connection with crown and bridge work, and among other things I saw that it would immensely simplify the technique of making the Carmichael attachment.

The preparation of the tooth for this attachment is a familiar procedure. It consists in cutting a groove mesio-distally across the occlusal surface of the bicuspid and extending this groove up to the gingival margin on both the mesial and distal surfaces. In other words, the groove is continuous, extending from the mesio-gingival margin down to and across the occlusal surface and up to the disto-gingival margin. In the preparation of the canine, the groove is cut in the same way except that it extends across the lingual surface of the canine and then up to the gingival margin both mesially and distally. When this has been done, the lingual portion of the tooth is "coned" so that the wax pattern will draw and the finished attachment will go to place without leaving a space at the neck of the tooth.

After trying a great many methods for making the wax pattern, I have developed the following technique, which is found to be by far the most satisfactory:

A matrix of thin copper or phosphor bronze is placed about the tooth in such a way that the lingual portion is surrounded by the matrix—the ends of which extend buccally and are held by the operator's left hand. This matrix should not be held closely against the lingual portion of the tooth; there should be, in fact, a space of 1/32 of an inch or more between the matrix and the lingual surface at all points.

The tooth and matrix are then wiped with a pledget of cotton dipped in liquid soap. A rather large piece of casting wax, having previously been mounted on the end of a probe, is now heated with sufficient rapidity over a flame for the exterior of the wax to be completely melted while the interior is still comparatively firm. When it is in this condition the mass of wax is placed over the tooth with the matrix in position and pressed home by an assistant, or the operator may use one of the fingers of the right hand not engaged in holding the probe.

If this technique is followed, it will be found that the wax has been forced up to and often under the free margin of the gum and that the pattern is perfect. It will be readily seen that if the heating has been properly done, the firm interior of the wax acts as a piston, and forces the fluid exterior to the finest detail, thereby insuring a perfect pattern.

The wax is now trimmed to proper shape and thickness, and at the cervical margin it is worked up under the free margin of the gum, using a warm instrument for this purpose. If the pattern is then mounted on a sprue and cast in 5 per cent. platinous gold, the result should be a very perfect Carmichael attachment.

In using this technique I have found it necessary to use a wax which will stay fluid rather longer than the ordinary casting wax. To obtain this, I melt together pink base wax 1 part, and S. S. White black inlay wax 4 parts, by weight. This is poured into an oiled dish to the depth of about one-quarter inch, and before it is entirely hard is cut up into small cubes.

The principle underlying this technique is that, in order to secure a sharp cast, it is necessary to have a mass of wax with a firm interior, which acts as

a piston, and a fluid exterior which can readily be forced into the finest detail.

A Crown with Cast Gold Base, Restoring a Large Portion of a Fractured Root.

By Dr. J. C. Curry, Philadelphia.

Occasionally we find portions of roots broken off, or so badly broken that it is not practical to retain them. I have been embarrassed by these conditions and used heretofore to remove the broken portion and try to restore the continuity of the surface by fitting around the tooth a band cut with a tongue so as to go under the gum, and in a measure make a non-irritating surface. Recently I have found another method which I submit to your consideration. The case in question was that of a young woman who, in going up stairs rapidly, sustained a jar so violent that the lower teeth were thrown against the upper in such a way that a section was split from the labial root of one of the upper teeth. The split extended to approximately two-thirds of the length of the tooth in such a way that it made a wedge with the planes extending upward and outward. I first arrested the hemorrhage with adrenalin, and then plugged the pocket with temporary stopping, which I allowed to extend a little over the margins. The next day I removed the stopping, repeated the adrenalin treatment, smoothed the margins, and took a wax impression of the firm part, allowing it to run out into the root-canal, which had been previously reamed out. I removed the wax impression and made a casting. After fitting the casting, I soldered a half-band to it, thus securing a base which will accommodate any kind of crown without causing irritation.

A Method of Protecting the Interdental Gum Septum in Cases of Peculiar Occlusion.

By Dr. Otto E. Inglis, Philadelphia.

For many years it has been known that when fillings are not contoured approximately in such a manner as to prevent the separation of the points of contact during mastication, food of shredded character, such as meat, will crowd into the interdental space and crush and inflame the gum septum. The mechanical irritation caused by this and the use of the toothpick and the attendant fermentation of the food particles gradually leads to an inflammation which may cause a deep-seated gingivitis, and even suppuration may follow. While usually classed with the pyorrheas this lesion has distinctive features, and usually responds happily to appropriate treatment by healing as far as is possible in consideration of the loss of tissue. It is astonishing how long patients will endure this condition in some cases, but often it is so annoying that relief is promptly sought. The tight contouring of fillings often produces the desired result, and if possible should be resorted to. At times several teeth are loosened by long-continued lack of contour contact, and in such cases, if there is a convenient filling, the teeth should be wedged until the teeth anterior and posterior to the wedge are tight; then a tight contour contact is made at that point, even though it be necessary to over-contour.

If such a condition exists and all the teeth involved are without fillings, it is best to wedge as before, cut a cavity in one tooth, and introduce an inlay with soldered contact point. The carbon impression paper is used to reduce any malocclusion caused by wedging. If a crown be present, it can be used like a sound tooth, and a cavity cut in it for the inlay. Sometimes in addition to the contact it may be well to allow a slight overlap of the inlay on to the marginal ridge of the adjoining tooth, which should be slightly ground so that antagonizing teeth shall not malocclude upon it.

The peculiar occlusion to which I wish to refer embraces that class of cases in which, owing to extraction and tipping forward, the distal cusp of a molar occludes between the mesial cusp of one molar and the distal cusp of another in

such manner as to force the teeth apart and force food into the space gained at the same moment. As this continues, both of the wedged teeth become progressively looser through a general nonseptic pericementitis, and a marginal gingivitis is established which may progress to deep-seated interdental gingivitis or pyorrhea. Especially when the distal tooth has no posterior support, contouring is often unavailing, though shortening the distal cusp of the occluding tipped tooth sometimes affords satisfactory aid.

For these cases I would offer a simple device which has proved useful. If two fillings are present, as is often the case, into one of them a trench is drilled about one-eighth of an inch deep and about a quarter of an inch long. In the adjoining tooth a shallow slot is cut about one-eighth of an inch long. A piece of iridio-platinum wire of the size of a tooth pin is fitted to extend from the distal end of one trench to the mesial end of the other. That portion which is to extend from the deeper on to the shallower trench should be flattened occlusally, and made into a rounded triangle on the contact side. Both sides are to be smoothed. The portion to be burnished should be serrated. Then soft amalgam is placed in both trenches, amalgamating the surface of the trench by rubbing. The wire is embedded into the soft amalgam and tapped to place, and the balance of the amalgam is wafered and trimmed to shape, being sure to expose the occlusal portion of the extending spur. This portion will play loosely in its trench, which it will fit as closely as the movement will permit. The portion in the deeper trench will be tightly held. If only one filling exists, it is trenched as before, and the marginal ridge of the adjoining tooth is slightly reduced. The wire is bent so that it will lie evenly in the trench and yet ride upon this ground point.

This device allows the spur to play in its trench, but as the teeth cannot move sufficiently to allow it to slip out, the return of the teeth to place returns it to its place. As food is forced up, this bar breaks its force so that shreds lap over it instead of being forced up to the gum. The gum usually responds by healing.

By this method, a wide space may be left at the gum, and, though food can enter it by floating to place, it can be washed out. Experience shows that such a space is better than close contact, as in the latter case food remains, to ferment. I have used this device for some fifteen years, and find it very satisfactory, employing at times a modification by fastening a spur to a crown.

The cleansing of these spaces with floss silk involves passing the silk through the gingival space and drawing it out around the spur, or through, in case of united crowns or inlays. As an aid to this, a wire bodkin is useful. To make these, the temper is drawn from the shank of an old Gates-Glidden drill, and the drill is bent into the form of a buttonhook. A six-inch length of fine regulating wire is thrown over this while in the handpiece. The loose end is grasped between the thumb and forefinger of the left hand. The bur is slowly revolved, and the wire run through the fingers. This twists the wire, but leaves a small loop or eye for the floss silk. This bodkin can be bent to a three-quarter circle and threaded through, coming forward toward the lips. It is grasped, pulled through, and the doubled floss thus introduced for use.

This device is as useful for cleansing fixed bridges as for the purpose described. Another useful device for cleansing the parts consists of a small tube of brass holding a wood point, which will cleanse the surfaces. The points are shoepegs, which can be whittled down to a conical point. This is also useful in cleansing bridge work and in self-prophylaxis generally.

Discussion of papers.

Dr. W. Sterling Hewitt. I wish to report a similar case to that which Dr. Salvas has described. The patient

was referred to me by a physician, with a very severe pain on the left side of the tongue. I had an X-ray made and consulted Dr. Stout in regard to the condition. I found two teeth, the upper left second molar and the lower left second bicuspid, badly affected by pyorrhea involving the apical space. I extracted these teeth, as the radiograph showed them to be in a rather hopeless condition. I also treated the pyorrhea, which had affected the rest of the teeth, and the pain in the tongue stopped. My treatment was pure guesswork, but it stopped the obscure pain on the side of the tongue which neurologists and nose and throat specialists had been trying for a long time to cure. I mention this simply because it is a curious case which seems to be parallel in some ways to the case reported by Dr. Salvas.

Dr. D. N. McQuillen. I was particularly interested in Dr. Salvas' remarks, because I think sometimes we do not look long enough for hidden causes. Within the last five years some rather remarkable cases of young girls about the time of puberty have come to my notice. One young girl, five years ago, presented regularly every month with intense pain in the lower first molar, which subsided in two or three days. Finally I called the mother and asked her if the child, who was about twelve years of age, was showing any signs of puberty, which the mother affirmed. I sent the patient to Dr. F. R. Packard, thinking of some possible enlargement of the turbinates. He treated the patient and the pain left, but recurred at regular intervals. This condition continued for about a year, and finally subsided. Only within the last few months Dr. Bell and I had a very similar case. The patient presented regularly every month with severe pain, localized in the lower first molar. After two or three months' observation, we persuaded the mother to take the child to Dr. Packard, who found the left turbinate very much enlarged. He treated her, and the pain entirely subsided. These cases show that we have to persist in finding the cause of these difficulties, and Dr. Salvas expresses a timely note of advice in regard to persistence in clearing up such obscure cases.

Dr. H. E. Roberts. Dr. Salvas has been more fortunate with his patient than I was with one of mine, in that his patient's husband was an intelligent man, willing to follow suggestions. I had a similar case of obscure pain in which I tried to get a radiogram. The patient had one made, but I have never been able to see it. It is in the hands of her physician, and he will not give it up. The pain has persisted for two years off and on, the patient being comfortable part of the time and in very great misery at other times. She insisted that the pain came from the upper left second bicuspid, but I could not find any pathologic condition in the tooth. As she persisted, however, I devitalized the tooth, and she seemed to be relieved. A short time afterward, however, she returned complaining of the same pain. Again at the insistence of the patient, the pulp was removed from the first molar. I tried to find out from the patient whether the rhinologist had ever been able to secure a passage between the sinus and the nose, and she said he had not, but that she had something like a clot or sebaceous mass which apparently came from the throat, or the posterior nares, into the mouth. The physician called it a mucoid cyst, and when this broke down, the rhinologist said, he could pass a sound into the sinus. The patient afterward had the impression that the first molar was the cause of the trouble, and insisted that it be extracted. I consented to this as it was of no great value, but the trouble remained. She continues to have these pains, and every once in a while something will rupture, giving her temporary relief, but I cannot obtain any information from the physician, and the patient is not willing to consult another. When this breaking-down of what the physician calls a mucoid cyst occurs, the patient has relief for a short time, but I wish I could get at the source of her trouble, like Dr. Salvas. I believe the trouble comes

from the antrum, and has nothing to do with the pulps of the teeth.

Dr. Edward C. Kirk. I was very much interested in Dr. Salvas' case report, but he has left me very much in the dark as to the cause of the difficulty which he was treating. From the report it seems that the extraction of two teeth brought permanent relief, but all we have learned as to the etiology of the case is that Dr. Cryer said it was due to "an impingement of the root of the teeth upon the superior dental nerve." Now just what does this mean? What is involved in this impingement? How do these roots impinge? What was the pathological condition about the apices of the roots concerned in the impingement and the relation of these to the nerves which produced the neuralgic pain? That is what we really want to know. It seems to me that, as far as the report goes, we have a statement in the form of words which do not convey a clear idea of the pathology of the lesion. I remember once going to see Harry Kellar in his legerdemain performance in which he did the well-known trick of apparently lifting a table from the floor by contact with the palm of the hand, which of course was done by means of a slotted finger ring on his middle finger that engaged the head of a pin driven in the top of the table. The audience was mystified; they of course had gone there to be mystified, and had paid their money therefor. A gentleman in the audience turned to his neighbor and said; "Isn't that wonderful? How did he do it?" The reply was, "By electricity." That explained everything and they were both happy, because they understood all about it. Similarly, the solution of this problem appears to be that "the roots impinged on the superior dental nerve." I should like to have a detailed definition of this explanation, and I regret greatly that Dr. Cryer is not here to tell us what to his mind that "impingement" meant.

There is another aspect of this question which has been referred to by Dr. McQuillen, namely, the multiplicity of lesions that can produce these paroxysms of neuralgia of an intermittent character. We see a great many of these cases at the university. I remember in particular the case of a patient who was brought by a physician to the clinic for surgical treatment, with the expectation and suggestion that one of the nerve trunks be resected. The patient had a history of paroxysmal pain extending over some eighteen months, and after very careful examination of the teeth we found an exposed pulp in one of the upper molars on the affected side; hence, instead of undergoing a surgical operation, the patient was referred to the operative clinic and under cocain pressure anesthesia the pulp was removed, which gave her permanent relief. There had been a slowly progressing caries with pulp-stone formation. This was distinctly a case of neuralgic irritation of the nerve trunk produced by peripheral irritation from progressing caries and finally pulp exposure.

In this connection I wish to call attention to something which does not seem to have made an impression on the minds of the dental profession, and that is the contribution made by the late Dr. Louis Jack in regard to diagnosis of pulp disturbances by the thermal test, the technique of which he has reported in full in several editions of the "American Text-book of Operative Dentistry." This test he calls the "temperature tolerance of the pulp," or the difference in the maximum and minimum ranges of temperature tolerance resulting in cases of pulp disturbances. I do not think that the dental profession has properly observed or appreciated the importance of this means of diagnosis. It is most important, and enables one to determine exactly which particular tooth is causing the trouble by the difference in thermal reaction when the test is properly applied.

Dr. Roberts' discussion brings up the question of obstreperous patients. I am quite unable to understand why we have such patients. I shall publish a report in the Dental Cosmos of a very interesting case which illustrates the difficulties which some of our colleagues

have in dealing with the cases that are unmanageable. How can a patient presume to come to a dental operator for treatment and object to his treatment? What right has the dentist to submit to such an attitude? Such patients would not dictate to their physician or priest. They presumptively go to the dentist as an expert, and it is beneath the dignity of the dental profession to submit to that kind of dictation. I submit that as a fundamental proposition.

Dr. E. R. Sausser. In the examination of the oral cavity for the origin of reflex pain, I think dentists usually are very unsystematic in their diagnostic procedures. Too often are such examinations made in a cursory way. Usually the teeth are first examined for cavities of large dimensions, and, there not being any, the patient is given the iodin treatment and told to take aspirin in the hope that this will allay the pain and cause the patient to forget his trouble. When the patient returns, the dentist thinks of some other simple condition. Not finding this, he decides that the trouble may not be of dental origin. Such efforts are feeble and reprehensible. If the dentist has qualified himself for the practice of dentistry, he should assume a more scientific attitude toward these cases. He should first study the case, and consider the history, sex, habits, etc., of the patient. Then, if necessary, he should secure a radiogram. With this aid, the shape of the pulp chamber should be very carefully studied—and we should be very familiar with the normal shape of the pulp chamber of each tooth, because abnormal conditions thereof can be the origin of the trouble. There are many conditions which we must look for, such as secondary dentin, pulp nodules, malposed and malformed roots, abscesses, etc., which conditions, one after another, must be eliminated before we can consider the examination a thorough one.

Dr. E. C. Palmer. Did you remove the fillings from these two teeth?

Dr. Salvas. Yes.

Dr. Palmer. I should never consider that tooth all right because it appeared to be so on the surface. I remember hearing Dr. Flagg tell of the case of the superintendent for the erection of the buildings of the Centennial Exposition, who gradually lost the sight in one eye, the other eye also beginning to be affected. On examination it was found that his teeth were apparently in perfect condition. Two teeth that were suspected contained beautiful gold fillings, but, as a last resort, these fillings were removed, and in one of the teeth an inflamed pulp was found under the filling. The tooth was devitalized, and the patient regained his eyesight completely, showing that the condition was caused by that tooth. Speaking of the necessity for anatomic knowledge, it is not the normal but the abnormal anatomy of the teeth which is important, especially when there is a filling in a tooth. Within the last ten days I had occasion to devitalize a canine on which I put a band in order to supply a missing bicuspid. The deciduous canine had been allowed to remain until middle life, and I had no more than penetrated the enamel when I perforated the pulp. The normal position of pulps does not give us any indication as to whether a pulp may not be abnormal in certain cases, or whether a filling may not be causing trouble.

Dr. J. C. Curry. In conjunction with a nose-and-throat specialist who had one of my patients under treatment for congestion of the frontal sinus, I finally decided to have a radiograph made, which revealed a third molar in the maxillary sinus.

Dr. Salvas (closing the discussion of his paper). The objection raised by Dr. Kirk is indeed pertinent. Let me remind you, however, that this case was reported merely as an incident of practice, and not as a treatise. The fact remains, nevertheless, that the failure to get at the cause is exasperating, to say the least. We were absolutely certain in this case that the pulps were not involved; there were no pulp stones; there was nothing to indicate that the teeth were in any way responsible for

the trouble. It was for the expert anatomist to see what we could not see. I regret that Dr. Cryer is not here, as he might be able to tell us more of the case from an anatomical point of view.

Dr. W. A. Capon. I should like to ask Dr. Palmer whether in his opinion there is any difference between the black copper cement mentioned and the lighter colors that are being marketed at the present time, and whether the black cement has better preserving qualities than do these others.

Dr. Palmer. I think black copper cement shows better after it has flaked off; it is stickier, and seems to have germicidal qualities.

Dr. E. T. Darby. In support of Dr. Palmer's argument, I wish to say that black oxyphosphate of copper is the only preparation that is fit to be used under these conditions. Red or white so-called oxyphosphate of copper is not the same material. I want to express in the highest terms my appreciation of the treatment which Dr. Palmer has applied to his daughter's teeth. It is a practice I have followed for years, ever since oxyphosphate came into use. Instead of using a solution of formalin, I use a solution of silver nitrate, the value of which should be equally as great in the treatment of permanent teeth as it is in the treatment of deciduous teeth. Furthermore, inasmuch as we use black oxyphosphate of copper, there can be no objection to silver nitrate because of its staining properties. I know of nothing better for the sulci of the first permanent molars than the treatment suggested. The teeth should be thoroughly cleansed first, all the food débris removed from the fissures, then the silver nitrate applied and the surface dried. Then the material is laid upon the surface, the index finger put over it and held there for half a minute, or vulcanizable rubber is put over it and held there until the cement hardens. The excess is scraped off, and the resulting filling is one of the best means for the preservation of the teeth. Dr. Kirk reminds me that Dr. Perry was in the habit of employing oxyphosphate of zinc for this purpose before the oxyphosphate of copper was placed on the market.

Dr. Palmer (closing the discussion of his paper). I just want to say to Dr. Darby that I do not use formalin, but iodin first, and then clean the teeth with alcohol, then with bichlorid, and with alcohol again, and then apply the oxyphosphate of copper. Someone asked whether this is good practice in permanent teeth? It has proven very valuable in the permanent teeth in the case described. I have used this method in many cases, and no tooth, after having been treated in that way, has required repair.

Dr. W. A. Capon. I am very much interested in the Carmichael attachment, having employed it very soon after it was suggested, but have found difficulty in properly introducing the wax around the gingival border as thin as I desired it. Dr. Guilford holds the matrix in one hand well to the border of the tooth and forces the wax in afterward. I cannot understand, however, if he holds the matrix as he says, how he gets the wax in the fine line he speaks of.

Dr. Guilford. The matrix is held in such a way that the margin is fairly heavy. The wax impression is removed immediately and put back, so as to make sure that, when finished, it will come off easily. Then it is trimmed fairly thick at the gum, and with a warm instrument pressure is created just sufficient to squeeze the wax out into a thin margin and under the free margin of the gum.

Dr. Otto E. Inglis. Having had some trouble in holding the metal strip in a manner similar to Dr. Guilford's, I devised an indirect method which has proved satisfactory to me. After preparing the tooth for the Carmichael attachment, I take an impression with Kerr's modeling composition, using all the available fingers of both hands to force the impression material to place without

allowing it to slide away from the tooth. My assistant then applies ice-water to the composition, so that it is quickly chilled. If the compound happens to get on the buccal side, where it is likely to cause the impression to draw, I cut it away with a chisel, and then withdraw the impression. I also take a small bite with pink paraffin wax. I believe it is commonly supposed that inlay investment compound cannot be used for making models, but that is not correct so far as the Taggart compound is concerned. The model can be made with it in the usual manner, and the modeling composition withdrawn after heating in water. This produces an accurate model of the tooth, but not a good replica of the portion of the tooth beneath the gum; therefore it is necessary to score the model at that point. I then take a narrow strip of 40-gage platinum plate, set it edge down into the scoring and close to the model, so that the wax will not go inside. I then place the wax bite on the occlusal surface of the model tooth, wax the case up, and carve. This secures the casting pattern. I then cut away all the model except the portion beneath the wax and platinum, leaving a little excess to catch in the investment; this is then spread, wetted, and invested, and the casting is made directly upon the original model. When cast, the gold will have picked up the platinum, but will not have stiffened it much. As the platinum is thin, it can easily be burnished to the cervix of the tooth in the mouth so as to render the adaptation exact. I then flow three pieces of solder on it to stiffen it. I find this quite an easy method, if one does not care to work with the wax pattern at the first sitting. While I have not tried it, I see no reason why a model made of investment material should not be used in the indirect method of constructing inlays, as a wax bite can easily be set up on it. A difficulty might arise in obtaining a correct impression, and by injuring the cavity margins on the model.

Dr. McCULLOUGH. Has the essayist had any difficulty in getting the cast model into position on the tooth?

Dr. GUILFORD. No. I have found, however, that in carving the model, the wax, being somewhat softer than ordinary casting wax, will become a little loose. In fact, I usually purposely loosen the model and then burnish the margins to fit exactly, and I then have no trouble in getting the casting to go to position.

Motion was made and carried that a vote of thanks be extended to the essayists of the evening.

Dr. DARBY. My attention has been called to the fact that since our last meeting two of our members have died, and it seems fitting that some action be taken by the society with reference to the death of Dr. Truman and Dr. Jack. I therefore move that the society take some action with reference to the demise of these two gentlemen.

The motion was carried.

Dr. Curry appointed a committee to draft resolutions on the deaths of Dr. Truman and Dr. Jack, consisting of Dr. Darby, Dr. Kirk and Dr. McQuillen.

The treasurer, Dr. Bassett, presented the Report of the Treasurer, and the Chair appointed as Auditing Committee to audit the books, Drs. Capon and Swing.

Motion was made and carried to adjourn.

NATIONAL DENTAL ASSOCIATION—SOUTHERN BRANCH.

Sixteenth annual meeting of the Southern Branch of the National Dental Association, and the forty-seventh annual meeting of the Georgia State Dental Society, held at Atlanta, Ga., June 4, 5, and 6, 1914.

THURSDAY—*Morning Session.*

THE sixteenth annual meeting of the Southern Branch of the National Dental Association and the forty-seventh annual meeting of the Georgia State Dental Society was held in Atlanta, Ga., Hotel Ansley, June 4, 5, and 6, 1914.

The meeting was called to order Thursday morning, June 4th, at 9.30 o'clock, in the ballroom of the Ansley Hotel, Atlanta, Ga., by the president, Dr. W. A. Dean, Tampa, Fla.

Rev. Dr. JOHN F. PURSER, Atlanta, invoked divine blessings on the deliberations of the meeting.

Mr. F. O. Foster, Atlanta, introduced Hon. JOHN M. SLATON, governor of the state of Georgia, who welcomed the association to the city of Atlanta.

Dr. B. HOLLY SMITH, Baltimore, responded to the welcome address on behalf of the association.

The first order of business was the reading of the President's address by Dr. W. A. DEAN, Tampa, Fla.

Dr. Tignor, vice-president, occupied the chair while the President read his address, as follows:

President's Address

By W. A. DEAN, D.D.S., Tampa, Fla.

Ladies and Gentlemen and Fellow Members of the Southern Branch of the National Dental Association,—It is with pleasure that I greet you again. A year ago you honored me with the high office of president of your organization, and the distinction accorded me in that trust arouses in me the deepest feelings of gratitude to you. If I have failed to fill the post with credit or satisfaction, it is not due to a failure to feel keenly the compliment nor is it from a lack of willingness to serve you. I fully recognize its meaning and come to you with no little trepidation to render an account of my stewardship. And before you sit upon my case, I would fain erect a sign first employed in a western mining camp on the occasion of the annual dance, when the violinist was in great danger of having his head shot off because of his lack of musical talent—"Please don't shoot the fiddler; he is doing the very best he knows how."

QUESTION OF DISCONTINUANCE OF THE SOCIETY.

You had for the principal item under consideration at Old Point Comfort, Va., last year, the question of whether or not it was wise or expedient to continue the Southern Branch. It was pointed out at that time that it was a third link; that we have the state organization, the Southern Branch, and the National Association, and the question seemed to be, "Can we get sufficient interest in the matter of attendance, the proper talent for programs, and the necessary finances to keep alive the three separate bodies?" After long and careful consideration it was unanimously determined to continue the Southern Branch, and there was enthusiasm enough apparent then to make the fu-

ture of our work seem simple. But the future—what is now past—did not sustain the hope, and it has been with the greatest difficulty that we have secured the co-operation here represented. Now, I am a believer in the idea that whatever is worth doing at all is worth doing well, and that what cannot be done thoroughly should not be done at all—but do not understand me to desire either to discredit your wisdom of a year ago nor to discourage your enthusiasm for the future. Instead, I propose one of two alternatives. We must, as I conceive it, either merge ourselves without reservation into the National organization, or lay the burden on the shoulders of a committee large enough and with force of character sufficient to carry us over the natural obstacles that we have met in the preparation of the program and other important features of this present convention. Now, it is undoubtedly the part of wisdom at all times to proceed with due caution and to hedge every proposition to substitute some new plan for the old one with all the safeguards necessary to prevent the mistake of rashness. But the word "progress," which has been so constantly upon the lips of the nation during the past few months, means the substitution of new ideas for old ones. I have always been on the fence as to the two signs hung out by rivals in the shoe-repairing business in a western town—the one, "John Smith's Shoe Shop, Established in 1876," while across the street his rival hung out, "Bill Jones' Shoe Shop, Established Yesterday: No Old Stock on Hand." But this is one of the matters that must be squarely met if we are to live as an organization; for when we cannot offer on our program and in the fellowship that our conventions furnish some values, we shall certainly cease to appeal to the busy, wideawake, and earnest fraternity of American dentists. Do not let us fool ourselves into the delusion that they will come, unless we have something worth while. They are ravenous for vital inspiration and instruction, but surfeited on platitudes and humdrum elementaries.

NAVAL RESERVE CORPS.

Another matter of importance is the possibilities of the Naval Reserve Corps of the United States. In this corps our government has made provision for dentistry to enter the navy on practically the same basis as medicine and surgery in general have been accorded, and promises much for our profession. I have some circulars regarding this matter, and in the open sessions I would be glad to have a free discussion thereof by all who have a taste for naval life, and will be glad to furnish information covering the question fully to anyone who applies for it.

WORK OF THE RESEARCH COMMISSION OF THE N. D. A.

The March number of the official *Bulletin* of the National Dental Association contained a most excellent article entitled "Report of Progress of the Scientific Foundation and Research Commission," by the Executive Board.

There are many features of this splendid report that are eminently worthy of our careful consideration and free discussion, and I hope the members will give each other the full benefit of any details concerning this work that may have come under their personal observation.

I want especially to call your attention to the scope of the work undertaken by this Research Commission by a very brief reference to the general captions that cover the more immediately important work it is accomplishing:

Tooth Decay, Its Causes and Prevention.

Oral and Dental Infections and Their Relations to General Systemic Infections and to Distant Infections and Manifestations.

Pyorrhea Alveolaris (So-called). Its Causes and Prevention.

Defective Tri-calcic Salt Nutrition (including Enamel Hypoplasia, Defective Tooth Formation, and Improvement in Artificial Baby Foods).

The Etiology of Dental Erosion and Its Prevention.

The Relation of Facial Deformity to Mentality and Imbecility, and Methods for Their Correction or Improvement.

The Relation of the Organs of Internal Secretion to Pathological Conditions in the Mouth, Including Its Secretion, Decay, etc.

Metallurgical Studies for Better Filling Materials and Inexpensive Platinum Substitutes.

A Knowledge of the Electro-chemistry of the Mouth, Including Its Relation to Obscure Neuralgias. Tooth-root Substitutes.

—and many other subjects and problems.

This Foundation is in my opinion of the utmost importance to all of us, and unless we become actively identified with it and support it with our interest as well as with our finances, we must all suffer an incalculable loss. This work promises what no branch of our profession has ever done, viz, to go to the bottom of those vexing and unsatisfied doubts and uncertainties that we have all experienced, and for the investigation of which we have hitherto depended almost wholly upon the medical world, which at best gave us only meager and sporadic help. This is an age when the old Arabic apothegm is most appropriate: "He that knows not, and knows not that he knows not, is a fool; shun him. He that knows, and knows not that he knows, is asleep; wake him. He that knows, and knows that he knows, is wise; follow him." I therefore recommend this Foundation to your most earnest consideration.

IMPORTANCE OF STATE ORGANIZATIONS.

Again, there can be no doubt in the mind of anyone who will but for a moment consider it, that we owe it to our best interests to identify ourselves with our state organizations, and in turn have these affiliate with the National society as bodies. There are of necessity matters of great importance that are peculiar to geographical boundaries, and the zest and uplift that come to those who mingle with their fellows of other states —of *all* of the other states—is such as to deserve our hearty interest, and unless we overcome the apathy that exists in certain quarters of our great country, we shall miss much.

CO-OPERATION URGED.

Finally, let me say by way of recapitulation—Whatever we accomplish, such conventions as this may be made invaluable to all those who attend them, or they may fall flat. Co-operation, therefore, is indispensable, and this in turn is the expression of natural needs and cannot be legislated by arbitrary dictums; we are not creating any new appetites in the human anatomy, but we should wisely and intelligently supply healthy nutriment to those that already exist. By proper feeding, hunger is only quieted temporarily, and is renewed again at the next meal-hour, whereas indigestion and all the calamities of dyspepsia follow gorging of any kind or nature; and it is my most earnest desire to call attention to the problems that have confronted us during my incumbency, and to have the benefit of your wisdom in their solution.

I will ask the committee that passes upon and reviews this message to consider carefully the matter of the time of our meetings as they are related to or conflict with the meetings of the other of our allied bodies—I have several letters from those who would have been with us at this time had it not been for the conflict of dates—and to make such recommendations to the Executive Committee on this subject as they may deem appropriate.

I want, before retiring from this platform, to go on record as fully appreciating the splendid work of the various committees, and also of the Georgia State Association, whose guests we are, and who have by their far-famed hospitality made us doubly grateful. To the Atlanta Association of Dental Surgeons I wish to express my profound admiration and gratitude for its strenuous labors on program and entertainment as well as for the evidences of progress and attainment that characterize them.

Again expressing to you all my sincere appreciation of the cordial support and loyal and generous co-operation with which you have invariably sus-

tained me. I pray your further indulgence while we conduct the session of this convention.

Dr. Holland moved that a committee of three be appointed to report upon the address of the President.

Dr. Tignor appointed the following committee—Dr. Frank Holland, Dr. Joseph Eby, Dr. N. A. Teague.

The next order of business was the calling of the roll and the payment of dues.

Dr. Corley moved that the members of the Georgia State Society not members of the Southern Branch be accorded the privileges of the floor. (Motion carried.)

The next order of business was the reading of the following papers, which were discussed together—"Preventive Medicine in Dentistry," by Dr. J. G. Reid, Marion, N. C., and "A Few Thoughts on Oral Hygiene and Surgery," by Dr. N. G. Slaughter, Athens, Ga.

Preventive Medicine in Dentistry.

By J. G. Reid, D.D.S., Marion, N. C.

Preventive medicine had its dawn in the hygienic measures of Egypt, Greece, and Rome, was mentioned in the Mosaic law and in the teachings of Mahomet, but the modern scientist has first fully realized its true worth and mission. During the nineteenth century such strides in medicine, and especially in surgery, have been made as could never have been dreamed of by our forefathers, and today the dental surgeon ranks with the medical surgeon in the practice of preventive medicine. The establishing of the science of bacteriology, the discovery of the microscope, and the proving of the pathogenic nature of the bacillus of anthrax, all these have their part. Ever since the discoveries of our honored Miller, biological and chemical, surgical and mechanical investigations have been greatly strengthened and improved. The dental surgeon's daily operations are preventive medicine—whether they consist in filling a cavity, restoring a tooth, making a Brophy operation for cleft palate, or performing any of the many operations which devolve upon the dentist for the cure or prevention of disaster and disease.

PREVENTION OF DISEASE IN SCHOOL CHILDREN.

Our children are our hope, our state's and nation's hope, and it is upon the subsequent efficiency of these citizens in embryo that the future prosperity of our country depends. I believe in the near future every state will have adopted compulsory education. This is necessary, and just as necessary it will be for the state to go a step farther, and supervise the physical conditions and environments during school life so as to insure their reaching maturity unimpaired by preventable ills. By so doing we shall lessen the number of public charges and other dependents. It has been proved conclusively that the harmful influence of physical defects and diseases so often present in school children without the knowledge of their parents and teachers is a potent factor in retarding or arresting the physical, mental, and moral development of the children, when allowed to extend through childhood years. On the other hand, it has been just as conclusively demonstrated that many such defects and diseases, while pernicious in their growth and development, are either readily preventable or curable; besides, unless such defects are detected by a competent physical examiner, their presence is often not discovered until great damage has been done. It is all-important, therefore, that we should have competent examination of all school children by physicians, dentists, and trained nurses.

THE DENTIST'S RÔLE IN PREVENTIVE MEDICINE.

When the Oral Hygiene Committee selected forty of the most backward and hopeless pupils of the Marion

graded school of Cleveland, Ohio, and made a test of this class by setting right every defect found by medical and dental skill, the result after one year's test astonished all our nation, and graded schools are adopting similar tactics everywhere.

The paper read by Surgeon-general Dr. Rupert Blue at the National meeting at Washington, D. C., enumerating the many infectious diseases and discussing the relation of preventive medicine thereto, was an excellent one, and his interest in our behalf, along with that of other prominent officials and men of note, is doing a great deal toward placing our profession where it should stand. The watchword of both the medical and dental professions should be prevention rather than cure.

Let me quote from the noted Dr. Osler, who, while sojourning in this country, said: "You have one gospel to preach, and you have to preach it early and late, in season and out of season; it is the gospel of cleanliness of mouth, cleanliness of teeth, and cleanliness of the throat. The three things must be our text throughout life."

The editorial in the April Cosmos of 1913 quotes Dr. Chas. H. Mayo, the eminent surgeon of Rochester, Minn., who declared that it is evident that the next great step in medical progress in the line of preventive medicine should be made by dentists. He asks the question, Will they do it? We are a profession which has suffered from lack of proper recognition, but whose *personnel* has been equal to that of any profession. The appeals of such men as Drs. Osler, Mayo, Blue, and a host of others, at the head of the medical profession, who recognize our part in preventive medicine, renders it possible to answer Dr. Mayo in the affirmative. Most assuredly we will rise to the task, aided by possibilities at hand, the scientific research work, and the oral hygiene movement that is spreading all over our land, and take our stand in the front ranks of surgery and preventive medicine. The authorities of our state are already coming to recognize us along with the doctors of medicine, and are appointing dentists to important positions. Now that our opportunity is at hand, we cannot sit down and wait for it to develop, but must each one put his shoulder to the wheel. We must do as Dr. Osler says, "Preach in season and out of season." We must make it a point to interest the children as well as their mothers; when we have accomplished this, we shall have the men's co-operation.

If we want things done, now is our time to join the progressive medical society whose heads have already recognized our part in surgery and preventive medicine; for in a progressive age, with a progressive President, a progressive Congress, both House and Senate, a progressive Legislature, we ought to be able to have such laws passed as a great profession in a great land needs.

PRESS DISCUSSIONS ON ORAL HYGIENE.

I would not have you think that I believe we are asleep. We are not. We are doing a great work, but the time is now ripe for us to be more widely awake, and to begin to reap the harvest that is in store for our profession; that is, place it where it rightly belongs. The many aseptically clean dental offices all over the country, the great movement in oral hygiene conducted by many of the states, cities, and towns, the excellent preachings of the medical profession as well as ours, and the placing of trained nurses in the graded schools—all are doing their work. I read not long ago in a Des Moines, Iowa, paper a comment on the duties of trained nurses in graded schools, also an excellent full-page article in the *Ladies' Home Journal* of September 1911, written by Luther Hasley Gulick, M.D., suggesting many brilliant ideas to the profession, and placing this problem in an ethical way, before the public.

DENTAL HYGIENE IN PRISONS.

Sheriff Quinn of Boston, Mass., lately published an article in one of the local

daily papers, saying: "Teach a man to care for his nails, his hair, his ears, his eyes, and particularly his teeth, and you teach him the first law-abiding principle of decency." This sheriff contends that a man's whole mental attitude is transformed if he practices habits of cleanliness and neatness. He has installed a dental chair in the Charlotte st. jail, and has arranged for dental treatment of all the prisoners in need thereof, showing his idea of how prisoners, even, ought to be treated. This is his idea of one of the first aids in the prevention of crime.

Statistics show that 4 per cent. of the annual death-rate is due to old age, 4 per cent. to accident, and 92 per cent. to preventable diseases. What a work for physicians and dentists! The mouth, the gateway to our body, if not kept clean furnishes an incubator for all disease germs to be carried directly into the system. When we have trained nurses and dental attendants in all our schools, large factories, prisons, and sick-rooms, when all the air supplied by ventilation is sterilized, when the patient's mouth is kept clean, in fact when everything is kept sanitary and everybody is taught sanitation, we shall have less disease, less crime, higher ideas, and a nobler civilization.

We find written in the Law of all laws, "For whatsoever a man soweth, that shall he also reap." Equally is it true, if we sow germs, we shall reap corruption; if we sow prevention, the harvest will be health and happiness.

We all agree that a dental office should be the cleanest place in all Christendom, and if we do our duty as dental surgeons it will be so. Cleanliness is next to godliness is a true and worthy saying.

As we live first for those who love us, let us each for himself say, I live in a great measure—

> For the wrongs that need resistance,
> For the cause that lacks assistance,
> For the future in the distance,
> And the good that I can do.

A Few Thoughts on Oral Hygiene and Surgery.

By Nathaniel G. Slaughter, D.D.S., Athens, Georgia.

When Dr. William Osler, probably the greatest living authority on general medicine, says there is no one single thing more important in the whole range of hygiene than hygiene of the mouth; when Dr. William Hunter, the great English surgeon, says no physician or surgeon would tolerate that a patient with a foul and septic ulcer in his forearm should from time to time apply his lips to the ulcer to clean it; and when Dr. Chas. Mayo says that the next greatest step in medical progress, in the line of preventive medicine, should be made by the dentist; when not only the members of the medical fraternity, but intelligent men and women everywhere are looking to us for counsel and advice in the prevention of not only diseases of the mouth, but countless other diseases that originate in and are aggravated by an unhealthy oral cavity, then it is time that we should wake up and realize that we have a duty to perform.

It is said that no work on internal medicine contains as yet any comprehensive discussion on oral sepsis and its relation to some of the most destructive diseases. Is there not an opportunity to co-operate with the medical practitioners in the study and treatment of diseases so closely related to the oral cavity? How often do we see blind abscesses from which pus is being constantly absorbed into the system, or a chronic abscess with a fistula is pouring pus into the mouth constantly—and often, if these lesions do not cause pain, dentists are content to pass them by, little expecting any serious complication.

Dr. C. N. B. Camac, in the February number of the *American Journal of the Medical Sciences,* reports several cases of arthritis and endocarditis, the infections coming from blind abscesses or pus cavities in the mouth.

Have you ever gone into a schoolroom filled with children from the most

intelligent and refined homes, where hygiene and preventive medicine are practiced, and also with children from other homes where hygiene is unknown, and where sanitary conditions are bad, and studied the faces of these children? How bright and cheerful the first, how pale, sallow, and dull the others! Have you ever talked with the teacher about the difference in the progress of these two kinds of children?

A short time ago a lady came to my office with three bright children of four, six, and eight years of age for examination, and though the mouths of the two youngest children were in perfect condition, the mother was very much distressed because the oldest child had two small cavities in the deciduous molars. On the other hand, how often children are brought to us at this age with their mouths literally filled with pus caused by broken-down, decayed teeth and chronic abscesses, pus germs constantly being absorbed into the system. Is it any wonder that we so often see enlarged tonsils and adenoids, stomach trouble, and anemia associated with mouth conditions of this sort? In truth, it is nothing short of criminal to bring children up without giving them a better dental equipment and appreciation thereof. And we are going to be held responsible unless an improvement is made in the hygienic condition of some of the children's mouths of the present day. It is true that we have made progress. We have accomplished a great deal more than the most optimistic believed us to be capable of. Oral hygiene, where practiced, has not only saved the teeth and prevented disease conditions of the mouth, but has gone far beyond that and prevented many other constitutional diseases. The very fact that we know that oral hygiene will accomplish so much should inspire us to do greater things. We should forget the past and press on toward the prize of the high calling which we represent. The very fact that we know these conditions will make our responsibility much greater, but our opportunity will also be greater.

Did you ever realize that if we can by the proper training and service change a weakling into splendid physical manhood, or alter the facial appearance of a young woman from one of idiocy to that of beauty, the application of oral hygiene is worth while?

A woman came to my office from a near-by town, stating that she did not consult the local dentist because, when she had gone to see him before, he examined her mouth without washing his hands. This shows not only lack of common decency, but of aseptic dentistry. Is it reasonable to expect an intelligent laity to follow our leadership in matters pertaining to preventive dentistry and medicine when such incidents as these occur every day?

I was talking to a prominent dentist of our state about the necessary precautions in operating upon tuberculous patients, and he told me that he was in the habit of spraying his mouth and throat occasionally while operating on such patients.

Let us catch a new vision of preventive dentistry, and by example and precept pass it on to those who need it most. Then will come to us the reward of duty well done, and we certainly owe to humanity the very best that we have. We owe to each other advice, counsel, sympathy, and fellowship, but with all of these, each man has to pave his own way, fight his own battles, and receive his own reward. A wise poet has most beautifully said—

It matters not how strait the gate,
How charged with punishment the scroll,
I am the master of my fate;
I am the captain of my soul.

Discussion of the two papers.

Dr. T. P. Hinman, Atlanta, Ga. It is with a considerable degree of appreciation that I begin this discussion. I appreciate the fact that the young men of the profession are awakening to the necessity of investigation along the line indicated in these papers. I cannot, at this time, pass the matter by without making a few statements with reference

to the work which has been done by the Scientific Foundation and Research Commission of the National Association. Both of the papers have called attention to the fact that oral infection is a source of systemic disorder. Dr. Slaughter calls our attention to the claim of a certain physician that arthritis, articular rheumatism, septic infection of the heart, endocarditis, etc., have been traced to oral infection, but I wish to impress upon you that we have had to wait for the dentist himself to demonstrate to the world the positive fact that infections from periapical alveolar abscesses do cause these troubles. It remained for Dr. Hartzell of Minneapolis to take cultures from an alveolar abscess and by injecting into rabbits produce septic endocarditis in twelve instances. The medical men said it was possible, but never demonstrated it. Dr. Slaughter calls attention to the fact that Dr. Mayo made an announcement that the next great step in preventive medicine would have to be taken by dentistry, and he, in 1913, threw down the gauntlet to the dental profession, which took it up and is now showing to the world that this great step is being taken, by demonstrating the possibility of systemic diseases of dental origin.

You have probably heard of the work of the National Dental Research Commission. Its purpose is to ferret out and demonstrate to the world not only the necessity of oral hygiene, but a great many other scientific facts. At this time I wish to state, with the permission of the chair, that this demonstration of septic endocarditis as well as articular rheumatism of dental etiology which Dr. Hartzell has made is due entirely to the aid which the Scientific Research Commission has given this researcher to enable him to carry on the work in the laboratories of the University of Minnesota. President Vincent of that university did not meet us halfway only; he came over the line, and gave us the use of all the equipment of the University of Minnesota so that we might be able to carry on this work. Dr. Hartzell, Dr. R. W. Bunting, Dr. Price, and Dr. Black are all working under this commission, devoting their time and energy gratuitously. With the money collected as a voluntary offering by the dental profession—and I am proud to say that they have responded generously, some societies having given as much as four thousand dollars—each one of these investigators is provided with an assistant who carries out his tests and ideas, the directors of this work receiving absolutely no remuneration whatever. If these men are willing to make such sacrifices, I think we as a profession should support them. I have just received a letter from Dr. Price telling me that he has recently succeeded in demonstrating a substitute for iridio-platinum, which has all the properties of iridio-platinum and is superior to it in some respects for dental use. From the standpoint of returns to you, that will mean a great deal. A piece of iridio-platinum seventeen inches long, of No. 16 gage, costs about seventeen dollars, but a piece of the same dimensions of the substitute, as demonstrated under the auspices of the Research Commission by Dr. Price, will cost, I believe, about one dollar. So you see that you will get your money back in the first year. I believe that the work of this commission will give dentistry a position not necessarily on a level with, but in some respects above the medical profession. I do not wish to disparage the work which the medical profession has accomplished, but I want you to realize that it is only by such researches that we shall be able to demonstrate to the world the necessity of oral hygiene and the establishment of physical perfection through oral health.

Dr. H. W. Morgan, Nashville, Tenn. Some three or four years ago, at a dinner, I heard one of the most prolific writers on dental subjects say that "The dental profession is not a reading profession," and he stated as evidence of his contention that he had written as many as ten books, and had never yet received from the sale of these books enough to pay for the binding of any one of them. He said he had written

about ninety-six separate articles, each of which contained some great truth relating to the profession of dentistry, but he had never seen any of his thoughts quoted with proper credit given to their author. This morning we have had a demonstration in contradiction of both these statements. Both of the essayists have quoted from that now famous article by Dr. Mayo. Nothing that I have ever read in the English language has been so often quoted, or has stirred the dental or any profession as that statement of Dr. Mayo. I do not believe that anyone will deny that these sentences have been more often quoted in the last fifteen months than anything ever written about dentistry.

The sentiments expressed by the essayists are being entertained by every man who is interested in dentistry and has its scientific progress at heart. We live in a scientific age. All that we as a profession are, all that the medical profession is, is the result of the work of scientists—not of men actively engaged in professional work, but of men of a scientific trend of mind and trained to scientific working and thinking. We cannot all be geniuses; we cannot all be inventors; we cannot all delve deeply into the realm of science. Here and there a man is endowed with the faculty to look deeper into the mysteries of nature than the rest of us. Sometimes, however, instead of lying deeper, the solution of a problem lies right on the surface, but we have overlooked it. And perhaps the greatest truths are scattered all around us, and we are overlooking them, while looking 'way beyond! The first essayist alluded to the contributions of the Hebrews to medicine. They have given us much, and perhaps were ahead of their time, surely much farther than the benighted Indian who still sounds the tomtom in the hope of scaring away the evil spirits. Coming down the ages, we find that it was the Greeks who were the forefathers of medicine and dental science, taking it probably to Rome. Who was it, however, that gave us our pharmacopeia, and who were true scientists for ages? It was the Arabians. They furnished us with a knowledge of materia medica upon which we have builded since that time. In all these ages medicine was gradually drifting toward greater knowledge, but only gained a secure foothold after many centuries of hard scientific effort, until the discovery that hydrophobia might be cured through vaccine therapy. After that came the work of Lister, who believed that germs were floating around in the atmosphere, and that if wounds were protected by water, no trouble would come from the atmosphere. What was the result of his work? The error was soon discovered. Our knowledge of preventive medicine has increased to the extent that at the great medical congress held in London last year, one-half of the entire time was devoted to preventive medicine. The medical profession has drifted away from the exclusive consideration of surgical procedures, and is studying the same subject, prevention, which we are discussing here. It is indeed a great age in which we live. All that was said by the essayists with reference to the examination of school children meets with the hearty approval of medical men today. The impetus came to us from Germany, Norway, and Sweden, where they first began the examination of children for defective eyesight, until today it includes every phase of the child's health. Such examinations should not only include the school children; indeed, I believe the trained nurse is going to have the authority to dismiss the school teachers when they are not fit to teach. When a school teacher comes into a schoolroom in a highly nervous condition, the nurse should have power to advise her to go home until she is able to teach. Much of the backwardness of children is due to the fact that teachers come to school unfit to put themselves in harmony with the pupils whom they are to teach. The problem of prevention broadens every year. Last year I received an application from the superintendent of an asylum in Little Rock, Ark., who wanted a dentist for that institution, and this year I had another such call from an

institution in Tennessee. The medical profession recognizes the fact that the mouth is the portal of entry for three-fourths of the diseases which the human body is heir to, and they realize that it is their duty not only to look after the public, but the unfortunates in these institutions. The work of prevention, therefore, which has been advocated by the essayists, deserves the highest commendation, as it is an important contribution to the efforts toward the relief of suffering humanity.

Dr. Reid (closing the discussion of his paper). I appreciate very much the discussion of my paper. Dr. Morgan's remarks about the ancients remind me of the statement that we are getting to where the Chinese have been for years. They pay their doctors for keeping them well, and if they become sick, they do not pay them. Though the Chinese are considered heathens, this seems to be a good plan.

The scientific work of the National Association is wonderful, and will surely lead to many important discoveries.

Dr. J. P. Corley, Greensboro, Ala. The presentation of such papers as these, by such men as these, before such a body as this, indicates that the star of scientific dental altruism has arisen. We might with profit and pleasure spend the rest of this entire session in discussion of these two papers. I cannot see the papers passed without expressing my gratitude and appreciation to the scientific dreamers who have entertained us with their papers.

Dr. Slaughter (closing the discussion of his paper). I wish in closing simply to thank Dr. Morgan, Dr. Hinman, and Dr. Corley for the discussion of these papers.

The next order of business was the reading of a paper by Dr. J. P. Corley, Sewanee, Tenn., entitled "Ways and Means."

The next order of business was the reading of a paper by Dr. H. C. Brown, Columbus, Ohio, entitled "The Status of Our Dental Organizations."

The next order of business was the reading of a paper by Dr. Gillespie Enloe, Atlanta, Ga., entitled "The X-ray as an Aid in Diagnosis."

[This paper is printed in full at page 409 of the present issue of the Cosmos.]

The meeting then adjourned until the Friday morning session.

Friday—*Morning Session.*

The meeting was called to order on Friday morning, at 11 o'clock, by the president, Dr. Dean.

The first order of business for the session was the reading of a paper by Dr. D. D. Atkinson, Brunswick, Ga., entitled "Impression Taking by the Green Method."

[This paper is printed in full at page 402 of the present issue of the Cosmos.]

Discussion.

Dr. P. E. Callihan, McRae, Ga. I have enjoyed Dr. Atkinson's essay very much, as I have also read with great interest the book to which he refers, which contains a description of this method in detail. There is so much in it that I would advocate, as he does, its purchase by anyone interested in this work. Like almost all dentists I was taught that for difficult impressions, plaster was the better material to be used, and I followed that plan for a long time; but after understanding this method, I have been able to take difficult impressions with compound in a very satisfactory manner, in fact, much more so than with plaster. Impressions taken in compound can be muscle-trimmed and corrected; which cannot be done with plaster. Compound is also indicated in cases where the plaster causes nausea, and where it is difficult to relieve this condition even after cutting away a good portion of the finished denture. By using a properly taken impression of modeling compound, we can secure a more comfortable and serviceable fit than with plaster alone. The es-

sayist has also fittingly pointed out that the fitting of the trial plate is the best time for securing thorough adaptation of the palatal surfaces, by allowing the patient to swallow and produce exaggerated movements of the mandible which make the yielding, warmed edge of the impression conform to the mouth, while otherwise we so often have to trim the finished denture.

In the more difficult lower cases I have made as many as a half-dozen plaster impressions before obtaining a satisfactory one; but I do not have such trouble since I have adopted the use of the compound.

Much that Dr. Atkinson has not mentioned may be found in the book. Without going into details, I wish to emphasize what the essayist has said about impression taking, because the entire success or failure of the construction of an artificial denture depends on the impression.

Dr. H. H. Johnson. I would like to ask Dr. Atkinson if the method he has outlined is intended only for edentulous jaws.

Dr. Atkinson (closing the discussion). In answer to Dr. Johnson I would say that this method is applicable to partial impressions of the upper and lower jaws, as well as for full upper and lower impressions. All of you who have made lower dentures appreciate the trouble of having a plate jump up all the time. As I said, you will have to study the book, and study it diligently, to understand this system, which is described there very much more fully than I could do it at this time. Dr. Lambright in one particular case asked me for an impression and requested me to send the bite along with it. After I obtained the impression and had muscle-trimmed it so that it would lie in the mouth properly, I put a little wax on the reverse side of the impression tray and had the patient bite into that, and when I sent him the case, both the impression and the bite were contained in that cup. Dr. Callihan has fittingly emphasized the correctability of the impression. There is one thing that one must avoid absolutely, that is, pressing so hard that the cup will come through the impression. If one falls short of material at any place, a little material is added to the impression, which is placed back in the mouth and made to conform to the jaw.

(To be continued.)

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

PUBLISHED BY

THE S. S. WHITE DENTAL MFG. CO., PHILADELPHIA, PA.

SUBSCRIPTION PRICE, including postage, $1.00 a year to all parts of the United States, Hawaiian Islands, the Philippines, Guam, Porto Rico, Cuba, and Mexico. Canada, $1.40. To other foreign countries, $1.75 a year.

Original contributions, society reports, and other correspondence intended for publication should be addressed to the EDITOR, Lock Box 1615, Philadelphia, Pa.

Subscriptions and communications relating to advertisements should be addressed to the BUSINESS MANAGER of the DENTAL COSMOS, Lock Box 1615, Philadelphia, Pa.

PHILADELPHIA, APRIL 1915.

EDITORIAL DEPARTMENT.

THE DEDICATION OF THE THOMAS W. EVANS MUSEUM AND DENTAL INSTITUTE SCHOOL OF DENTISTRY UNIVERSITY OF PENNSYLVANIA.

PROFESSOR ADAMI has very pertinently said that the development of a science is strikingly similar to that of the intellect of a child—which in the early period of growth is concerned mainly with the observation of phenomena about the causes of which he becomes increasingly curious, and rapidly passes into the stage of the perpetual "Why?"

In his search for the causes of phenomena he is, for the time being, satisfied with the explanations of his teachers and elders, and in this stage his sole dependence is upon authority. While many do not pass beyond this stage of deference to authority, others later discover that the explanations of their authorities are not always adequate or satisfying. They then venture to formulate explanations for themselves, and occasionally light upon truths having great breadth of scope and application. Stimulated by the discovery of their powers of generalization, they blithely construct hypothesis after hypothesis, only to find that many of them are disappointing because their conclusions have been drawn from insufficient data. They thus learn that scientific truth is not so easily wooed or quickly won, and go patiently to work

extending their observations of phenomena, content to study their relationships in the hope that some time the arcana of their inquiry may be revealed. The individual thus passes into the stage of intellectual manhood and of unfettered reasoning.

The simile is as directly applicable to the evolution of dentistry as it is to any other science, or department of human activity which develops into a science.

Dental education in its inception was confronted with problems the solution of which was attempted after the manner in which the undeveloped mind of the child studies phenomena, as portrayed by the foregoing quotation from Professor Adami. Its teaching and its practice were empirical, and its authority was the *ipse dixit* of the self-constituted teacher. The widening of the scope of dental knowledge has followed the discovery of the practical inadequacy of the data obtained from these earlier observations. We have, in our turn, passed through the age of hypothesis, the age when what was "theory" was justly regarded with suspicion, and the alternative faith in "practice," which was essentially a cloak for empiricism, was held up as the only safe mode of procedure; and while the age of empiricism is not by any means wholly passed, we have fully entered upon the more virile stage of scientific rationalism.

The demand is everywhere made for scientific investigation of the problems of dentistry in order that we may arrive at a basis of truth in relation to them. Hence it is that this general demand for scientific accuracy in connection with the principles and practice of dentistry has exerted its compelling influence upon the sources of dental education, with the result that the older methods are obsolete and dental educational methods are being revolutionized in response to the new and general demand for a broader scientific curriculum for the dental practitioner.

When, after what threatened at one time to be interminable litigation, the residue of the estate of the late Dr. Thomas W. Evans of Paris became available for the furtherance of dental educational ends, it was found that the amount practically available for the purpose was inadequate to fully carry out his intentions, and in order that the dental profession might secure to the fullest extent possible the benefits in an educational way which it was the expressed purpose and intent of Dr. Evans that the dental profession should receive from his benefaction, a co-operative affiliation was arranged and agreed upon between the trustees of

the Evans estate and the trustees of the University of Pennsylvania whereby the resources of both institutions might be practically utilized for the common purpose which both corporations had in view. As an outgrowth of the affiliated activities of the two corporations the educational institution known as The Thomas W. Evans Museum and Dental Institute has been erected at Fortieth and Spruce sts., Philadelphia, in which ample provision has been made for the carrying on of three correlated departments of dental education. First, an undergraduate school for the training of dental students in preparation for the degree of Doctor of Dental Surgery; second, a department of postgraduate instruction equipped for the advanced training of qualified dental practitioners in subjects relating to dentistry upon an elective basis; and third, provision for original scientific investigation open to those fitted to engage in research work under the guidance of competent teachers and with the facilities of the Institute at their disposal.

The building and its equipment represent a pecuniary outlay approximating nine hundred thousand dollars. Its installation has been designed and selected with reference to the scope and character of the educational plan, which embraces in general every recognized phase of dental activity, but the material features of the Institute are the outgrowth of and dependent upon the *motif* or principle which is the foundation of its educational plan, viz. that its educational work shall be conducted in harmony with the scientific spirit—that not only its research work, but its undergraduate instruction, shall be rational and not empirical.

On the 22d of February the Evans Institute was formally dedicated to its educational purposes. The trustees, officers of instruction, delegates, invited guests, and students formed in academic procession and proceeded to the Institute building and to the clinical operating room, in which the fifteen hundred persons constituting the audience were seated. After an invocation by the Rev. Joseph Wilson Cochran, and the singing of the National anthem by the audience, the president of the Thomas W. Evans Museum and Institute Society, Hon. John Weaver, made a brief opening address, and then introduced in succession Mr. John Howard Mummery of London, Eng., Prof. Wm. Simon of the Baltimore College of Dental Surgery, and Dr. Edward C. Kirk of the University of Pennsylvania, each of whom delivered an address. Mr. John T. Windrim, architect of the Institute, then

formally presented the key of the Institute to President John Weaver, who accepted the key on behalf of the Thomas W. Evans Museum and Institute Society, and then presented the key to Dr. Edgar F. Smith, Provost of the University of Pennsylvania, who accepted the key on behalf of the University; after which the following were called upon to receive academic honors at the hands of the Provost of the University on behalf of its board of trustees:

Mr. John T. Windrim, architect of the Evans Institute, to receive the degree of Master of Science in Architecture.

William Simon, Truman William Brophy, Edward Hartley Angle, Eugene Solomon Talbot, John Howard Mummery, Edouard Charles Godon, Wilhelm Dieck, Greene Vardiman Black, for the honorary degree of Doctor of Science.

Edwin Tyler Darby, Edward Cameron Kirk, for the honorary degree of Doctor of Laws.

It had been hoped and expected that both Prof. Dr. Wilhelm Dieck of the Dental Institute of the University of Berlin and Dr. Charles Godon of l'École Dentaire de Paris would have been able to be present and to receive their degrees in person, but owing to the exigencies arising out of the European war, neither was able to be absent from his post of duty. The degrees in these cases, as well as in the case of Dr. G. V. Black, who was unable to be present on account of ill health, were conferred *in absentia*.

After the singing of "Hail Pennsylvania!" by the audience, the benediction was pronounced by the Rev. Joseph Wilson Cochran, and an inspection of the new building was made. The day following the formal dedication a demonstration of the activities of the Institute and its clinical facilities was given; sixty-three clinical demonstrations were made in the large clinical operating room of the Institute. The dedicatory exercises closed with a banquet under the auspices of the Dental Alumni Society, held in the old Dental Hall of the University, which had been the home of the dental school for eighteen years.

The dedication of the Evans Institute is not to be considered merely as the inauguration of a new dental school, or the rehabilitation of an old one. It is in a very large sense to be understood as the launching of a new educational enterprise. It is the expression of an earnest effort not only to reflect in a practical way the intent and purposes of its benefactor and an educational demand of modern dentistry, but also to provide for its future

development upon a broad scientific basis. As an indication of the growing importance and the breadth of relationship which dentistry now enjoys, the Evans Institute must be regarded as the expression of one of those forward steps which in the domain of dental education is the analog of that splendid example of the relationship of dentistry to public health service embodied in the materialization of the benefaction of the brothers Forsyth in the Forsyth Dental Infirmary for Children in Boston.

Legitimate Practice and the Harrison Anti-Narcotic Law.

We are officially advised that the Commissioner of Internal Revenue has ruled that the term "legitimate practice of his profession," as used in the Harrison Anti-Narcotic Law, requires that a physician, dentist, or veterinary surgeon in order to register under the provisions of this law must have complied with all of the laws of the state in which such physician, dentist, or veterinary surgeon resides.

WILL EMETIN CURE PSORIASIS? Editorial.

IRRITATION FROM EMETIN. By Dr. E. F. Bowers, New York City.

Evans and Middleton preface their article with a careful summary of the various steps which have led to the discovery of endamœba buccalis as the specific exciter and emetin hydrochlorid as the specific drug for the treatment of pyorrhea alveolaris, noting with most highly commendable accuracy the publications whence their information is derived

—which, unfortunately, is not a general habit of dental writers. Among the accessories to and refinements of emetin administration enumerated by them, those which have not been mentioned in these columns are the use of air pressure to separate the gums from the tooth, suggested by Dr. S. H. Chase; the use of blunt-pointed needles indicated by Dr. Kent Wood; and the replacement of the hypodermic needle by a dental file suggested by Dr. E. J. Hart—the hanging drop of emetin solution adapting itself by capillarity to the smallest pockets, where no needle could be introduced.

The present study constitues a brief preliminary report of a series of cases under observation in the University of Wisconsin medical clinic. In all, seventy-two oral cases have been examined by the usual method—heated stage, warm slide, and cover-slip, the material scraped from the depth of the pocket being immediately mixed with warm normal salt solution and mounted. Seventy cases showed endamœbæ ranging in size from 8 to 32 microns in diameter, filled with granular material, but no contractile vacuoles; the pseudopodia varied widely in size, length, and activity; the ectoplasm was decidedly hyaline, and only after an interval was there an outpouring of the granular endoplasm into the newly formed hyaline pseudopod. These amœbæ fall under the heading of *endamœba gingivalis* of Gros (1849). The type of *endamœba kartulisi* of Doeflein (1901) was associated with the endamœba gingivalis in two cases. An unclassified amœba was noted in two cases of pernicious anemia along with the type gingivalis. The two negative cases showed considerable gum retraction with dentinal erosion.

Evans and Middleton attach considerable importance to the mechanical interference by metallic fillings, crowns, or plate attachments with the normal adaptation between the cementum and the circular ligament; these appliances, if constructed faultily, are a frequent source of pyorrhea, as every dentist knows, or should know. Of the seventy pyorrhea cases with amœbæ present, fifty-four were treated by the local injection of 0.5 per cent. emetin hydrochlorid solution. The results were practically uniform in the marked improvement of the pyorrhea. The period of treatment varied from four to twelve days, with an average of about seven. In a few instances the patients complained of tender gums, but the great majority remarked early in the course of the treatment on the new experience of an ability to brush their teeth without the pain or the bleeding noted prior to the treatment. After an interval of from several days to a week following the last treatment, which corresponds to an apparent local cure, a re-examination for amœbæ was made. Even though the second examination was negative, as a precautionary measure a subcutaneous course of emetin was instituted. Two plans of dosage were followed: A series of small doses, 1/8 grain daily doses of the hydrochlorid for eight days, or a shorter series of larger doses, ½ grain repeated with a day intervening, followed by ¼ grain on two successive days. The reason for this supplementary treatment has been to insure the death of any endamœbæ penetrating the deeper tissues of the gums, and therefore possibly unscathed by the local injections. Another rational procedure would be periodic subcutaneous injections, at monthly intervals, for a period of several months, to prevent the multiplication of encysted amœbæ which resist the biochemical amœbicidal action of ipecac. Only five cases have been treated by these writers with subcutaneous injections alone. The results in these have been entirely satisfactory, but with ambulatory cases they have not felt justified in using the rather large doses suggested by Bass and Johns. In regard to local reaction on the subcutaneous injection of emetin hydrochlorid, in some cases a wide indurated areola of inflammation about the point of injection has been noted following the third or fourth dose of only ¼ grain, sometimes attended by a temporary exacerbation of the general symptoms, usually followed by a marked improvement. This reaction they consider as an index of a point of saturation, when, with the death of numerous amœbæ, the strength of emetin in the blood having reached a lethal point, a great amount of bacterial and possibly amœbic toxin is liberated.

In regard to the exact method of action of either toxin, we may assume the selective action of the specific toxins to determine the system or the structure involved. The liver is to a great degree responsible for the disposal, breaking up, or removal of toxins arising within the body. It is therefore barely possible that certain of the systemic dis-

orders may arise from a disturbance of the normal metabolic function of the liver. As to hemic complications, the degrees of secondary anemia noted by these writers might readily arise from a bacterial hemolytic toxin, but their observations on the active lysis of engulfed red corpuscles in numerous instances lead them to the belief that the endamœbæ, either through an intracellular or extracellular hemolytic toxin, or both, may be even a more important factor.

In conclusion, they would impress the facts that constitutional disturbances are very frequent complications of endamœbic pyorrhea; that arthritis, particularly of the type of arthritis deformans, is the most frequent complicating disorder, and that the results from the local and general administration of emetin hydrochlorid in the relief of the pyorrhea and the marked improvement of the arthritic condition are very encouraging in a large percentage of cases. In addition, unexpected relations between pyorrhea and certain remote conditions are established through the response to the emetin treatment.

Bass and Johns, following up their inaugural article on "The Cause and Cure of Pyorrhea Alveolaris" (see review in DENTAL COSMOS, February 1915, p. 223) present a very extensive paper on the technique of obtaining the material for microscopic examination, the method of staining the slides and identifying the endamœbæ in pyorrhea dentalis and alveolaris, and give a description of the disease and the manner in which it is produced, and their manner of treatment, at the same time offering a liberal number of beautiful photomicrographs which are by far the best that have as yet been published in this connection. The summary of their findings is that pyorrhea dentalis and alveolaris is practically a universal disease, which leads to the loss of the teeth by a long suppurating process. All people have it sooner or later. It begins in early adult life or earlier. The specific cause of the disease is endamœba buccalis and possibly other species, which infect and destroy the peridental membrane. The pyorrhea results largely from the secondary infection. The demonstrable endamœbæ can be destroyed by giving ½ grain of emetin hydrochlorid hypodermically for three to six successive days. Apparently equal endamœbicidal effect is produced by two or three Alcresta ipecac tablets (Lilly) taken by the mouth three times a day for four to six successive days. The lesions require variable lengths of time to heal, but many could not reasonably be expected to heal in less than several weeks or months. The treatment must be repeated from time to time until the lesions all heal, on account of relapse, or probable reinfection of the lesions as a result of the great prevalence of the infection. Injecting ipecac or emetin into the worst lesions ought to be of service and can be carried out by patients in many instances. Rinsing the mouth thoroughly with a solution of fluid extract of ipecac is believed to protect, to some extent, against reinfection, and actually cures the disease in its earliest stage in some instances.

In the same number, the *Journal* editorially comments on the recent articles by Barrett, Smith, Bass and Johns, Evans, Middleton, and others, and emphasizes the need of cooperation between the physician and dentist and better knowledge by each of the field of the other, saying that the dentist has not usually been trained to recognize or appreciate the danger of these chronic suppurations to the general health, and the physician, including perhaps the bacteriologist, has not made a sufficiently close study of the tissues involved in these suppurations to enable him to draw proper conclusions, especially with reference to the complete cure of such cases, under the most favorable treatment imaginable. After discussing the nature of the dental and adjacent tissues, their structure and functions, and their mode of involvement by pyorrhea alveolaris, the *Journal* remarks that, on account of these conditions, the word "cure" should be used with caution. Evidently some of those who have been studying these cases have considered them cured when no more endamœbæ were demonstrable, apparently without considering the tissue changes and conditions which would prevent the closure of the pocket. A case should not be considered cured while there remains the constant irritant—the denuded cementum—which maintains the harbor for a reinfection. This fact seems already partially recognized in the above report of Bass and Johns, as they state that reinfection has occurred in about 12 per cent. of cases within four weeks.

It is also stated that a previous injury or inflammation seems necessary "to furnish a kind of pocket" in order to provide a nidus

for the endamœbæ, and that they are not known to live on open surfaces. These statements should impress on both dentist and physician the possibilities of greater watchfulness of the gingivæ, and more careful management of operative procedures to prevent the injury which prepares the pocket for the endamœbæ. The pus pocket is always preceded by a gingivitis which may be so insidious as scarcely to attract the patient's attention. Most cases may be cured by very simple procedures, if undertaken previous to the detachment of the tissue from the root.

Ricker uses emetin hydrochlorid, hypodermically, injecting into the subcutaneous cellular tissue ½ grain daily for three successive days, then every fourth day until the gums are entirely healed and the teeth tight. He also employs emetin locally to the pockets and walls of the pockets by means of a syringe, using a ½ per cent. solution. Oral hygiene by the patient is insisted on, the mouth to be washed after every meal with a good antiseptic wash, followed by a few drops of fluid extract of ipecac, applied to the gums and teeth by means of the tooth-brush. Instrumentation is absolutely necessary, consisting in scaling of tartar, removal of ill-fitting bridges and crowns, and the polishing of projecting fillings, before starting the emetin treatment. He reports a great saving of time and apparently permanent cures.

Kells insists that the dentist must learn to recognize amœbæ, if necessary, by taking lessons from a bacteriologist; else slides must be made and sent to a laboratory for diagnosis. He prefers Bass' method of injecting emetin hydrochlorid hypodermatically in the arm, and emphasizes the necessity of sterility of the syringe, solution, and field of injection. His method of treatment is as follows: If, upon examination of the mouth, pyorrhea is either suspected or recognized, a microscopic examination is determined upon. A note is made from around which teeth the scrapings are to be taken, and a microscopic glass slide is prepared accordingly, the symbols of the teeth from which scrapings are to be taken being etched on the slide with a small pointed carborundum stone, so that they are indelible. The positive or negative result of the microscopic examination of the slide is also marked thereon by the same means with plus or minus symbols, and the slide is preserved for the sake of record.

Scrapings are taken from the pockets, recorded, and smeared very thinly opposite their respective symbols. These scrapings should be taken from the bottoms of the pockets, and should be as free from blood as possible. Sometimes a toothpick properly trimmed, at other times Younger scalers, are used for this purpose. The patient's name and the number of the slide are then recorded on a sheet prepared for the purpose, and kept in a loose-leaf daybook.

An immediate examination of the slide may be made for the live amœbæ, but as time may usually be much better employed than in such search while the patient is in the chair, the slide is immediately properly heated to fix the specimens. At convenience the slide is stained and a microscopic examination is made, the result being recorded in the book. If the examination proves negative, assuming that it might be through error in technique, at the next sitting a duplicate is made. Every effort must be made to recognize positively the amœbæ. If the case is a bad one, one half-grain emetin hydrochlorid in 1 cc. of distilled water is injected in the left arm near the shoulder, for three successive days. Unless the solution is freshly made, and therefore warm, the syringe should be heated by being well rinsed with boiling distilled water, which will in turn warm the emetin to the proper temperature for injecting. Only fresh solutions should be used, which are readily made by dissolving one tablet in 1 cc. of distilled water at the time of use, or, if well taken care of, sufficient solution for three days can be prepared at once. In some cases, slight soreness of the arm follows the injection.

If the disease is limited apparently to one or two teeth only, instead of giving the hypodermic of emetin, one bottle of forty tablets of ipecac, which does not dissolve in the stomach, is prescribed, three to be taken twice daily after meals. The patient is instructed to put two drops of fluid extract of ipecac in a small quantity of water and to rinse the mouth most thoroughly immediately before retiring, after the teeth have been properly brushed and cared for. After the lapse of about one month a second microscopic examination is made. If amœbæ are found, a second series of emetin is injected. Kells fittingly points out that "This treatment will not bring the dead to life,"

but that it justifies the hope that, if used in time, it will prevent the ravages of the disease.

Harrison, in *Oral Health*, confirms the findings and technique of the previously mentioned writers, and makes a plea for accurate case histories in co-operation with the research work in this field so far accomplished. He is personally making blood and urine examinations in his cases, with the hope of establishing valuable data. In the examination of cases he condemns pressing of the soft tissue over the pyorrheal pockets.

In its March issue, the *American Journal of Clinical Medicine* gives what practically amounts to a symposium on emetin in various fields of application, as in bronchitis and tuberculosis, in controlling hemorrhage following naso-pharyngeal operations and gunshot wounds of the chest, in pellagra, and in dysentery. A most meritorious investigation is that of Nielsen on the physiologic action of emetin hydrochlorid, illustrated by excellent tracings. His conclusions are that the hemostatic action of emetin hydrochlorid in therapeutic doses is a consequence of its vaso-constrictor properties, confined to the capillary circulatory system, in conjunction with a decrease of the rate of the heartbeat produced at the same time. Apparently it does not influence either the physical composition or the coagulability of the blood. In toxic doses it causes increased salivation, nausea, vomiting, slowing of pulse, decrease of temperature, and muscular weakness. In lethal doses it produces central paralysis and arrests the heart in diastole. The vomiting produced by toxic doses is due to local irritation of the gastric mucous membrane. The results obtained with pregnant and non-pregnant uteri in guinea-pigs seem to indicate that the action of emetin hydrochlorid in this organ is not of therapeutic importance.

Commenting on Dr. Wm. R. Chapin's experience of a cure of psoriasis following emetin treatment of pyorrhea alveolaris, published in February Cosmos 1915, p. 189, *Clinical Medicine* says that psoriasis may prove to be a disease of amœbic origin, and research workers should be encouraged to study this disease anew with this thought in mind. Probably the best results could be secured by injecting emetin hydrochlorid hypodermically in ½ to 1 grain doses. Since psoriasis is one of the most common of all skin diseases, there should be no lack of clinical material.

To avoid irritation from hypodermic injections of emetin, Bowers suggests injecting first into one arm, then into the other, alternately. To avoid the occasionally quite severe reaction following the introduction of emetin into pyorrhea pockets, *Clinical Medicine* advises the use of very weak solutions initially, to be carried not too deeply into the surrounding inflamed tissue. In the beginning of treatment a blunt-pointed hypodermic needle should be employed and the pocket simply be flooded with the solution, no effort being made to penetrate the tissues.

The wealth of material which is being offered in current dental and medical literature in regard to emetin hydrochlorid, which bids fair to assume the nature almost of a panacea, is surely gratifying, and it is to be hoped that the sanguine expectations attaching thereto will not be disappointed.

[*La Revue de Stomatologie*, Paris, April 1914.]

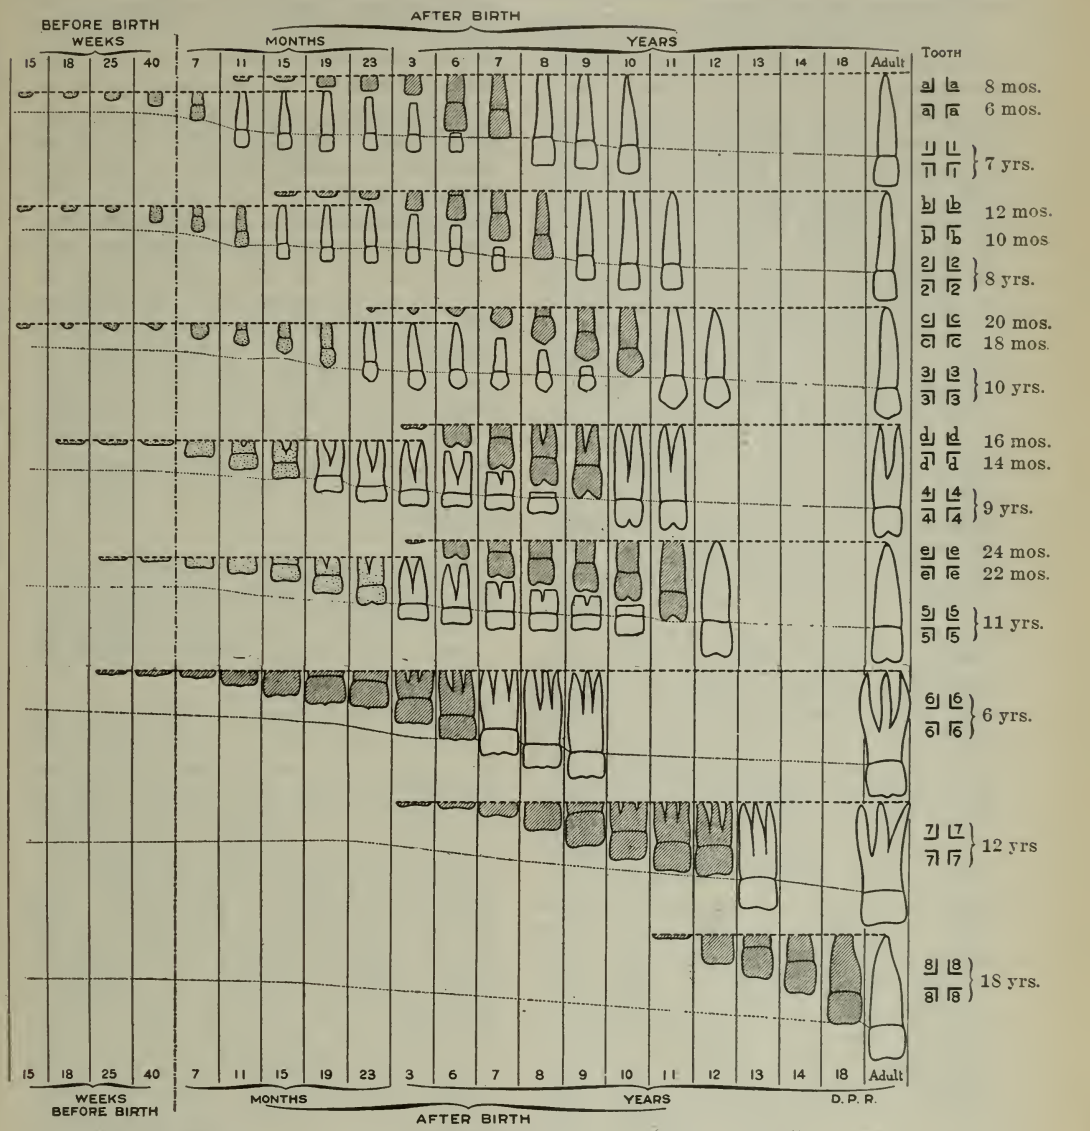
CHRONOLOGICAL TABLE OF THE DEVELOPMENT OF THE DECIDUOUS AND PERMANENT TEETH. By Dr. Pierre Robin.

Since Dr. C. N. Peirce published in the Dental Cosmos for August 1884 his table on "Calcification and Decalcification of the Teeth," which has since made the rounds of dental text-books, no effort has been made, as far as we know, to present in a convenient diagram the different phases of development, eruption, and absorption of the deciduous and the permanent teeth. Such a table permits of information at a glance during clinical examination, and Dr. Robin's diagram therefore is of great value.

The table is divided into two zones by a vertical line of dots and dashes—the zone on the left of this line corresponding to the period before birth, the zone on the right of it to the period after birth. Each of these zones is itself divided by continuous vertical lines which represent the periods in which the observations were made. Before birth, the time is reckoned in weeks, after birth up to the twenty-third month, in months, and after three years, in years.

In each horizontal field are represented all

Dates of Eruption of the Deciduous and Permanent Dentitions. (*By Dr. Pierre Robin.*)



The follicular period of deciduous teeth shown by dotted area; that of permanent teeth by lined area.

Average period of eruption of teeth {
- Deciduous teeth (in pairs) every two months, starting at six months.
- Successional permanent teeth, every year, starting at seven years.
- Remaining permanent teeth, every six years, starting at the sixth year.

Remarks.

(1) The development of the teeth is regular and continuous.
(2) In development, the tooth does not force its root into the jaw.
(3) The papilla, from which the tooth develops, remains fixed, as a centre, around which the tooth grows in length and the jaw in size.
(4) The dates in the table are the mean of those at which the upper and lower teeth erupt.
(5) In each jaw, teeth of the same name are symmetrically arranged on the right and left sides, and usually erupt simultaneously.
(6) The eruption of the temporary teeth in the lower jaw precedes, as a general rule, that of the corresponding upper teeth by two months.

the stages of evolution of a deciduous tooth and its permanent successor.

The intra-follicular period of development of each tooth is represented diagrammatically in stippling for the deciduous teeth, and in cross-line shading for the permanent teeth. This phase of the development is placed above the dotted line which represents the gingival margin. The follicular period ceases when the tooth perforates its follicle and makes its appearance at the gum margin, represented by the dotted line. As soon as this takes place, the development is extra-follicular, and the teeth are now represented in plain-line diagrams. When the neck of the tooth reaches the gum margin, its eruption is complete.

The extremity of the root occupies during the development of the tooth the base of the dental papilla, and the development of the roots is usually followed by that of the alveolar process and jaws, as the eruption of the deciduous and permanent teeth takes place. This explains the apparent contradiction of the forcing of the root into the body of the jaw. The dental papilla must be considered as a center. These papillary centers constitute a line around which the jaws develop in an eccentric manner. The gingival edge, therefore, diverges progressively until adult age from these papillary centers, which in the table are represented by the line of dashes. This explains why the gingival border —dotted line—describes a curve which diverges from the papillary centers in the permanent as well as in the deciduous dentitions, from the beginning of calcification of the enamel organ until adult age. This curve, co-ordinating the age and the length of the root, indicates in a very exact manner the increase in the size of the jaw. This growth takes place in every direction around the papillary centers, in the bucco-lingual, mesio-distal, and vertical planes. In this latter direction it is chiefly the lengthening of the alveolar process which contributes to the increasing distance between the gingival margin and the papillary centers—a phenomenon which is particularly well shown in the table.

At a glance, the beginning of calcification of each follicle, and the advance in development of the tooth is very easily seen for any age, and the absorption of the deciduous teeth and the development of the permanent ones is equally easily calculated. The location of any hypoplasia observed on deciduous or permanent teeth enables one to determine the age at which these lesions arose. By questioning the patient or parents it can be ascertained whether such hypoplasia was contemporaneous with any other phenomena which may have played a part in producing the tissue lesions.

Early extraction of deciduous teeth may often be deferred when the prospective date of their loss can be fixed. The operator appreciates that by taking care of the deciduous teeth the child will profit by their prolonged masticatory function. All caries which appears in a deciduous tooth more than two months before it should be lost normally, must be treated, such treatment preventing pain, abscess, indigestion, gastro-intestinal intoxication, and maxillary and facial deformities.

[*La Stomatologia*, Milan, April 8, 1914.]

THE EFFECTS OF STIMULATION OF THE DENTAL PULP UPON RESPIRATION AND CIRCULATION. By Prof. Dr. A. Arlotta.

Arlotta demonstrates the results of his interesting experiments concerning the effects of thermal and electric stimulation of the pulp and the dental nerves upon circulation and respiration by a series of record charts, which lead to the following conclusions:

Electric or thermal (cold) stimulation of the dental pulp produces a reflex action upon respiration, consisting in a diminution of the rate of respiration. The expiratory phase is notably prolonged, confirming the influence of stimulation of the trifacial nerve upon expiration. In the majority of cases no reflex action of pulp stimulation upon the cardio-vascular system is noted. Stimulation of the mental nerve trunk produces the same marked effects upon circulation and respiration as stimulation of the central root of any other sensory nerve trunk.

While these findings are important from a scientific point of view, the writer does not claim any practical value for them to the extent that pulp treatment in patients with pathological alterations in their circulatory or respiratory system is contra-indicated, especially if the infliction of pain in the pulp is eliminated by suitable means.

RÉSUMÉS OF PAPERS PRESENTED AT THE SIXTH INTERNATIONAL DENTAL CONGRESS,

London, Eng., August 3, 1914.

THE BEARING OF A THEORY OF MAXIMUM SHEAR ON THE MECHANISM OF MASTICATION IN MAN. By D. M. Shaw, London, Eng.

Tooth forms and jaw movements are found to be dominantly adapted for *shearing*—not compression—stresses, contrary to views expressed in current text-books on anatomy and occlusion. (See *Dental Record*, vol. xxix, p. 453, and vol. xxxii, p. 613.)

Overlap and sharpness, which make shearing obvious in incisors, are both present also in buccal teeth. Internal cusps are needed to help the tongue in holding food in position for finer reduction. Degree of reduction plus nature of food are the governing conditions in mechanism "design."

A working diagram was shown of normal chewing stroke or cycle; the position of maximum shear coincides with maximum food-strain.

Following cusp wear, jaw movements are always definitely modified to secure the optimum shear available.

In phylogeny, the lingual cusp evolves by acquiring progressively three different utilities: (1) Small surface modification shielding the gum by deflecting hard food; (2) its development to food-holding—tongue-assisting—prominence; (3) further elevation to shearing and "crushing" utility, the "fifth" cusp in the lower first molar being an example.

The importance of optimum sharpness is illustrated by the discovery of the tongue-shielding "umbicle."

Section II.—*Dental Pathology and Bacteriology.*

PATHOLOGY AS INFLUENCED BY THE STUDY OF MALOCCLUSION OF THE TEETH. By Dr. Henry C. Ferris, New York, N. Y.

The writer maintains that the physician's attitude toward the physiological and pathological influence of the oral cavity is inconsistent and untenable.

He reports a physiological experiment upon a sixteen-year-old normal subject to show the reflex action through function upon the enzymic index, and notes a difference occurring between the molars and premolars.

There are three premises upon which the effects of malocclusion may be based: (1) Malocclusion due to congenital or hereditary tendencies; (2) malocclusion when the child is born normal, and the developmental forces are interfered with after birth—infectious diseases, traumatic injury, etc.; (3) malocclusion due to loss of function of the organ owing to environment, dietetic habit, or mutilation of the arches by extraction. The latter class being considered as a primary factor in disease.

The effects of different classes of malocclusion upon the system are considered, as follows: Circulatory system; respiratory system; digestive system; urinary organs; nervous system.

Repressive tissue changes involve the circulation of the blood, atrophy, degeneration, and necrosis.

Progressive tissue changes involve restoration of bone.

He discusses types of inflammation, plant parasites — bacteria micro-organisms — infectious diseases, malformations, and lesions.

He presents illustrations from practice—two cases, with slides, one of corrected acidosis, one of corrected chronic constipation—with quantitative physiological records, verified by a pathological laboratory medical and dental attendant.

Section III.—*Dental Surgery and Therapeutics.*

AN IDEAL CEMENT FOR STOPPING ROOT-CANALS. By Dr. Vincenzo Guerini, Naples, Italy.

An ideal cement for filling the root-canals can only be obtained by a method which permits of hermetically sealing the apical

foramen without leaving compressed air in the canal, and which is carried out with a substance not only antiseptic, but also free from irritating properties, so as to avoid the possibility of an apical periodontitis or even of an alveolar abscess.

The essayist's cement perfectly fulfils all these requirements. The paste made with it can be shaped in small, conical pinlike sticks, by rolling it between the finger and a suitable plate. One takes these small sticks with converging forceps or other suitable instrument and introduces them into the root-canal, reaching and filling the apical foramen and then compressing the cement in the canal cavity. In from ten to twelve minutes the cement is hardened, and one can proceed to fill the cavity at the same sitting. By the proper use of this cement no failures occur, and even in the cases where a previous apical periodontitis exists, this becomes cured.

ORAL SEPSIS—THE GENERAL EFFECTS UPON THE SYSTEM WHICH MAY BE ATTRIBUTED TO TOXEMIA OF ORAL ORIGIN. By Sir Rickman J. Godlee, Bart., Past President of the Royal College of Surgeons of England.

This report refers to the short time that has elapsed since the attention of the profession was directed to the question of the general effects on the system that may follow on the existence of oral sepsis. The essayist suggests that some caution is necessary in drawing deductions, and that there is a danger of mistaking mere coincidence for causation. Reference is made to the necessity for removing all sources of oral sepsis in certain conditions requiring surgical operation, and to the advisability of doing so in every case that comes under the care of the surgeon. An enumeration is made of the various diseases which have been supposed by different observers to have been caused by oral sepsis, and the verdict of the profession on this matter is very briefly discussed.

Section V.—*Dental Prosthesis.*

DETACHABLE GUM FACINGS. By Ernest Fogg, Newcastle-on-Tyne, Eng.

This paper is a description of a continuous-gum facing made detachable, and not subjected to heating, soldering, pressure in packing, or vulcanization. Continuous-gum work and its drawbacks, and gum blocks and their disadvantages, are discussed. Hitherto it has been impossible to obtain from the manufacturer anything in the nature of a continuous gum extending all around the mouth.

The method suggested is a detachable gum facing which is removed from the case just before the investing for soldering, or before the flasking for vulcanizing, afterward being replaced and cemented in position or otherwise held, and in connection with detachable teeth can be employed all around the mouth.

In practice the metal, wax, or other plate forming the foundation of the denture is first placed in position.

A gum facing of suitable size, shape, and color, is then selected and slightly oiled, and into the recesses therein detachable double-headed pins are fitted and the gum blocks are adjusted to the foundation, thus forming the gum line with the pins in position. Teeth of suitable stock, size, shape, and color are now adjusted at the required angle in the sockets provided in the gum facings, and both the blocks, pins, and teeth temporarily fixed in position by wax or suitable material.

The gum blocks are now removed, leaving the pins embedded in the wax and the teeth in position on the model, or, if detachable teeth are used, their supports.

The work is now ready for flasking, casting, soldering, or other treatment. The plaster is carefully manipulated around the exposed parts of the pins and the bed of wax or metal which is to form the bed for the gum blocks, and if the teeth are to be received in the first part of the flask, around and over the teeth. The plaster is then greased in the usual way, and the second half of the flask run in.

The parts of the flask are now separated and the wax or other material boiled out, and the work packed and vulcanized, or, if the work is to be soldered, plaster investments are employed in the customary way, the work is removed from the flask or investment, trimmed up, and polished.

The gum blocks are now placed in position upon the half portions of the pins which project from the vulcanite or other material employed, being received in the recesses in the backs of the gum blocks. The gum blocks rest around the necks of the teeth, and are

retained there by suitable cement or other medium, screws, etc.

The gum blocks are formed to go between, and to receive one, two, or any desired number of teeth.

Section VI.—*Orthodontics.*

THE INFLUENCE OF INTERNAL SECRETIONS IN REGULATING THE GROWTH OF THE JAWS. By Arthur Keith, M.D., Conservator of the Museum and Hunterian Professor, Royal College of Surgeons of England.

The essayist gave, in the first place, an epidiascopic demonstration of the changes which affect the masticatory system in acromegaly, founded on a study of six cases. The skulls of these were shown. He tends to prove that all of the changes in acromegaly are due to a reawakening of growth processes which normally cease at the end of adolescence. To explain the phenomena of acromegaly it is necessary to suppose that the anterior part of the pituitary body can exercise a direct influence on the growth of the skeleton. It must also be supposed that this influence is operative during normal growth, as well as in abnormal growth, and that through an internal secretion or hormone, the pituitary can sensitize the osteoblasts of the jaws, and thus can regulate the growth of these parts.

In support of this thesis, the reporter exhibited the skeleton of a boy of eighteen years, showing the condition which Mr. Hastings Gilford has named progeria. The condition is the opposite of acromegaly. Those parts of the skeleton which in acromegaly are overgrown are here markedly undeveloped. This is particularly true of the jaws and apparatus of mastication. The condition of the pituitary in progeria is unknown, but it is clear that, if we explain acromegaly as due to the condition of hyperpituitarism, we must regard progeria as due to one of hypopituitarism.

The essayist drew attention to the growth changes to be seen in the facial development of cretins and cretinoid cases of achondroplasia. These changes affect bones which are developed in cartilage or in membrane overlying cartilage. The only explanation which can be offered by the facial and other skeletal changes in cretinoid cases is that they are due to a defective action or secretion of the thyroid gland. The facial changes which result from defects of the thyroid are totally different from those ascribed to a defective action of the pituitary.

The essayist showed a case in which the hypertrophy is confined to the maxillæ, teeth, and apparatus of mastication of the right half of the head, the parts of the left side being normal. Such cases must modify our explanation of cases of generalized hypertrophy, such as acromegaly. In cases where all the tissues and parts of the body undergo an abnormal growth, we are tempted to suppose that some hormone or internal secretion, which normally stimulates growing tissues, is thrown into the circulation to an excessive amount. Such an explanation breaks down when applied to cases of local hypertrophy. We have to fall back on a more complicated explanation—one which supposes that growth and hypertrophy are due to the interaction of at least two factors. Dr. T. R. Elliott found that adrenalin, in causing a tonic contraction of the non-striated musculature, acted neither on the nerve fibers nor on the muscle fibers, but on a substance or element interposed between them. Adrenalin is an internal secretion or hormone, and it is legitimate to infer that the hormones which stimulate or regulate growth may act not directly on the tissues but on an element interposed between nerve terminals and the growing cells. Hypertrophy might be due to a change either in the hormone or in the "interposed" element. In localized cases the hypertrophy is evidently due to a change in the interposed element; in generalized cases, to a change in kind or in amount of the internal secretion. The occurrence of localized cases thus does not invalidate the explanation offered for acromegaly, viz, that it results from a condition of hyperpituitarism.

Castration has a direct effect on the development of the skeleton, including the jaws and apparatus of mastication. Removal of the testes causes a structural change in the pituitary, and it may be through the pituitary that the testicles react on development. Cases of defective growth of the maxillæ in eunuchoid individuals have been recorded.

No experimental proof is brought forward of the thesis maintained by the reporter that the growth of the palate, mandible, face, and apparatus of mastication is regulated by internal secretions. It is manifestly very diffi-

cult to design or carry out experiments which will effect a slight increase or decrease in the normal action of one of the glands of internal secretion. On the other hand, diseases of the pituitary or the thyroid do occur, and when they are studied they afford evidence that they exercise a direct influence in the development and growth of the bones.

Further, the essayist is of opinion that an explanation of the kind put forward is needed to account for the phenomena of normal maxillary growth and tooth eruption. For the proper and orderly eruption of the teeth it is necessary that the development and growth of the lower and upper jaws be accurately co-ordinated. In each there is an army of osteoblasts; it is patent that the armies must work in harmony to get effective results. To get that harmony we must postulate a co-ordinating mechanism, such as that put forward in this paper.

THE ANATOMICAL PRINCIPLES OF THE ORTHOPÆDIC ARRANGEMENTS OF THE JAWS ACCORDING TO PERSONAL INVESTIGATION. By Schroeder-Benseler, Cassel, Germany.

The orthopedic arrangements of the jaws as regards their scientific consideration and classification, from the standpoint of etiology and treatment, should be treated separately from orthodontics.

To discover the causes and consequences of irregularities of the jaws and teeth it will be absolutely necessary to observe a great many skulls, and also to examine clinical cases.

The foundation of all this investigation is the normal occlusion. It is necessary to question the normal bite and the value of the measurements of the breadth and height of the upper jaw. The relation of the osseous formation and the architecture of the upper jaw to normal occlusion is of great importance, especially the measurements of the breadth in the interior of the nose. On this basis we are able to arrange the orthopedic treatment of the jaws in order to obtain perfectly unrestrained nasal breathing.

A CRITICISM OF THE NEW SCHOOL OF ORTHODONTICS. By Wm. Rushton, L.D.S.Eng.

Orthodontic practitioners are divided into the "eclectic" school, which adopts any method, surgical, mechanical, or both, in the best interests of the patient, and the "new" school, as contained in Dr. Angle's work "Malocclusion," where the ideal insisted on is a full complement of teeth in normal relations.

The author sets forth the difference between the two schools, showing why, in his opinion, the tenets of the former are preferable to those of the latter.

The new school lays undue stress on malocclusion, and condemns extraction. Their operations are long, tedious, and dangerous to the tissues, and the results are often not so permanent nor so pleasing.

The eclectic school considers how utility and beauty can be secured at least cost of time, inconvenience, and danger. The practitioner may resort to extraction when he considers that rapidity, permanence, and superiority of results justify it. Malocclusion, if slight and not unsightly, is ignored, provided that the bite is functional. Reciprocal traction and artificial substitution of extracted teeth is deprecated.

Section VII.—*Oral Surgery and Surgical Prosthesis.*

CYSTS OF DENTAL ORIGIN. By Dr. L. Widman, Stockholm, Sweden.

The essayist advocates the classification and terminology according to Louis Ombrédanne, who classifies cysts as follows: (1) Adamantine cysts; (2) follicular cysts; (3) paradental or periodontal cysts.

The first two named are developments originating from the tooth follicle, whereas the last named arise from a chronic inflammatory cause.

RESULTS OF THE OPERATIVE TREATMENT OF CLEFT PALATE. By H. Blakeway, M.S., F.R.S.C., London, Eng.

The chief aim of operative treatment is to produce a palate which is functionally perfect for the purpose of speech. In deciding to what extent this ideal is approached three main methods of operation have to be considered: (1) Operations aiming at median suture of the soft parts of the palate, especially Langenbeck's. (2) Lane's operation. (3) Brophy's method.

The results of Langenbeck's operation as performed by expert hands are known. It

is difficult to obtain sufficient information concerning Lane's and Brophy's methods.

The essayist compiles results of each of the three methods, with special reference to (*a*) mortality, (*b*) closure of the cleft, and (*c*) results as regards speech.

MYELOID SARCOMA OF THE JAWS. By Arthur W. W. Baker, M.D., F.R.C.S.I., M.Dent.Sc., Dublin, Ireland.

This communication deals chiefly with the report of a case of commencing myeloid sarcoma of the lower jaw in a young female, who was a patient attending the Dental Hospital of Ireland. The sarcoma completely disappeared without operation after removal of a portion of the growth for histological examination. The patient was seen in consultation by the late Professor Bennett, who agreed with the diagnosis, which was further confirmed by Dr. Earl, a pathologist, who prepared a section from the portion removed from the tumor.

SOME CLINICAL OBSERVATIONS OF REGENERATION OF THE MANDIBLE AFTER CARIES AND NECROSIS. By M. H. Cryer, M.D., D.D.S., Professor of Oral Surgery, University of Pennsylvania, Philadelphia.

There is considerable difference of opinion as to the agencies responsible for regeneration of the bone. The writer inclines to agree with Macewen that the growth of bone does not depend upon the periosteum. The growth of the mandible depends on an interstitial process which varies in different portions of the bone at different periods of life. The regeneration of new bone is brought about through the working of the osteogenic system in the bone remaining.

The writer discusses the causes of loss of mandibular bone by necrosis, and cites interesting cases, the earliest found being those of Percy of Paris in 1791, also others under his own observation. The periosteum is absent in many cases, having been lost by suppuration, but the great majority of them, when properly treated, recover without formation of sequestra. In severe cases sequestra are thrown off, but new bone is formed without loss of the contour of the face. A report is offered of cases in which new bone has been regenerated to fill up gaps or to reunite one segment of bone to another. The essayist gives illustrations, X-ray and others, of cases of varying etiology, such as tuberculosis, phosphorus poisoning, injections, use of hydrogen dioxid, and local septic conditions of the teeth.

Section VIII.—*Anesthesia, General and Local.*

IMPROVEMENTS IN LOCAL ANESTHESIA BY NOVOCAIN-SUPRARENIN. By Richard H. Riethmüller, Ph.D.Univ.Pa., D.D.S., Philadelphia, Pa.

The modified instrumentarium suggested consists of an automatic specimen jar with tightly clamped lid and porcelain stand—to avoid oxidation—which allows for suspension of two syringes and one pair of aluminum tweezers—to avoid disintegration by iodin—in a modified alcohol-glycerin solution; a glass tray with metal inset for resting sterile syringes and preventing accidental dulling and contamination of needles, and with a small covered tray for keeping needles, hubs, wrench and broaches in antiseptic solution; also a bacteria-proof stock flask for Ringer solution. A new safety irido-platinum needle is suggested, constructed on the principle of the Gates-Glidden drill, with weakest part near the hub to facilitate withdrawal of an accidentally broken needle, and adjustable safety ring to prevent disappearance of needle fragment in the tissues. The metal parts of the syringe in contact with the novocain solution should be enameled to avoid decomposition of the solution. Statement of date of manufacture of tablets should be insisted upon, as also tightness of rubber stoppers in tubes. Ampules should be tested in vacuum. The technique of injection should be practiced in green skulls and a dry skull in which the mucous membranes have been reproduced in wax up to the reflection. Colorless iodin solutions (iothion) are advocated for sterilizing the field of injection and the operator's palpating finger. The location of the mandibular foramen in mixed races, such as American, requires further anatomical study. Lancing of the gums before extractions, blood-pressure studies, external mandibular injection in ankylosis and infection, and the draining of the wound after apical root resection, are advocated.

PERISCOPE.

Thymol in the Treatment of Alveolar Abscess.—Thymol dissolved in oil of eucalyptus is very useful in the treatment of blind chronic alveolar abscess.—*La Odontología Colombiana.*

A Good Means for Disengaging Adhering Impressions.—If an impression sticks to the palate, the patient is requested to close the lips and to puff out the cheeks forcibly, which will separate the impression from the palate.—*La Odontología Colombiana.*

Investing Wax Models for Cast Gold Inlays.—Instead of using a fine brush to paint the investment on the wax model, the model is dipped in the investment, which by the use of a chip-blower or the breath is several times blown off. The cast will come out perfectly smooth.—E. W. FELLERS, *Nebr. Dental Journal.*

Controlling Hemorrhage after Extraction.—The method suggested, the efficacy of which the writer vouches for, though it would seem rather heroic, consists in filling the mouth full of common wheat flour, and having the patient close the mouth firmly enough to force the flour into the socket of the bleeding cavity and hold it there till a blood-clot is formed and the bleeding arrested.—W. L. MARCY, *Dental Digest.*

Polishing Celluloid.—Celluloid and kindred substances are best polished by rubbing with twilled muslin interwoven with paper, using as abrasive pumice with water, oil, or soft soap, or tripoli and oil. The smooth surface then is coated with soft soap and fullers' earth applied by the hand and rubbed until the soap disappears, leaving the desired polish. *Techn. Rundschau,* per *Deutsche Zahnärztl. Wochenschr.*

Method of Adjusting a Gold Inlay.—A quick and accurate method of adjusting a gold inlay, especially one of the large compound variety, consists in heating it to a dull red and then cooling it without dropping it into acid. The inlay is then inserted in the cavity with a slight rocking motion. Any prominent point will be indicated by a bright mark on the oxidized gold, indicating the points requiring relief.—*Oral Health.*

Hints on Soldering in Porcelain Work.—Borax must not be allowed to touch the porcelain. The investment is heated on each side and from below until the surfaces to be soldered are sufficiently hot to make the solder flow, at the same time making sure that the porcelain is hotter than the pins, and having perfect union of the parts to be united. If the solder flows to one side more than to the other, increase the heat of the investment on the sluggish side.—S. H. VOYLES, *La Odontología Argentina.*

Fetid Breath and Its Diagnostic Indications.—Of fetid odors, Dr. Hutchinson of London has indicated the following types: (1) Putrefactive type, as in cheese; (2) sulfureted hydrogen type, as in gangrene; (3) garlic type, as from arsenic or bismuth; (4) sweetish type, as in diabetics and beer drinkers; (5) toxic or hepatic types, as in biliousness and dyspepsias. But we can also recognize others, as (6) ammoniacal types, as found in urinary disorders; (7) acid types, as found in rheumatism; (8) aromatic types, as found after use of foods and drugs.

Different degrees of heat and moisture in the breath modify its odor. Odors also vary in intensity and pungency. Other distinctions are made but are difficult of application. In fine, it may be said that some of these substances baffle description, beggar language, and outrage our sensibilities.—T. W. CORWIN, *Items of Interest.*

Root Implantation, Physiological and Mechanical.—The writer's experiments made clear that, whereas metal was retained in the jaw-bone, the bone tissue did not take kindly to it. Roots denuded of peridental membrane were exfoliated. Autogenous and homogenous tooth-roots with peridental membrane upon them were retained. Alien tooth-roots not nursed upon the blood of the individual into whom they were transplanted were lost, except in one instance, where a sheep tooth-root was retained, but only mechanically. Alien grafts—tooth-roots—when nursed upon the blood of the individual into whom they were transplanted were retained. Powdered bone incorporated in vaselin, when introduced into tissue, invites calcarious de-

posits and the formation of new bone. Best of all, the possibility of transplanting alien tissue is no longer in doubt.—H. J. KAUFFER, *Items of Interest.*

The Philosophy of Prevention.—It is necessary in each community to give the widest possible publicity to the campaign for better health through sound teeth. Mothers must be taught how to preserve the teeth of infants; children be trained in the art of the tooth-brush, floss, and antiseptic wash; teachers prepared to impart the lessons of oral hygiene. The school curricula should include oral hygiene. Tooth-brush drills in schools are effective. Dental inspection, an effective system of follow-up to induce parents to have the teeth of their children cared for by the family dentist, the establishment of dental clinics for the free treatment of children whose parents are too poor to pay for private treatment—these are the foundation stones of health and efficient life, so far as oral hygiene is concerned.—E. F. BROWN, *Health News.* (N. Y. State Dep't. of Health.)

Convenient Oxygen.—The administration of gaseous oxygen, for anesthesia or therapeutically, may possibly in the future be facilitated by the provision of means for its ready evolution as wanted, instead of by cumbersome storage. Instead of using strong mechanical containers, chemical constraint can be substituted. Thus a commercial form of fused sodium peroxid called Oxone, with a specific gravity of 2.43, is a substance in which oxygen is held in chemical bonds, but is released by the application of water. A pound of this reagent holds 2.2 cubic feet of gas, or 60 liters of oxygen, at normal pressure and temperature. Thus a pound should furnish enough oxygen for thirty minutes of use. The oxygen evolved is said to be 99 to 100 per cent. pure, the only impurity consisting of a slight vapor caused by the energy of reaction. This is readily absorbed by passing the gas through water.—*British Dental Journal.*

Need of an Anesthetist at Any Operation under Anesthesia.—An inquest was held on Marie J. Van D., aged sixty-four, a Belgian refugee, who collapsed after extraction of two teeth under gas at the Southwestern Dental Dispensary. A qualified dentist and a female nurse were present at the time. The pathologist stated that death was due to the bursting of an aneurism of the brain. The fact that the woman had been given gas might have accelerated the rupture, but, on the other hand, it was an accident that might have happened at any time. That was the third case of rupture of an aneurism the pathologist had reported upon in the last ten days, and he stated that there were often no symptoms to be seen at all. No doctor could have told that this woman had one, and once it was ruptured, nothing could be done. In reply to the coroner, the patnologist said that he deprecated the practice of one man giving nitrous oxid and operating. In no other operation would one man do both. We cannot but feel sympathy for the dentist under his trying experience.—*Brit. Journ. of Dental Science.*

Osmium-platinum Alloy.—A new alloy, osmium-platinum, is the subject of a United States' patent. The rarer metals of the platinum group are not easily obtained in a state of purity, and therefore no great success has attended efforts to combine them as bivalent alloys. It is now stated that highly refined platinum and osmium have successfully been combined in widely varying proportions yielding alloys of commercial value. Alloys containing from 1 to 10 per cent. of osmium and from 99 to 90 per cent. of platinum are chiefly used. Great purity of the respective metals is essential to success, as even small percentages of other elements are very detrimental to the properties of the resulting alloy. One part of osmium in an alloy with platinum will take the place of two and one-half times its weight of iridium, and this is one of the metals hitherto most used. The new alloy is very resistent to acids, and also possesses great hardness and tensile strength. Wires of the finest caliber are drawn with comparative ease.—F. ZIMMERMAN, *Chem. Engineer,* per *Brit. Dental Journal.*

Mustard Oil in Odontalgia.—In a preliminary communication Adolf Schwarz states that he has accidentally come across a remarkable action of oleum sinapis æthereum—of the Austrian Pharmacopœia—on the sensory nerve endings of the trigeminal nerve. If a person suffering from toothache takes a small quantity of mustard oil in a bottle, and, after closing one nostril, inhales once the fumes of the oil, the first effect is a reddening of the face, flow of tears, and difficulty of respiration. Within a very short time all pain in connection with the tooth has disappeared. If he has inhaled too much vapor, respiratory reaction and the reaction to sneezing and to coughing are abolished, and the patient suffers some distress for the time. Provided that only one short inhalation is taken, the relief of pain is almost instantaneous and lasts for some hours. He has found that the pain of middle-ear disease can also be relieved by the same means, and is complete

enough to render the operation of paracentesis painless without any narcosis. The patient remains fully awake, and in no case is any unpleasant after-effect produced. He has carried it out in about sixty cases, including delicate women and decrepit old people.—*Muench. Med. Woch.*, per *British Dental Journal.*

Effect of Hydrogen Dioxid on Metals and Its Use in Sterilizing Instruments.—In the sterilization of dental instruments by chemical disinfectants, the heavy metal salts such as bichlorid of mercury are unsuitable because they attack the metal instruments. Other strong disinfectants are usually too toxic or impart a disagreeable odor to the instruments. Thymol, owing to its low degree of solubility, permits of only weak, hence ineffective solutions. The writer's experiments have shown that from 1 to 3 per cent. solutions of pure hydrogen dioxid (perhydrol) are most effectively bactericidal, and do not only not attack the instruments in the least, but even preserve iron objects, which show no change whatever when immersed therein for days, while in water they will rust after a few hours. To be sure, the hydrogen dioxid employed must be absolutely pure, for impure H_2O_2 preparations, such as the official hydrogenium peroxydatum medicinale 3 per cent., contains acid, and attacks iron very quickly. Hence the behavior of iron toward H_2O_2 preparations can be regarded as a test for the purity of the latter. The purity test of absolute H_2O_2 preparations is preferably made with copper.—W. Eichholz, *Medizinische Klinik*, per *Oesterreichische Zeitschr. f. Stomatologie.*

Suggestions for Crown and Bridge Work.—(1) Nearly all prosthetic castings should be made in combination with iridio-platinum or gold in wire or plate form as a means of reinforcement. (2) Iridio-platinum, on account of its great strength and freedom from oxidation, affords the best reinforcement. (3) 24-karat gold reinforced with iridio-platinum is the best for inlay abutments. (4) The reinforcement plan expedites as well as strengthens the work and obviates bulkiness, which it is in many instances so essential to do. (5) It is best not to heat any alloy of gold containing base metals to the point of oxidation when casting upon it. (6) It is unnecessary and detrimental to heat a flask to a red heat or anywhere near it when burning out wax. (7) The elastic limit of scrap or junk gold is practically *nil*, and it should not be used where much strain will be brought to bear upon it. (8) Alloys of gold with platinum will become very brittle when cast a few times. This, Dr. Taggart tells us, is due to contamination with silica contained in the investment. (9) The casting process makes possible the employment of almost all forms of porcelain teeth, and provision should be made for cementation rather than casting directly on to the porcelain. (10) Nearly all inlay abutments, regardless of size and shape of cavity, should have some form of supplemental pin anchorage.—F. E. Roach, *Dental Summary.*

External vs. Internal Incision in Alveolar Abscess.—One hears the opinion expressed that external incision for the evacuation of pus from alveolar abscess is never justified. The reason given is that it leaves a scar. I am of the opinion that a small linear scar is to be preferred to an ugly disfiguring scar which may result from permitting the pus to point on the face without surgical aid; besides, delay in discharging pus may result disastrously from general infection. The object of pus drainage is to lessen or prevent toxemia. Alveolar abscess is not without danger, and one is not justified in taking chances with his patients, especially if they may be avoided. In serious inflammation in the region of the angle of the mandible, accompanied by much swelling and trismus, pus is not easily evacuated into the mouth. Incision inside the mouth in such a case may not reach the pus, and even if it is reached, on account of the swelling it may be difficult to fully evacuate it and keep up the discharge. In such a case it is far safer to make an incision through the skin under the base of the jaw followed by blunt dissection until the pus is found. Gravity favors the discharge from such an incision, and drainage is more easily maintained. Pus, like water, drains best down hill. The scar of such an incision is linear and not easily observable. The one method is poor surgery, the other good surgery.—T. L. Gilmer, *Dental Review.*

Occupational Stigmata of the Teeth.—A few occupational dental stigmata have been known of old, notably in connection with various metals. With the modern advances in dentistry and in occupational diseases much has come to light. Some of the leading occupational stigmata which are of interest to the dentist are as follows: Confectioners are peculiarly subject to caries. The sugar dust forms oxalic acid in the mouth, and this attacks the exposed tooth to a uniform extent, as well as the root. In workers in hydrochloric acid, the enamel is attacked

and the dentin turns brown. Changes in the teeth are noticeable after the first three weeks of exposure; the teeth feel sore, and thence the entire crown disappears. Unsatisfactory attempts at prevention have been made, such as a sponge held in the mouth. This absorbs the fumes of hydrochloric acid, but becomes a source of irritation to the lips. Mechanical defects in the teeth are common whenever the latter are used for tightly holding hard substances, such as nails, or for biting threads. The incisors naturally suffer, and it should be readily possible to state whether a tailor is right- or lefthanded. The so-called lines above the roots of the teeth, believed formerly to have great significance, can be prevented by proper mouth hygiene, so that, if all workers in copper, brass, lead, etc., were cleanly in this respect, no stigmata would be in evidence.—Kraus, *Berliner Klin. Wochenschrift*, per *Universal Med. Record.*

Noise vs. Silence in the Dentist's Operating Room.—Efficiency engineers recommend that noise be eliminated from workshop and factory. Experiments prove beyond question that men working in a quiet, dignified atmosphere can do more and better work than when their attention is distracted by noise. Violent atmospheric vibrations unquestionably destroy nerve energy; we all know how difficult it is to concentrate our minds amid distracting noise.

Dentists should bear this in mind. The operating room should be in the quietest nook that can be selected. Assistants should be trained to handle instruments in such a manner as to render these manipulations noiseless. Equipments should be used that work without friction. Not long ago the writer sat in the waiting-room of a prominent dentist. The electric engine in use at the chair made such violent vibrations as to be easily audible in the adjoining room. Imagine the effect it must have on the operator to listen to this harsh, grating noise several hours each day. No wonder he leaves the chair utterly exhausted at three or four o'clock in the afternoon, and who will doubt that his nerve force is wasted and his efficiency lowered by this useless noise.

Every operator should make his operating room a zone of quietude, and strive to eliminate the nerve exhaustion that follows constant and irritating noise.—M. Dewey, *Internat. Journ. of Orthodontia.*

Apicoectomy.—Root amputation, in the treatment of dento-alveolar abscesses, is an operation of necessity and not of choice. Although when properly carried out it almost invariably gives good results, it should be resorted to only when other less radical methods have failed.

The conditions where this operation is indicated are the following: Where the area of necrosis is so large, and the infiltration of pus into the surrounding tissues is so extensive that thorough asepsis cannot be established, and all of the infected and broken-down tissues cannot be eliminated by the medicaments conveyed through the root-canal or canals of the offending tooth. When a broach is broken in let us say the apical third of the root, which precludes the possibility of properly cleansing and filling the root, it is good practice to fill the latter to the broach and amputate the part containing the foreign body. Multi-rooted teeth in which one root has been devitalized by extensive pyorrhea or by atrophy of the gums and the alveolus, are also good subjects for this procedure. The pulp chamber and the canals of the retained roots should be filled, and the one bereft of its bony support should be amputated.

Before undertaking this operation it is advisable to have the root-canal rendered aseptic and filled, and to secure a good radiograph to show the condition of the root and its surrounding tissues and its position.

A semilunar incision is produced with a sharp lancet, cutting through the tissues to the bone, about one-half of an inch from the gingival margin, with its crescent toward the crowns of the teeth. With a periosteum elevator this flap of tissue is raised, and the bone exposed. A small ridge produced by the root of the tooth will usually indicate about the position of the apex. With a surgical bur, a trephine, or else with a chisel, the bone overlying the apex is removed and the apex exposed. By doing this we have a clear field of operation, and will avoid such undesirable mistakes as injuring or amputating the adjacent teeth. We can now with a fissure or round bur cut away the portion of the root penetrating the abscess cavity and devoid of its bony support. The stump end should be rounded off and smoothed next with a curet or finishing bur, and the entire abscess tract curetted out, removing all the débris and infected tissues. The cavity is flushed out with an antiseptic solution, and dressed so that the edges of the wound can be approximated.

Where the area of infection is not very extensive after a few dressings, the wound can be left unpacked, and the patient instructed to use an antiseptic mouth-wash.—A. Berger, *Items of Interest.*

Hints, Queries, and Comments.

A METHOD OF PREPARING THE GINGIVAL BASE FOR A GOLD INLAY.

We all recognize that the gingival margin of a cavity is the danger-point in our fillings and inlays, especially the latter. We also know that non-cohesive foil can be adapted to cavity walls and margins more closely than any other form of gold. The line of cement at the gingival margin of a gold inlay, no matter how closely we have burnished our inlay margin to the cavo-surface angle, should be a source of anxiety to every dentist. The following plan may be new, or it may not be; it is certainly efficacious: Apply the rubber dam and prepare the gingival base as for a cohesive gold filling, with convenience points at the axio-gingival point angles. Start the filling in these points with cohesive foil and build across the axio-gingival angle; then place three cylinders of non-cohesive gold at the gingival base with their ends extending beyond the gingival margin. Press these cylinders into place, using a foot plugger—*but do not mallet.* The middle cylinder acts as a wedge. Hold this non-cohesive layer in position while you extend the cohesive foil from the axio-gingival angle toward the margin to cover it. When you have a layer of cohesive foil completely over the floor, mallet the mass into position. This drives the non-cohesive foil into place. In finishing the floor or base of gold, use a broad foot plugger with fine serrations; also mallet and finish the margin of gold to perfect adaptation. The thickness of this base need not be more than one millimeter; the finely serrated floor makes an ideal base for the inlay, and you have no contact of cement with gingival margin. When the base is completed, remove the dam and proceed as usual. I find that the added time for this method of inlay work is not more than thirty minutes, and I am a slow operator.

Albert J. Butler, D.D.S.

Pasadena, Cal.

Obituary.

DR. H. B. McFADDEN.

[See Frontispiece.]

Died, from pneumonia, February 14, 1915, at his home, 3505 Hamilton st., Philadelphia, Henry Birkinbine McFadden, D.D.S.

Dr. McFadden was the son of Dr. Wm. Henry McFadden, a graduate of the University of Pennsylvania, class of 1849, and Sarah Evans (Yocum) McFadden. He was born in Germantown, Philadelphia, October 30, 1861, and received his early education in the public and private schools of Philadelphia.

He was graduated in dentistry with the class of 1882 of the dental school of the University of Pennsylvania, and later continued his studies under Prof. Charles J. Essig. He began the practice of his profession at his residence, 3505 Hamilton st., Philadelphia, May 1, 1883. For ten years Dr. McFadden was demonstrator of mechanical dentistry in the dental school of the University of Pennsylvania, where he was an earnest and efficient teacher. He always maintained an active and earnest interest in dental society affairs. He held membership in the National Dental Association, of which he was treasurer from 1911 until the time of his death; he was also a member of the Pennsylvania State Dental Society and its second vice-president, a member of the Academy of Stomatology of Philadelphia, the Odontographic Society of West Philadelphia, the First District Dental Society of the State of New York, and the Dental Alumni Society of the University of Pennsylvania. He was a member of the University of Pennsylvania Club of New York City, of the Union League of Philadelphia, of the National Dental Protective Association,

the National Mouth Hygiene Association, of the University Lodge No. 610, Philadelphia, the Corinthian Chasseur Commandery Knights Templar, the Crescent Boat Club, and various other social, Masonic, and professional organizations. He was unmarried.

Dr. McFadden's remains were interred at Laurel Hill Cemetery, Philadelphia, February 17, 1915.

Dr. McFadden was a striking and interesting personality. Warm-hearted and affectionate in disposition, kindly and generous in his relations with humanity, sympathetic and responsive, his was a nature which drew about him hosts of friends and gave him a popularity of the kind which "doth honor a man," but the outstanding attributes of his character which more than all else won for him the confidence and esteem of his colleagues, and which more than all else contributed to his popularity and success in the activities of his profession, were his sterling integrity and his high sense of personal honor. His loyalty as an attribute of character was perhaps equally pronounced. To him a friendship was sacred, and his loyalty to his friends was unshakable. Nevertheless, his loyalty to truth and righteousness, as he saw the truth and as he understood righteousness, dominated all other considerations, and it is this combination of attributes in a man which in their totality are sufficiently remarkable to place them almost in the category of peculiarities. All who knew him trusted him, for he never broke faith. These qualities combined with his intense interest in all that had to do with the advancement of his chosen profession made him a tower of strength in the counsels of those who were immediately concerned with dental professional activities. He was a wise counselor and an earnest and indefatigable worker in any cause that concerned the welfare of his profession.

His death came almost without warning in its suddenness. He was chairman of the committee having in general charge the social entertainments related to the dedication of the Evans Institute, and in the midst of his activities he was stricken, his death resulting from acute pneumonia in about three days. His decease cast a gloom over all of the exercises, and a burden of sorrow upon the hearts of all of his friends who were associated with him or who participated in the activities of that occasion. The announcement of his death will bring sorrow to a very wide circle of friends and acquaintances, and all will concur in the belief that by his death the profession of dentistry has sustained an irreparable loss.

DR. J. CARROLL WHINNERY.

DIED. December 25, 1914, at Los Angeles, Cal., J. CARROLL WHINNERY, D.D.S.

J. Carroll Whinnery was born in Salem, Ohio. His early education was obtained in the public and high schools of that city; later he attended Union College at Mount Vernon, Ohio.

He was graduated from the Boston Dental College on March 1, 1876. For five years he practiced in San Francisco, and in 1882 located in Omaha, at which place he continued practice until he retired, a few years before his death.

Dr. Whinnery had returned to California in the hope of regaining health, but had been there only one week when the end came.

The deceased was the first dean of the old Omaha Dental College, in later years consolidated with the dental department of Creighton University.

DR. RALPH E. LUTHER.

DIED. February 12, 1915, at St. Luke's Hospital, Chicago, Ill., from pneumonia, in his thirty-ninth year, RALPH E. LUTHER, D.D.S., of Batavia, N. Y.

Ralph E. Luther was born in Warsaw, N. Y., October 26, 1876. He was a graduate of the Warsaw high school, and the dental department of the University of Buffalo, class of 1900, and in September of the same year commenced the practice of dentistry in Batavia.

He married Miss Marion Duncan in 1901, and is survived by his wife, two sons, Duncan and John, his mother, Mrs. Mary E. Luther, two brothers, Kendrick of Syracuse, and Guy S. of Schenectady, and a sister, Mrs. Roy McGregory of Batavia.

He was a charter member of Mu Chapter Xi Psi Phi Fraternity, and had served as deputy supreme president. He was a member and past president of the Eighth District and of the Batavia Dental Societies, member of the Dental Society of the State of New York and chairman of the committee on Oral Hygiene, member of the National Dental Association, and of the Rochester City Dental Society. He was also a member of the

Masonic fraternity, and various other local organizations, but was particularly active in affairs of the Young Men's Christian Association and the Boy Scouts, where he rendered much valuable service by his untiring energy and enthusiasm.

Dr. Luther took a prominent part in matters connected with Oral Hygiene, and was one of the pioneers in the work in this state. He had made a specialty of pyorrhea work, and just prior to his death had completed a course in Chicago. He was a man of fine ability as an operator, and gave much promise of a brilliant future. He was an upright, conscientious, high-class professional man, one who observed all the finer rules of conduct toward his patients and the profession. He was a splendid type of a high-toned professional gentleman. In his death the profession loses an intelligent, able, and indefatigable worker, and his family and friends a kind, generous and lovable companion and friend. His loss will be mourned by a large circle of friends and acquaintances, who honored him for his many attractive qualities of heart and mind.

H. J. B.

DR. WILLIAM ERNEST WALKER.

Died, November 21, 1914, in New Orleans, La., of uremia, in his forty-seventh year, William Ernest Walker, D.D.S., M.D.

William Ernest Walker was born in New Orleans, La., on March 3, 1868, as the son of Dr. J. R. Walker, who practiced dentistry in New Orleans up to the time of his death in 1887, and Jeanie Mort, who was known to the dental profession as a contributor of many articles and practical hints to various dental journals under the *nom de plume* of "Mrs. M. W. J."

The deceased attended the public schools of New Orleans, and served his dental apprenticeship in his father's office, later being graduated with high honors from the Baltimore College of Dental Surgery in 1889. He first engaged in dental practice in Bay St. Louis, Miss., and then moved to Pass Christian, Miss., where he enjoyed a large *clientèle*. While practicing in the latter city, he occupied the chair of clinical dentistry in the Dental Department of the Southern Medical College in Atlanta, Ga., at the same time taking a medical course.

After two years' sojourn in Atlanta, he became connected with the Baltimore College of Physicians and Surgeons, occupying the chair of operative dentistry while completing his medical studies. After obtaining the degree of M.D., he resigned his professorship in order to devote all his time to dental practice.

The deceased became more and more interested in orthodontia, and, after moving to New Orleans about twelve years ago, gave up the general practice of dentistry, and limited his practice to orthodontia and facial orthopedia, in which specialty he was remarkably successful. During his first few years of practice in New Orleans, the deceased was dean of the New Orleans College of Dentistry, where he taught orthodontia.

At the time of his sudden and untimely demise, Dr. Walker was secretary and treasurer of the American Society of Orthodontists, member of Delta Sigma Delta Fraternity and of numerous local, state, and national dental and medical associations.

As a fruit of his painstaking studies, the deceased first pointed out the anatomical fact of the downward and forward movement of the condyles, and invented the well-known anatomic articulator, the predecessor of many similar devices. He also designed a number of appliances of special interest and value for the orthodontist.

"IN MEMORIAM" RESOLUTIONS.

Dr. James Truman and Dr. Louis Jack.

The Academy of Stomatology of Philadelphia, on January 26, 1915, passed the following resolutions upon the death of Dr. James Truman and Dr. Louis Jack, as prepared by the committee to whom the matter was referred:

Whereas, Death, which cometh unto all, having removed from among us James Truman, D.D.S., LL.D., and Louis Jack, D.D.S., it becomes our mournful pleasure to record a few of their many and brilliant virtues. It is not often that the dental profession is called upon to lament within so brief a period the death of two such exalted characters. Their lives had run parallel for sixty years. Graduated, as they were, as classmates in 1854 from the Philadelphia College of Dental Surgery, which afterward changed its name to the Pennsylvania College of Dental Surgery, they had lived and labored for nearly sixty years in the same community,

with the same aims and aspirations, and for the uplift of dentistry as a profession. There were certain characteristics which they shared in common. They were dignified in manner, urbane in disposition, strictly honest and moral in character, noble and ethical in their dealings with their fellow men. Exalted in their chosen profession, they were comrades whom we honored as dentists and loved as men; therefore be it

RESOLVED, That it is the sense of the Academy of Stomatology of Philadelphia that in the death of these fathers in dentistry the profession at large, and this society in particular, have lost two of their most honored and distinguished members.

RESOLVED, That these resolutions be engrossed upon the records of the Academy, and that a copy be sent to the family of one, and the surviving relative of the other.

EDWIN T. DARBY,
DANIEL NEALL MCQUILLEN,
EDWARD C. KIRK,
Committee.

SOCIETY NOTES AND ANNOUNCEMENTS.

DENTAL SOCIETY MEETINGS:

April, May, and June.

APRIL.

CONNECTICUT STATE DENTAL ASSOCIATION. Hartford. Three days: April 20th to 22d.

MICHIGAN STATE DENTAL SOCIETY. Grand Rapids. Three days: April 15th to 17th.

MISSISSIPPI DENTAL ASSOCIATION. Jackson. Three days: April 20th to 22d.

ODONTOLOGICAL SOCIETY OF WESTERN PENNSYLVANIA. Pittsburgh. Two days: April 13th and 14th.

SOUTH CAROLINA STATE DENTAL ASSOCIATION. Columbia. Four days: April 27th to 30th.

SOUTHERN MINNESOTA DISTRICT DENTAL SOCIETY. Mankato. Three days: April 12th to 14th.

MAY.

DENTAL SOCIETY OF THE STATE OF NEW YORK. Albany. Three days: May 13th to 15th.

ILLINOIS STATE DENTAL SOCIETY. Peoria. Four days: May 11th to 14th.

INDIANA STATE DENTAL ASSOCIATION. Indianapolis. Three days: May 18th to 20th.

INTERSTATE ASSOCIATION OF ANESTHETISTS. Cincinnati, Ohio. Two days: May 4th and 5th.

KANSAS STATE DENTAL ASSOCIATION. Topeka. Three days: May 25th to 27th.

LAKE ERIE DENTAL ASSOCIATION. Cambridge Springs, Pa. Three days: May 20th to 22d.

MASSACHUSETTS DENTAL SOCIETY. Boston. Three days: May 5th to 7th.

NEBRASKA STATE DENTAL SOCIETY. Omaha. Three days: May 18th to 20th.

SUSQUEHANNA DENTAL ASSOCIATION OF PA. Wilkes-Barre. Three days: May 18th to 20th.

TEXAS STATE DENTAL ASSOCIATION. Galveston. Four days: May 19th to 22d.

JUNE.

KENTUCKY STATE DENTAL ASSOCIATION. Ashland. Three days: June 8th to 10th.

LOUISIANA STATE DENTAL SOCIETY. New Orleans. Three days: June 3d to 5th.

MAINE DENTAL SOCIETY. Portland. Three days: June 28th to 30th.

MINNESOTA STATE DENTAL ASSOCIATION. Minneapolis. Two days: June 11th and 12th.

MISSOURI STATE DENTAL ASSOCIATION. Jefferson City. Three days: June 10th to 12th.

NEW HAMPSHIRE DENTAL SOCIETY. Weirs. Three days: June 22d to 24th.

NORTH CAROLINA DENTAL SOCIETY. Wrightsville Beach. Three days: June 23d to 25th.

TENNESSEE STATE DENTAL ASSOCIATION. Sewanee. Three days: June 24th to 26th.

Examiners' Meetings.

CALIFORNIA BOARD OF EXAMINERS. San Francisco, June 4th; Los Angeles, June 18th.

MARYLAND BOARD OF EXAMINERS. Baltimore. May 27th and 28th.

MICHIGAN BOARD OF EXAMINERS. Ann Arbor. June 14th to 19th.

NEBRASKA BOARD OF EXAMINERS. Lincoln. June 9th.

NEW HAMPSHIRE BOARD OF REGISTRATION. Manchester. June 14th to 16th.

NORTH CAROLINA BOARD OF EXAMINERS. Wrightsville Beach. June 21st.

SOUTH CAROLINA BOARD OF EXAMINERS. Columbia. June 15th.

TEXAS BOARD OF EXAMINERS. Dallas. June 21st.

VIRGINIA BOARD OF EXAMINERS. Richmond. June 8th.

WISCONSIN BOARD OF EXAMINERS. Milwaukee. June 21st.

DENTAL RED CROSS FUND.

At the meeting of the American Institute of Dental Teachers held at Ann Arbor, Michigan, on January 26th, it was decided to take steps that should result in the raising of a fund to be used through the Red Cross Society in giving relief and aid to the soldiers in Europe who are suffering from oral and dental injuries. The president was instructed to appoint a committee to take charge of this matter. President F. W. Gethro, under this instruction, appointed the following Executive and General committees:

Executive Committee.

C. R. E. Koch, *Chairman;* John F. Biddle, *Sec'y;* Henry W. Morgan, E. A. Johnson. Ellison Hillyer.

General Committee.

E. C. Kirk, Philadelphia.
J. H. Kennerly, St. Louis.
H. C. Miller, Portland, Ore.
D. M. Gallie, Chicago.
John F. Biddle, Pittsburgh.
E. T. Darby, Philadelphia.
Alfred Owre, Minneapolis.
B. Holly Smith, Baltimore.
E. A. Johnson, Boston.
Frank Holland, Atlanta.
D. M. Cattell, Memphis.
Frederick R. Henshaw, Indianapolis.
S. W. Bowles, Washington.
E. H. Smith, Boston.
A. H. Hipple, Omaha.
Ellison Hillyer, New York.
Truman W. Brophy, Chicago.
D. H. Squire, Buffalo.
H. E. Friesell, Pittsburgh.
Henry W. Morgan, Nashville.
I. N. Broomell, Philadelphia.
Wallace Wood, New Orleans.
Frank T. Breene, Iowa City.
H. L. Banzhaf, Milwaukee.
J. G. Sharp, San Francisco.
G. V. Black, Chicago.
W. T. Chambers, Denver.
H. M. Semans, Columbus.
J. D. Patterson, Kansas City.
N. S. Hoff, Ann Arbor.
C. N. Johnson, Chicago.
H. L. Wheeler, New York.
L. E. Ford, Los Angeles.
C. R. E. Koch, Chicago.
H. B. Tileston, Louisville.

The Executive Committee is preparing contribution certificate booklets, each containing twenty certificates or coupons certifying that the holder thereof has contributed twenty-five cents to this fund. This certificate will be neatly lithographed, something like national currency. It will be printed in lilac ink—the color of the dental profession—and bear upon its face the red Geneva cross.

It is hoped that the dental schools, dental students, and dental societies, as well as the profession at large, will become sufficiently interested in this propaganda to secure a large enough fund through these small contributions to secure real relief for the class of war sufferers for which it is designed. That it may aid in the establishment of several special hospitals or wards devoted to dental and oral surgical injuries, within the belligerent zone of Europe, is the ultimate purpose of this movement.

Make applications for booklets to any member of Executive or General Committees.

INTERSTATE ASSOCIATION OF ANESTHETISTS.

The Interstate Association of Anesthetists will hold its organization meeting in conjunction with the Ohio State Medical Association in Cincinnati, Ohio, May 4 and 5, 1915, at which time an elaborate scientific program devoted exclusively to recent advances in anesthesia and analgesia will be presented, as follows:

"Foreword," Robert Carothers, Councilor First District O. S. M. A. "Selection of the Anesthetic," Emmett F. Horine, Louisville, Ky. "Nitrous Oxid Anesthesia in Obstetrics," Arthur E. Guedel, Indianapolis, Ind. "Blood-pressure under General Anesthesia," E. I. McKesson, Toledo, O. "Conductive Analgesia for Intra-oral Operations," Hugh MacMillan, Cincinnati, O. "Alkaloidal Medication in Relation to Anesthesia and Analgesia," Isabella C. Herb, Chicago, Ill. "Anesthesia for Brain Surgery," Charles K. Teter, Cleveland, O. "Use of Music during Analgesia," W. P. Burdick, Kane, Pa. "Magnesium Sulfate Narcosis," D. D. DeNeen, Cincinnati, O. "Ethyl Chlorid Anesthesia," R. A. Rice, Columbus, O. "Intravenous Anesthesia," C. L. Candler, Detroit, Mich. "Preparatory, Operative, and Postoperative Precautions for Hazardous Anesthetic Risks," Moses Salzer, Cincinnati, O. "Vapor Anesthesia for Intra-oral Operations," Paul R. Coble, Indianapolis,

Ind. "Local Anesthesia for Hernia Operations," Chas. T. Souther, Cincinnati, O. "Surgical Mortality from the Standpoint of the Anesthetist." H. W. Kearney, Washington, D. C. "Nitrous Oxid-Oxygen Analgesia in Dentistry," Edward S. Barber, Chicago, Ill. "Posture and Muscular Relaxation as Factors in the Newer Conception of Shock," Willis D. Gatch, Indianapolis, Ind. "Spinal Anesthesia," John Overton, Tulsa, Okla. "Acapnia." E. M. Sanders, Nashville, Tenn. "Local Analgesia for Nose, Throat, and Larynx Operations," Myron T. Metzenbaum, Cleveland, O. "Anesthesia a Full-fledged Specialty," W. Hamilton Long, Louisville, Ky. "Anesthesia, Anesthetists, and Workmen's Compensation Laws," F. H. McMechan, Cincinnati, O. "Intratracheal Anesthesia," B. Merrill Ricketts, Cincinnati, O. With Demonstration of a Portable Field Apparatus by Major Allie Williams, U. S. A., Washington, D. C.

Headquarters, assembly-room, and exhibits will be in the new Hotel Gibson, in which all the sections of the Ohio State Medical Association will also meet. An informal organization dinner will be served on the evening of May 4th, after which the visiting anesthetists will be the guests, at a "smoker," of the Local Entertainment Committee, headed by Dr. E. O. Smith. Visiting ladies will be entertained by Dr. Nora Crotty and her committee at a reception and theater party.

Anesthetists, surgical and dental, as well as interested surgeons and general practitioners who wish to participate in the proceedings are cordially invited to attend. For further information and dinner reservations address

F. H. McMechan, M.D., *Sec'y*,
1044 Wesley ave., Cincinnati, Ohio.

AMERICAN INSTITUTE OF DENTAL TEACHERS.

At the last annual meeting of the American Institute of Dental Teachers, held at Ann Arbor, Mich., the following officers were elected for the ensuing year: H. M. Semans, Columbus, Ohio, president; S. W. Bowles, Washington, D. C., vice-president; J. F. Biddle, 517 Arch st., N. S., Pittsburgh, Pa., secretary-treasurer. Executive Board—A. W. Thornton, Montreal, Canada; R. W. Bunting, Ann Arbor, Mich., A. D. Black, Chicago, Ill.

The next annual meeting will be held at Minneapolis, Minn., January 25, 26, and 27, 1916.

MICHIGAN STATE DENTAL SOCIETY.

The next meeting of the Michigan State Dental Society will be held at Grand Rapids, April 15, 16, and 17, 1915.

F. Ward Howlett, *Sec'y*, Jackson, Mich.

SOUTHERN MINNESOTA DISTRICT DENTAL SOCIETY.

The Southern Minnesota District Dental Society will hold its annual meeting April 12, 13, and 14, 1915, at Mankato. A literary and clinical program will be carried out.

G. W. Norris, *Sec'y*,
Tracy, Minn.

CONNECTICUT STATE DENTAL ASSOCIATION.

The fifty-first annual meeting of the Connecticut State Dental Association will be held at Hartford, Conn., April 20, 21, and 22, 1915.

Charles H. Riggs, *President*.
Hartford, Conn.
Elwyn R. Bryant, *Sec'y*,
New Haven, Conn.

PHILADELPHIA DENTAL COLLEGE.

Alumni Society.

The annual meeting of the Alumni Society of the Philadelphia Dental College will be held in the College building, Eighteenth and Buttonwood sts., Philadelphia, Wednesday, April 14, 1915.

Dr. Wm. A. Spring, president of the American Dental Society of Europe, will read a paper, entitled "The Career of the American Dentist Abroad," at 10 o'clock on Wednesday morning, after which a luncheon will be served in the College building. The clinics will be held in the afternoon at 2 o'clock, and the annual banquet at 6.30 P.M.

S. I. Williams, *Sec'y*.

ODONTOLOGICAL SOCIETY OF WESTERN PENNSYLVANIA.

The thirty-fourth annual meeting of the Odontological Society of Western Pennsylvania will be held at the Monongahela House, Pittsburgh, Pa., Tuesday and Wednesday, April 13 and 14, 1915.

The first regular session of the society will open on Tuesday at 10.30 A.M. The Executive Council will meet at the hotel at 10 A.M. for

the transaction of business in the interest of the society.

The clinics and exhibits will be at the Monongahela House. Exhibitors are cordially invited to visit this meeting, and requested to make early reservation for space. Address Dr. Leslie Waddill, Jenkins Arcade, Pittsburgh, Pa.

A cordial invitation is extended to all ethical dentists in Pennsylvania and adjoining states.

KING S. PERRY, *Sec'y*,
719 Jenkins Bldg., Pittsburgh, Pa.

SOUTH CAROLINA STATE DENTAL ASSOCIATION.

NOTE CHANGE OF DATE.

THE annual meeting of the South Carolina State Dental Association will be held at the Jefferson Hotel, Columbia, S. C., April 27 to 30, 1915.

Special public session, devoted to the relationship of defective teeth to the public health, will be held in the afternoon and evening of April 29th.

P. D. BROOKER, *President*,
Columbia, S. C.
E. C. DYE, *Sec'y*,
Greenville, S. C.

SECOND DISTRICT (N. Y.) DENTAL SOCIETY.

YOU are invited by the Second District (N. Y.) Dental Society to attend a dinner and meeting on Monday evening, April 12, 1915, in the new Hotel Bossert, Brooklyn, N. Y.

Reserve this evening for a meeting that will signalize a marked advance in scientific dentistry. Dr. Elmer S. Best of Minneapolis, Minn., will read his paper on "The Responsibility of the Dentist in Pulpless Teeth." This is the result of over two years' experiment, study, and trial. Some of the ablest men in the medical and dental professions will discuss this problem.

The dinner, an informal one, will be $ per person. Tables for six and eight will be reserved upon receipt of check made payable to Arthur M. Hunter, treasurer of the dinner committee, 67 Hanson Place, Brooklyn.

A. M. NODINE, *Chairman*,
F. C. WALKER,
A. H. HUNTER, *Committee*.

MISSISSIPPI DENTAL ASSOCIATION.

THE fortieth annual meeting of the Mississippi Dental Association will be held in Jackson, April 20, 21, and 22, 1915.

M. B. VARNADO, *Sec'y*, Osyka, Miss.

MASSACHUSETTS DENTAL SOCIETY.

THE fifty-first annual meeting of the Massachusetts Dental Society will be held May 5, 6, and 7, 1915, in the Hotel Somerset, Boston, Mass.

A. H. ST.C. CHASE, *Sec'y*.

ILLINOIS STATE DENTAL SOCIETY.

THE fifty-first annual meeting of the Illinois State Dental Society will be held at Peoria, May 11, 12, 13, and 14, 1915.

J. N. BARCUS, *President*,
HENRY L. WHIPPLE, *Sec'y*.

LAKE ERIE DENTAL ASSOCIATION.

THE fifty-second annual meeting of the Lake Erie Dental Association will be held at Hotel Bartlett, Cambridge Springs, Pa., May 20, 21, and 22, 1915.

J. F. SMITH, *Sec'y*,
Erie, Pa.

NEBRASKA STATE DENTAL SOCIETY.

THE forty-eighth annual meeting of the Nebraska State Dental Society will be held in Omaha, Nebr., May 18, 19, and 20, 1915.

WM. A. MCHENRY, *President*,
H. J. PORTER, *Sec'y*,
Cambridge, Nebr.

KANSAS STATE DENTAL ASSOCIATION.

NOTE CHANGE OF DATE.

THE Kansas State Dental Association will hold its next annual meeting at Topeka, Kans., May 25, 26, and 27, 1915.

A most unique program will be presented. Dr. Thos. P. Hinman of Atlanta, Ga., will be the guest of honor.

A. L. BENTON, *Sec'y*,
Garnett, Kans.

DENTAL SOCIETY OF THE STATE OF NEW YORK.

THE forty-seventh annual meeting of the Dental Society of the State of New York will be held at Albany, N. Y., Thursday, Friday, and Saturday, May 13, 14, and 15, 1915.

The Executive Council will meet at the Hotel Ten Eyck, Wednesday afternoon, May 12th, at 3 P.M., for the transaction of business.

The first regular session of the society will open on Thursday at 10.30 A.M. The literary program will be rendered in the auditorium of the Educational Building. Headquarters for Officers and Executive Council will be at the Hotel Ten Eyck.

The clinics and exhibits will be at the Hotel Ten Eyck. Exhibitors are cordially invited to visit this meeting, and requested to make early reservations for space. Address Dr. O. J. Gross, Schenectady, N. Y., for space.

A cordial invitation is extended to all ethical dentists in New York and sister states.

A. P. BURKHART, *Sec'y*,
52 Genesee st., Auburn, N. Y.

INDIANA STATE DENTAL ASSOCIATION.

THE next annual meeting of the Indiana State Dental Association will be held in Indianapolis, on May 18, 19, and 20, 1915. A distinctive feature of this meeting will be that the program will be made up exclusively of Indiana dentists. A cordial invitation is extended to members of other dental societies to attend the meeting.

A. R. ROSS, *Sec'y*,
Lafayette, Ind.

TEXAS STATE DENTAL ASSOCIATION.

THE thirty-fifth annual meeting of the Texas State Dental Association will be held in Galveston, Texas, May 19, 20, 21, and 22, 1915. The special feature of this meeting will be postgraduate lectures and clinic work.

Dr. G. Walter Ditmar of Chicago will present modern scientific bridge work and removable partial dentures, with preparations, technique, and principles involved. Dr. B. F. Thielen will present "Plate Work." Dr. T. G. Duckworth, "Orthodontia." Dr. R. D. Griffis, "Nitrous Oxid Analgesia and Anesthesia." Dr. Julian Smith, "Pyorrhea." Dr. J. M. Murphy, "Local Anesthesia."

Exhibitors are requested to attend, and to write to Dr. A. L. Frew, Dallas, for space. General clinics, on last day. Clinicians will write Dr. W. H. Nugent, Fort Worth. For any other information write the secretary.

C. M. MCCAULEY, *Pres.*, Dallas.
W. O. TALBOT, *Sec'y-Treas.*, Fort Worth.

LOUISIANA STATE DENTAL SOCIETY.

THE next Louisiana State Dental Society meeting will be held in New Orleans, La., June 3, 4, and 5, 1915, at the Grunewald Hotel.

P. W. TROWBRIDGE, *Sec'y*.

TENNESSEE STATE DENTAL ASSOCIATION.

THE forty-eighth annual meeting of the Tennessee State Dental Association will be held in Sewanee, Tenn., June 24, 25, and 26, 1915.

C. O. RHEA, *Sec'y*,
Nashville, Tenn.

NORTH CAROLINA DENTAL SOCIETY.

THE next annual meeting of the North Carolina Dental Society will be held at Wrightsville Beach, June 23, 24, and 25, 1915.

R. M. SQUIRES, *Sec'y*,
Wake Forest, N. C.

SUSQUEHANNA DENTAL ASSOCIATION OF PENNSYLVANIA.

THE fifty-second annual meeting of the Susquehanna Dental Association will be held at Irem Temple, Wilkes-Barre, Pa., May 18, 19, and 20, 1915.

GEO. C. KNOX, *Recording Sec'y*.

NEW HAMPSHIRE DENTAL SOCIETY.

THE next meeting of the New Hampshire Dental Society will be held at the New Hotel Weirs, Weirs, N. H., June 22, 23, and 24, 1915.

C. S. COPELAND, *President*,
L. I. MOULTON, *Sec'y*.

MINNESOTA STATE DENTAL ASSOCIATION.

The thirty-second annual convention of the Minnesota State Dental Association will be held in Minneapolis, Minn., June 11 and 12, 1915.

Max E. Ernst, *Sec'y*,
St. Paul, Minn.

MAINE DENTAL SOCIETY.

The fiftieth anniversary meeting of the Maine Dental Society will be held in the Lafayette Hotel, Portland, Me., on June 28, 29, and 30, 1915.

I. E. Pendleton, *Sec'y*,
Lewiston, Me.

KENTUCKY STATE DENTAL ASSOCIATION.

The Kentucky State Dental Association will hold its forty-sixth annual meeting at Ashland, June 8, 9, and 10, 1915. The program will be carried out on the progressive clinic order. All reputable dentists are invited to attend.

Chas. R. Shacklette, *Sec'y*,
Louisville, Ky.

MISSOURI STATE DENTAL ASSOCIATION.

Change of Date of Meeting.

The Golden Jubilee meeting of the Missouri State Dental Association to be held at Jefferson City, Mo., has been postponed until June 10, 11, and 12, 1915. Elaborate preparations are being made to celebrate the semi-centennial meeting of this association on an elaborate scale. Special announcement later. For information address

S. C. A. Rubey, *Sec'y*,
1017 New York Life Bldg., Kansas City, Mo.

RICHMOND COUNTY (N. Y.) DENTAL SOCIETY.

On February 10, 1915, at the Hotel St. George, the Richmond County Dental Society of the dentists practicing on Staten Island was organized for the mutual benefit of all practicing dentists of the island, and for the promotion of friendly relationship between the members of the profession, the following officers being elected: C. G. Stiles, president; J. A. Smith, vice-president; D. J. Machol, secretary; L. A. Lamonte, treasurer.

The regular monthly meetings of the newly organized society will be held on every second Monday of the month. The first regular meeting was held on March 8th, every practicing dentist of Staten Island, but one, attending.

NEW JERSEY STATE DENTAL SOCIETY.

The forty-fifth annual convention of the New Jersey State Dental Society will be held at Asbury Park on July 21, 22, 23, and 24, 1915.

The headquarters will be located at the Coleman House. The ballroom will be used for all meetings of the society. The glass-inclosed Casino over the ocean, just across the ocean drive from the Coleman House, has been secured for the exhibits and clinics. With over 2000 more square feet of floor-space than the pavilion used last year there should be adequate room.

Dr. Chauncey F. Egel of Westfield, N. J., is chairman of the Exhibit Committee, and reports that applications are already being made for space. Dr. W. W. Hodges of Perth Amboy is arranging for an attractive list of clinics. The Essay Committee, under the chairmanship of Dr. James I. Woolverton of Trenton, will have three essayists of prominence to present.

A cordial invitation to attend is extended to all ethical practitioners.

John C. Forsyth, *Sec'y*,
430 E. State st., Trenton, N. J.

MARYLAND BOARD OF EXAMINERS.

The Maryland Board of Dental Examiners will meet for examination of candidates for certificates May 27 and 28, 1915, at the Dental Department of the University of Maryland, Baltimore, at 9 A.M.

For application blanks and further information, apply to

F. F. Drew, *Sec'y*,
701 N. Howard st., Baltimore, Md.

VIRGINIA BOARD OF EXAMINERS.

THE regular annual meeting of the Virginia State Board of Dental Examiners, for the examination of applicants to practice dentistry in the State of Virginia, will be held in the city of Richmond, Va., June 8, 1915, commencing at 9 A.M.

For further particulars apply to

J. P. STIFF, *Sec'y*, Fredericksburg, Va.

NEBRASKA BOARD OF EXAMINERS.

THE next meeting of the Nebraska Board of Dental Examiners will be held at Lincoln, Nebr., beginning at 9 A.M., Wednesday June 9, 1915.

All applications must be in the hands of the secretary not later than June 1, 1915. Application blanks may be obtained by addressing

J. H. WALLACE, *Sec'y*,
212 Brown Block, Omaha.

NEW HAMPSHIRE BOARD OF REGISTRATION.

THE annual meeting of the New Hampshire Board of Registration in Dentistry, for examinations, will be held June 14, 15, and 16, 1915, at Masonic Banquet Hall, Manchester, N. H.

For application blanks or further information address

HARRY L. WATSON, *Sec'y*,
913 Elm st., Manchester, N. H.

WISCONSIN BOARD OF EXAMINERS.

THE Wisconsin State Board of Dental Examiners will convene in Milwaukee, at Marquette University, on June 21, 1915, at 2 P.M., for examination of applicants.

High-school diploma, application, and $25 fee to be filed with the secretary ten days prior to above date. Dental diploma to be presented in advance of the examination.

Junior dental students presenting a clear card for two years' unconditional work from a reputable dental college and filing a high-school diploma, or its full equivalent, will be permitted to participate in the theory examination in the following six major subjects: Anatomy, physiology, histology, chemistry, bacteriology, materia medica. Satisfactory grades made in these subjects will be credited at subsequent examinations.

Special application blanks for this examination and $10 fee, together with high-school credits, to be filed ten days in advance.

S. H. CHASE, *President*,
W. T. HARDY, *Sec'y*,
1404 Majestic Bldg., Milwaukee, Wis.

CALIFORNIA BOARD OF EXAMINERS.

THE next meeting of the Board of Dental Examiners of California for the purpose of examining applicants for a license to practice dentistry will be held in the city of San Francisco, beginning on June 4, 1915. This examination will be followed by one to be held in the city of Los Angeles, beginning on June 18, 1915. For further particulars, address

C. A. HERRICK, *Sec'y*,
133 Geary st., San Francisco, Cal.

MICHIGAN BOARD OF EXAMINERS.

THE next regular meeting of the Michigan State Board of Dental Examiners, for the examination of applicants who wish to practice dentistry in Michigan, will be held in the dental college at Ann Arbor, beginning Monday, June 14, 1915, at 8 A.M., and continuing through Saturday, June 19th.

For application blanks and full information apply to

A. W. HAIDLE, *Sec'y*, Negaunee, Mich.

NORTH CAROLINA BOARD OF EXAMINERS.

THE next regular meeting of the North Carolina State Board of Dental Examiners will be held at Wrightsville Beach, Wilmington, N. C., beginning promptly at nine o'clock on Monday morning, June 21, 1915. Full information and application blanks may be secured by addressing

F. L. HUNT, *Sec'y*, Asheville, N. C.

SOUTH CAROLINA BOARD OF EXAMINERS.

THE next annual meeting of the South Carolina State Board of Dental Examiners will be held at Columbia, S. C., beginning at 9 A.M., Tuesday, June 15, 1915.

All applications must be in the hands of the secretary not later than June 5th. Application blanks and instructions from

R. L. SPENCER, *Sec'y*, Bennettsville, S. C.

MAINE BOARD OF EXAMINERS.

The Maine Board of Dental Examiners will meet in the State-house, Augusta, Me., July 1, 2, and 3, 1915.

I. E. Pendleton, *Sec'y*,
Lewiston, Me.

TEXAS BOARD OF EXAMINERS.

The next regular meeting of the Texas State Board of Dental Examiners for the examination of applicants for license to practice dentistry in the State of Texas will be held in the high school building, Dallas, Texas, beginning June 21, 1915, at 9 A.M.

No interchange of licenses with other states. No diplomas recognized. Rules governing examinations and official application blanks will be sent upon request.

All parties desiring to take this examination should send their application, accompanied by fee of $25, to the secretary not later than June 15th.

For further information address

C. M. McCauley, *Sec'y*,
434 Wilson Bldg., Dallas, Texas.

ARMY DENTAL SURGEONS.

Memoranda of Changes.

For the week ending January 16, 1915:

First Lieut. Alden Carpenter is granted two months' leave of absence, to take effect upon his relief from his present duties.

For the week ending Saturday, February 6th:

Acting Dental Surgeon Charles E. Sherwood is relieved from duty at Schofield Barracks, Hawaii, and will proceed to his home, and upon arrival at home report by letter to the Surgeon-general of the army for annulment of contract.

(Same.) Granted leave for twenty-five days, to take effect upon his arrival in the United States.

For the week ending Saturday, February 13th:

Acting Dental Surgeon Oscar G. Sketlon is relieved from duty at Fort Huachuca, Ariz., and will proceed to Douglas, Ariz., for station and duty, reporting upon arrival by letter to the commanding general, Southern department.

United States Patents

PERTAINING OR APPLICABLE TO DENTISTRY

ISSUED DURING FEBRUARY 1915.

February 2.

No. 1,126,949, to Georges A. Brouillet. Process of filling teeth.

February 9.

No. 1,127,635, to Robert M. Kerr. Dental impression tray.

No. 1,128,045, to Gustaf Libert. Tooth-cleaning device.

THE

DENTAL COSMOS.

VOL. LVII. MAY 1915. No. 5.

ORIGINAL COMMUNICATIONS.

THE TREATMENT OF INTERSTITIAL GINGIVITIS AND PYORRHEA ALVEOLARIS.

By EUGENE S. TALBOT, M.S., D.D.S., M.D., LL.D., Sc.D., Chicago, Ill.

TWO methods of treating interstitial gingivitis and pyorrhea alveolaris have recently been instituted which will bear critical analysis. The first is that of "vaccine therapy," the second "emetin treatment." As a matter of convenience we will discuss the second theory first.

EMETIN TREATMENT.

Dr. M. T. Barrett of Philadelphia first published a paper* read before the Pennsylvania State Dental Society in Philadelphia, July 1, 1914, entitled "The Protozoa of the Mouth in Relation to Pyorrhea Alveolaris."

On August 1, 1914, Dr. Angelo Chiavaro of Rome, Italy, read a paper before the American Dental Society of Europe, at Paris, entitled "Researches upon the Endamœba Buccalis."† In summing up his findings Professor Chiavaro concludes that—"The endamœba has no pathogenic action; on the contrary, as it feeds on bacteria, it is most probably an adjuvant in the autodisinfection of the mouth."

PROBLEM OF THE PATHOGENICITY OF THE ENDAMŒBA BUCCALIS.

Barrett, who was assisted in his work by Dr. Allen J. Smith, professor of pathology in the University of Pennsylvania, shows that the endamœba has been found by other scientists in different localities of the mouth. Their own experiments thus far have been confined to the contents of pyorrhea pockets, for he says: "While thus far we have found our organisms only in the contents of pyorrhea pockets, and have failed in some normal mouths to encounter them; and while, for another reason, to be given hereafter, the organisms seem distinctly pathogenic to us, it should be at once stated that these points of difference are by no means at this time of differential importance." The other reason seems to be that—

* DENTAL COSMOS, August 1914, p. 948.
† *Ibid.*, September 1914, p. 1089.

"While confident of the actual pathogenic importance of these parasites from their uniformity of occurrence and distribution, and from the evidence of their ingestion of leucocytes and erythrocytes, we did not feel justified in attempting inoculation experiments, although these are contemplated in animals in future work. It was believed, however, that evidence might be obtained in the matter of pathogenicity of the organisms by having recourse to the use of emetin, which has been found practically a specific remedy against the endamœba of dysentery within the past few years."

It will be observed that one believes that the endamœba is not pathogenic, the other that it is. In a later paper,* "Clinical Report upon Amœbic Pyorrhea," Dr. Barrett says: "As a matter of fact, in a large number of cases which have thus far come under observation, the parasites have been found present in the contents of the pyorrhea pockets almost uniformly; yet there have been a few cases in which they have not been discovered, and in any case it would be illogical to deny associated importance to the myriads of other organisms which are also found in the lesion. However, the fact of the presence of these protozoa in so large a proportion of the pyorrhea pockets, and the disappearance of the suppuration under appropriate treatment by a known amœbicide such as emetin, have served to justify the claim that they are the immediately important factors in an overwhelming number of pyorrhea cases, and that this group of cases may with propriety be denominated as amœbic pyorrhea, in contradistinction to the smaller class of cases in which they are not found, and which are due probably to other causes."

ADJUVANT IODIN TREATMENT.

Again, under the subheading "Adjuvant Iodin Treatment in Refractory Cases," he says:† "In exceptional subjects, response to the emetin treatment has been found encouraging at first, but to be limited. The quantity of pus diminishes in such cases, and the general appearance of the tissues improves. The patients invariably feel better, and there is unmistakable improvement; yet prolonged treatment with emetin does not effect a complete cure. There is obviously something more to be done, as the structures lack desirable 'tone.' One may suspect that in these cases bacteria of importance remain after the destruction of the endamœbæ by the emetin; as a matter of fact it has been found that a 1 per cent. solution of iodin in normal salt solution has usually completed the removal of the persisting condition. In the experience of the writer, but a single case of this sort has failed thus to clear up, and this instance will be more fully discussed below. The iodin application, following the use of emetin, should be employed daily, the drug being well introduced into the pockets as was the emetin. Good results should follow two or three applications."

CRITIQUE OF DR. BARRETT'S WORK.

Dr. Barrett's reasoning in these two articles, passages of which have just been quoted, would hardly inspire one with confidence either in his etiology or treatment, since he has not followed the law of Koch, which must be adhered to to obtain results. The law of Koch may be stated as follows:

(1) The organisms must be present in all cases of this particular disease.

(2) The organisms must be isolated from the disease body and propagated in pure culture.

(3) The pure culture of the organisms, when introduced into susceptible animals, must produce the disease.

(4) In the disease thus produced, the organisms must be found distributed as in the natural disease.

Dr. Barrett does not seem to have confidence in the endamœba as the cause of pyorrhea. He says, "It should be stated here that none of those who

* DENTAL COSMOS, December 1914, p. 1345.
† *Ibid.*, p. 1347.

have been engaged in this study have held or now believe that all cases of pyorrhea are due primarily or alone to the presence of the oral endamœba." Again, the treatment seems not to be satisfactory, since he says, "In exceptional subjects response to the emetin treatment has been found encouraging at first, but to be limited." He then resorts to the iodin treatment.

It has been estimated that there are at least 150 varieties of germs in the mouth. Why select one of the least harmful, according to Chiavaro, and give it all the credit for pyorrhea, and leave some of the most pathogenic as not worthy of consideration? If we use emetin and destroy the endamœba, what becomes of the other 149 germs? What shall we do with the streptococcus group, the staphylococcus group, and the pneumococcus, as well as other pathogenic bacteria in the mouth? Why spend time examining the contents of the pockets to see if the amœba is present, in order to use the emetin, when with a "Krupp siege-gun prescription of iodin" the entire 150 varieties of bacteria may be annihilated at one explosion, if it comes in contact with them?

In a specific disease, such as diphtheria, typhoid fever, and amœbic dysentery, if the cause of the disease is removed the patient gets well. Every person after the first teeth have erupted has an inflammation of the gums and alveolar process to a greater or less extent throughout life, while only 10 per cent. of all people have pyorrhea. The question is naturally asked, What causes the 90 per cent. of inflammation? After reading the two articles one is all at sea as to what is to be expected from this method of reasoning.

If, as he says, he "has failed in some normal mouths to encounter amœbæ," one naturally draws the conclusion that he did find them in some normal mouths, as others have. If he thought they were the cause of pyorrhea, why did he not inoculate animals and obtain the disease and then cure it by the use of emetin. The amœbæ, according to other observers, are also found in decay of the teeth, in the throat, and in other parts of the mouth; why will it not cure diseases of these structures?

Later investigations however, do not pan out as well, for he says that "None of those who have been engaged in the study have held or now believe that all cases of pyorrhea are due primarily or alone to the presence of the oral endamœba." Again, he says, "After using the emetin treatment the patients invariably feel better, and there is unmistakable improvement; yet prolonged treatment with emetin does not effect a complete cure." After all, he must resort to the iodin treatment, for he says, "There is obviously something more to be done. . . . As a matter of fact, it has been found that a 1 per cent. solution of iodin in normal salt solution has usually completely removed the persisting condition." Hence it will be seen that he does not consider that emetin is a specific for pyorrhea. In order to get good results the deposit must be removed from the roots of the teeth. He lays considerable stress upon this procedure. If the disease is due to the amœba, and it can be cured by the application of emetin, why remove the deposits? My experience has been that by removing the deposits alone the pus infection nearly or quite ceases. The presence of pus is a splendid diagnostic sign that the deposits are not all removed.

INADEQUACY OF THE TERM "PYORRHEA."

For more than twenty-five years I have tried to educate the dentist, and more especially the dental teachers, that the term "pyorrhea" is not the proper term to use in describing the disease of the gums and alveolar process in which there is a progressive absorption and eventually exfoliation of the teeth. I have laid particular stress upon the fact that teachers could not make clear and students could not understand the pathology of the disease by the use of this term. Only last month a prominent teacher stated in a dental society, in dis-

cussing "pyorrhea," that "In the use of emetin the pus germs are destroyed, and the disease gets well." Such ignorance of the simplest principles of pathology should prohibit him from teaching. Such loose terms have confused some of the medical profession in regard to the pathology. Since the vaccine treatment has been employed I am constantly being asked by laboratory men and practitioners to give my views in regard to the etiology and treatment of the disease, since they are at sea in regard to the nature and pathology of the tissues expressed by the term "pyorrhea."

THE WRITER'S FINDINGS.

Others have done research work upon this disease, and their conclusions should be worthy of consideration. I shall briefly state here the result of over thirty-five years' study of this disease. We have two distinct and separate conditions to deal with—first, an inflammation of the gums and alveolar process; second, pus infection. Every animal —including man—who possesses only two sets of teeth has the inflammatory process going on in his mouth throughout life, to a greater or less extent. Only about 10 per cent. of the patients have pyorrhea. Two conditions are necessary for a man or an animal to have pyorrhea—first, inflammation; second, pus germs to infect the part. Hence, although a person may have the inflammatory process going on in his mouth throughout the process of the exfoliation of the teeth, without pus germs are present, infection cannot take place. This explains why so few people have pyorrhea and yet lose their teeth.

The inflammation, which I have termed "interstitial gingivitis," may begin at the gum margin, at the apical end of the root, or at any point midway between the end of the root and gum margin, and extend throughout the length of the alveolar process. Absorption of the bone is due to the inflammatory process, and is not caries of bone.

No one up to the present time has been able to produce the inflammatory process by infection. Many, including myself, have tried it. On the other hand, I have demonstrated to my own satisfaction that the inflammatory process is due to irritation, both local and constitutional. I do not believe that pyorrhea has anything to do with the inflammatory conditions. Hence a drug may be applied and the pus germs destroyed, but the inflammation still remains. No matter what the treatment may be, the inflammation and absorption are never cured. The tooth so far as the disease is concerned is a foreign body, since arteries and nerves do not enter its structure. In order that we may understand my conclusions, we must study the nature of the tissues under discussion.

The pathologic changes which take place are due to the unique function of these structures. The evolution of the face due to environment and change of food causes the jaws to recede, as large jaws and teeth are not required for mastication. My researches have shown that formerly the jaws measured an average of 2.50 inches from the outside of the first molar to the outside of the other. Today the average is about two inches. The antero-posterior length has diminished in proportion. The result is that the alveolar process, which was once short and thick, has become long and thin. The blood supply of the jaws and alveolar process is diminished. The bone which covers the roots of the teeth, originally was quite heavy and well nourished. At the present time it is often as thin as a sheet of paper, and in some cases there is little or no bone on the outer surface of the roots of the teeth.

With this evolution of structure going on, the jaws and their alveolar processes may be called transitory structures. This, however, is not all. At birth there is no alveolar process; when the first set comes into place the process builds itself about the roots to hold them in position: when they are shed the bone absorbs away. As the second teeth erupt the bone is redeposited to a greater ex-

tent, because the roots are longer and more work is required of them. When these teeth are removed the process rapidly absorbs away. The bone, therefore, is expressly intended to hold the teeth as long as they remain in the jaws. Again we note that the alveolar process is a transitory structure. We have, then, in the alveolar process, a doubly transitory structure, very susceptible to disease. The alveolar process is an end organ. The arteries and nerves that supply the process are small and tortuous, and extend as far as the root of the tooth. The tooth, so far as the disease is concerned, is nearly a foreign body. The nerves and arteries do not enter the tooth substance. Poisons circulating in and about them set up irritation and inflammation. The higher vertebrates have only two sets; while the two sets are intended to last throughout their lives, yet there is an atavistic tendency to absorption of the alveolar process. If man could live long enough in a fairly healthy condition he would lose this second set of teeth. After the process has obtained its growth it becomes senile, so to speak, having performed its function, the art of mastication having in a sense been lost; a low vitality results with absorption, which I have called "osteomalacia." All animals possessing two sets of teeth have this disease. Dogs, especially house-dogs, are the best animals upon which to study. After this explanation of the structures and function of the tissues involved, we can understand how the slightest irritation, either local or constitutional, will set up irritation, followed by inflammation and absorption of bone as a result, which will continue until the tooth becomes loose and drops out. Place a rubber ring around the neck of the tooth against the gum: in the healthiest mouth an inflammation of the gums throughout the alveolar process to the end of the roots is the result, and if pus germs are in the mouth they will infect the tissues. The so-called "pyorrhea" is a secondary condition. Treat a patient with mercury for a specific disease —until when? Until the gums become sore and inflamed—and then stop. Why watch the gums and not the fingers or toes or other structures? Because the alveolar process is a transitory process and an end organ. Therefore the process is one of the first if not the first structure in the body to respond to constitutional irritation.

I could go on indefinitely with illustrations which have come under my observation, but enough has been given to show the relation between systemic disturbances and alveolar inflammation. In a general way, therefore, a local or a constitutional irritation such as the metal or drug poisons or auto-intoxication will start the inflammation and absorption. Germs are always present in the mouth. Infection is always a secondary consideration, and therefore cannot be the sole rôle of the disease. I am considering the cases which come to the dentist and are called pyorrhea, interstitial gingivitis, or Riggs' disease, and not such infections as tuberculosis, anthrax, actinomycosis, etc., which have other constitutional symptoms and require the care of a general practitioner of medicine. Focal infection from the mouth producing systemic disease is not considered in this paper. It seems to me, therefore, that the only influence pus infection—pyorrhea—has in connection with the disease "interstitial gingivitis" is that it is a medium through which the absorbed alveolar process is conveyed from the process and deposited upon the roots of the tooth, and is called by the dental profession "serumal deposits."

THE VACCINE TREATMENT.

After what has been said in regard to the etiology of the disease, it is useless to spend time in discussing the subject of vaccine treatment. I can only say that, so far as we know at the present time, the disease being due to irritation and not to infection. the effect of this treatment would be almost *nil*.

The first thing to do in the treatment of the mouth is to place the mouth in a presentable condition, by the application of iodin about the gums, teeth, and

mucous membrane. The number of visits and applications will depend upon the condition of the mouth and the fastidiousness of the operator. No operator is justified in placing his hands in or spending much time examining a dirty mouth.

Give the patient a gum-wash and a gum-massage brush, and request him to use both vigorously until presentable for operating. The gum-massage brush should be made of unbleached bristles to obtain stiffness. Remove all irritants, both local and constitutional. See that the patient is in good health. Place the eliminating organs in a normal condition. Deplete the gums and alveolar process of stagnant blood; stimulate the bloodvessels and nerves to a healthy action. This may be accomplished by vigorous gum massage and astringent gum-washes or by vacuum treatment, or both. This treatment will improve the health of the tissues, but will not completely cure the disease.

CONCLUSIONS.

The following points have been brought out by the author in his more than thirty-five years' research:

(1) The evolution of the head, face, and jaws has caused the alveolar process to become more susceptible to disease. The processes are longer and thinner, and the blood supply is lessened.

(2) The alveolar process is a doubly transitory structure.

(3) The alveolar process is an end organ or structure.

(4) The tooth so far as this disease is concerned is a foreign body.

(5) The alveolar process when it has completed its growth about the second set of teeth becomes senile, and a low form of bone absorption begins, and continues throughout life.

(6) The alveolar process when completed loses its vitality, the resistance is lowered, and irritation and inflammation attack the tissues.

(7) Any constitutional disease will lower the vitality of the alveolar process.

(8) The disease which attacks the gums and alveolar process is divided into the inflammation and pus infection.

(9) The inflammatory process is due to both local and constitutional irritation.

(10) Infection as a cause of the inflammation and the absorption has not yet been demonstrated.

(11) Inflammation always precedes pus infection.

(12) The irritation and inflammation may begin at the gum margin, at the apical end, or at any point between the neck of the tooth and end of the root—hence the term Interstitial Gingivitis.

(13) Every animal, including man, which has two sets of teeth, has the disease to a greater or less extent after the eruption of the first set.

(14) The nearer the animal lives to nature, the less liable is he to have the disease; on the other hand, wild animals domesticated are very susceptible to the disease.

(15) Only about ten to fifteen per cent. of humans have pus infection.

(16) Outside of calcarious deposits, modern dentistry has caused more inflammation and absorption of the alveolar process than any other one cause.

(17) Deposits upon the roots of teeth —not tartar—are the absorbed alveolar process and not "serumal deposits."

(18) The absorption of bone is a natural process and is not caries. I have called it juvenile and senile osteomalacia, depending upon the age of the patient.

(19) The disease is progressive: it is never cured in the sense that other diseases of the body are cured.

(20) The alveolar process, when once destroyed, is never reproduced after the patient has attained his growth.

TREATMENT.

(1) Use iodin to destroy germs and clean up the mouth before scaling the teeth.

(2) Use gum-massage brush and gum-wash three times a day.

(3) The soft-bristle tooth-brush is of no use in treating this disease.

(4) The gum-massage brush should be made of the stiffest unbleached bristles.

(5) The ordinary tooth-brush will not reach the gum margins.

(6) Remove all irritants, both local and constitutional.

(7) By removing deposits about the root of the tooth the pus ceases to exist.

(8) See that the patient is in good health.

(9) Place the eliminating organs in a normal condition.

(10) Deplete the gums and alveolar processes of stagnant blood. This may be accomplished by scarifying the gums and depleting the tissues while removing the deposits by vacuum treatment, and by vigorous action of the gum-massage brush.

(11) Stimulate the tissues to a healthy action.

These points have all been brought out in my researches, and have been published from time to time. They cannot, therefore, be ignored. Those who read papers or do research upon the subject of "interstitial gingivitis" and "pyorrhea alveolaris" must either indorse these statements or after a reasonable amount of research disprove them. Too many papers are read and much time wasted by essayists, who only express their views upon this subject, which makes their papers worthless.

MODERN CROWN AND BRIDGE CONSTRUCTION.

By THOMAS P. HINMAN, D.D.S.,
PROFESSOR OF OPERATIVE DENTISTRY AND ORAL SURGERY, ATLANTA DENTAL COLLEGE, ATLANTA, GA.

(Read before the union meeting of the Georgia State Dental Society and the Southern Branch of the National Dental Association, Atlanta, Ga., June 4, 1914.)

(1) Crowns.

IN modern crown and bridge work such a great advance has been made recently that I thought at this time it would be wise to discuss some of the newer methods. For a long time I have noticed that the labial and lingual surfaces of the gum would recede at the gingival, and was at a loss to discover the cause. After years of observation I have found a logical reason for this recession. The reason is, that these surfaces, *i.e.* the lingual and labial, of the crowns were not correct anatomically. In most crowns the lingual surface is left comparatively flat, or in some instances concave, when it should be concavo-convex, the convex surface being, of course, near the gum line, and reproducing the marginal ridge. If the labial is also left convex, the crown correctly adjusted, and the root surface properly covered, there will be no recession, because the food will be deflected from contact with the gingival margin of the gum, thus shielding it from injury.

The recession of which I speak is caused by the food being driven against these tender surfaces, causing a tearing away of the gum. This same thing is true in the construction of all-gold crowns; unless they are properly contoured either on buccal or lingual surfaces, the same unfortunate condition will arise.

(2) Root Preparation.

In the preparation of the roots of the anterior teeth, instead of making a perfectly flat stump, the root should be cut concave mesio-distally to conform with

the outline of the gum margin. If this is done properly, the inflammation so frequently observed in the septal area will not occur. The reason for this inflammation is that the septal tissues are interfered with by the crown's pressing against them. Of course, it must be understood that proximal contact must be carefully carried out. In the preparation of the root for an all-gold crown, it is the exception to find a proper amount of removal of tooth structure; frequently just enough of the tooth is cut away to allow the gold to pass between the teeth and skirt out at the bottom, allowing the gold to impinge on the gum tissue. If a proper technique is followed, this operation is very much simplified. My rule is to first cut away enough of the occlusal surface to allow a proper restoration in gold. These cusps should contain a considerable amount of metal; frequently I find they are made of a single layer of No. 28 gage, the operator failing to cut away sufficient tooth structure to allow enough gold to be placed in position to make the crown sufficiently strong to resist the wear of mastication.

On the mesial side, a seven-eighth inch depressed rubber and carborundum stone is used to cut off the entire mesial surface. This cut should be made liberal, beginning about 3/32 of an inch from the point of approximal contact, and the entire mesial surface removed in one slab, the line of cut gradually diverging toward the mesial surface in such a manner as to produce the reverse of the natural tooth form. The same process is used on the distal surface; then the lingual and labial surfaces are ground away, beginning at the gingival and cutting toward the occlusal. This being properly done, we have left a stump in the shape of a pyramid, the apex of which has been previously cut off. All that remains, then, is for the corners to be rounded, which may be done with a No. 9 corundum stone; the balance of the trimming should then be done with Ivory's cervical trimmers, which I have found the most perfect I have been able to secure.

The measure is taken, and the band that is made should be larger toward the occlusal surface than where it fits around the stump. This will allow for proper contouring. After the band has been made and contoured and adjusted, it is returned to the mouth, and an impression and bite taken. This is placed in a small articulator and the occlusal surface restored in wax. When invested and cast, we are able to produce a crown far better in appearance and anatomical form than by any of the methods of stamping cusps from fixed forms.

A more perfect crown may be produced by making a parallel band of 32-gage platinum on which, after adapting to the root, is soldered a flat top of the same metal. This cap and band are placed in the mouth and an impression and bite taken; these are placed in a small articulator and the whole platinum surface covered with inlay wax by melting. This wax is then carefully carved to correct form, the cusps and bite-planes restored, and the whole invested and cast. This gives a perfect seamless crown which, for adaptation and contour, cannot be surpassed.

In the construction of the so-called Richmond crown, when the root is properly prepared, the circumference of the stump is much smaller than the natural root-end; if due allowance is not made in placing a cap on the band, we will have a surface that is abnormally small to put the porcelain facing to. This produces a very unsightly appearance, which may be obviated by allowing the cap to extend beyond the area of the band about 1/32 of an inch, trimming this band to an even extension all around. Solder is then flowed around the band to fill the triangle left by the projecting cap. This will give a normal size to the cap, allowing a proper width of porcelain at the gum line. Crowns made by this method have a better cosmetic appearance, and the gingival tissues are restored to their normal relation, adjusting themselves in such a manner as is conducive to their health.

In the adjustment of single all-porcelain crowns to the anterior teeth, I have experienced a great deal of difficulty in grinding a satisfactory joint, as well as

frequently finding that the porcelain was either smaller or larger than the root-end. To obviate this difficulty and to facilitate perfect adjustment, I have hit upon the following simple method, which obviates the necessity of casting or soldering the joint between the crown and the root-end.

We will illustrate by using a pinless crown of any make. The root-end is prepared as directed in the first part of this paper, being sure, however, to cut the root-end under the gum line, especially on the labial surface. The canal is enlarged to admit a 16-gage wire—and I have found that clasp wire is a very satisfactory substitute for platinum for such work. The end of the wire is pointed and pushed through a disk of 3/1000 pure gold. The pin and disk are placed on the tooth, and the pin pushed home. The disk is then burnished against the root-end. This construction is removed and the disk soldered to the pin with a very minute quantity of solder, returned to the mouth, and the disk carefully burnished and trimmed to fit the root-end. The wire pin is cut off, allowing about 1/8 of an inch to extend beyond the disk so as to allow a firm hold for the cementation of the crown on the pin.

The construction is removed; then an impression is made, which should include the adjoining teeth, and a model run in plaster. This model should have one coat of shellac to give its surface additional resistance. The porcelain crown may then be accurately ground to fit the gold disk, which represents the root-end, as every surface is visible. The crown should then be cemented to the disk and pin, and when the cement has thoroughly set, the whole construction is removed from the model and the joint polished of any overhanging or excess cement; the crown is then ready for cementation in the mouth.

By this method, all porcelain crowns may be adjusted perfectly to root-ends in a rapid and satisfactory manner, with the additional advantage that the greater part of the work is accomplished out of the mouth.

(3) Bridge Work.

For many years, in bridge construction the sole aim of the operator seemed to be the restoration of the labial surfaces of the missing teeth, very little attention being given to the lingual aspect of the restoration. All have observed the lack of correct enunciation, especially of the sibilants, by persons who were wearing anterior bridges, where no attempt was made to restore the individual lingual surfaces of the teeth. Such bridges cause a decided defect in pronunciation, and are far from being a satisfactory restoration. They might be likened to a building with a superb front, with noble columns, and a back containing only a hovel. It is just as important to make a correct lingual surface to crowns and bridges as it is to have correct shade and contour of the porcelain facings.

Such bridge work is readily constructed by the use of the Goslee teeth, or if it be impossible to secure them, the lingual surfaces may be restored by using any interchangeable facing, and casting lingual contour on the backing. This work requires individual saddles, but these are so readily made by casting that their construction should be no hindrance.

In the construction of the individual saddle bridge, the dummies should be constructed separately, polished to a pumice finish, and then assembled on the model and attached to each other by soldering only the incisal half, thus allowing a free space at the gingival portion between the dummies, making a restoration of the septal area. This facilitates cleansing and produces a more sanitary bridge than the old so-called self-cleanser, which, in truth, was just the opposite—a filth accumulator.

Time forbids my going into the full technique of this form of construction, but in recommending it for your consideration, I feel justified in doing so by years of careful observation and practice.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

PROBLEMS OF PAIN AND OTHER ORAL SENSATIONS.

By ARTHUR HOPEWELL-SMITH, L.D.S., L.R.C.P., M.R.C.S., Philadelphia, Pa.,
PROFESSOR OF DENTAL HISTOLOGY, HISTO-PATHOLOGY AND COMPARATIVE ODONTOLOGY,
SCHOOL OF DENTISTRY, UNIVERSITY OF PENNSYLVANIA.

(Read before the Academy of Stomatology of Philadelphia, at its monthly meeting, held January 26, 1915.)

INTRODUCTORY.

THAT the mouth is the most important external orifice of the animal body is a self-evident proposition. The statement admits of no refutation. Its position at the entrance to the alimentary tract dominates the situation, for it is the *via media* which intervenes between outside conditions and that complex internal mechanism or those groups of mechanisms whose function is to sustain life. Containing no organs in themselves vital to those potential or animating principles or states of being which are designated by the word life, it is a more or less simple cavity when considered from the anatomical point of view.

Yet, regarded physiologically, present knowledge is very incomplete and scanty; and even histologically, but little is known with certainty about the nature of its confines.

In man it is a remarkable cavity, too, in the tolerance with which it—the site of much-continued traumatism, the receptacle for all kinds of foreign bodies—allows itself with impunity to suffer all kinds of abuse, such as the diurnal variations in temperature induced by constant contact with all manner of hot and cold, solid and liquid foods. The relatively infrequent occurrence of malignant diseases of the various parts of its mucous membrane is truly an extraordinary thing, if one attempts to estimate the approximate numbers of extraneous substances in the form of mechanical appliances which are being employed by many millions of people, and to take into account the amount of harm they do. As to the real nature of the properties of the mucous membranes lining its walls we have but little information. They must be remarkable, powerful, distinct from and even more delicate than those of the general integument which clothes the body—remarkable because of the limited area which they cover; powerful in withstanding injuries and diseases; different from those of the corium, for they do not govern or regulate body temperature and possess only local second-rate excretive or secretive functions which are unessential to life; and delicate, inasmuch as, by reason of being in a sense protected from outside interferences by the lips, they respond very readily to various tactile, thermal, and electrical impressions, probably more quickly than the epidermis itself.

The propinquity of sensitive and insensitive areas in the mouth is remarkable and noteworthy. For instance, the inner margins of each gingival trough, at the cervical portions of the teeth, are exquisitely painful to the touch on applying the fine point of a probe or explorer, on account of the presence in this region of the free edge of the periodontal membrane, which is here merely covered with a thin layer of epithelium; whereas the upper boundaries of the same trough and the tissues over the alveolar processes of the jaws are insensitive and practically immune to pain when receiving tactile stimulation.

A similar and familiar instance is

supplied by the relationships between the conjunctiva and the fold of the eyelid; a more remote likeness exists in the parts at the junction of the soft tissues and the bed of the nails of the fingers—the so-called "nail-groove."

If one adds to the foregoing considerations the presence in the mouth of those unique bodies the teeth, and that marvelous organ the tongue, it will be at once conceived that in this region of the body there still exists a large field for original observation, replete as it is with unsolved problems of a physiological and pathological nature, which are frequently demanding greater and greater attention on the part of the microscopist, physiologist, and pathologist.

The subject covers a vast field. Within the limits of this address it is only possible to discuss certain aspects of some problems of pain and oral sensations which, though very recondite, are of profound significance and importance.

PART I.—Physiological Considerations.

In spite of becoming accustomed to having placed within it all kinds of food, the mouth instantly, by means of the co-ordinated impulses on the part of the sensory nervous mechanism, working in conjunction with the motor apparatus of its parts, rejects any particle which is unsuited to the process of ultimate metabolism. Thus nature guards the functions of the oral cavity.

The nerves distributed to the tongue and boundaries of this cavity are not solely responsible for this rejection of improper foodstuffs; experience and the other organs of the senses, and certain centripetal aisthenic (*αἰσθάνεσθαι*, "to perceive or feel") ideas associated with them play their part.* Three illustrations from the animal world will make clear this point.

A butterfly is attracted to its food or is repelled by the sense of sight, and is therefore the subject of a largely-developed opsaisthenic faculty. It will flutter toward a colored object—say a piece of red paper lying on the roadway—thinking that it is a flower, and will as quickly fly away with disgust on discovering its mistake.

Rhinaisthenics, or osphresis, the critical olfactory sense, actuates the female mosquito, and other mature *diptera,* to attack the exposed parts of animals, including man, whence it can indulge its blood-sucking proclivities.

Coming higher in the scale of life, a dog seeks its food mainly through the exercise of its power of gumaisthenics or the sense of taste, backed by experience or the activities of memory and imagination: though of course here again the olfactory sense is an important adjuvant. A dog rejects, as a rule, the eating of such things as oysters, but an educated town-bred "toy" dog will eat them with evident relish, as well as such articles of diet as cucumber, asparagus, nuts, etc. In this respect it resembles man, who, as Sir Ray Lankester points out, "in many things is still entirely guided by unreasoning mechanical instinct, and in others is partly impelled by the old inherited instinct, partly restrained and guided by reason based on experience and memory." Experience and memory both come within the ken of an intelligent or what we call an "educated" dog.

Thus it is apparent that the aisthenic

* This term, originally suggested by the late Alfred Smee, F.R.S., in "The Mind of Man," 1875, comprises "those representations which are carried to the brain through the medium of the nerves from impressions made on the eye, ear, nose, tongue, and skin." The phrase and its derivatives are used in this paper as a distinctive expression from the more modern term "æsthetic" (or "esthetic"), which conveys a different meaning, and nowadays is differently applied. Thus esthetics means "the theory or philosophy of taste" and "the science of the beautiful in nature, and more especially in art." Further, this word must be carefully distinguished from "sthenic" and its converse "asthenic" (derived from *σθένος*, meaning "strength"). "Asthenic" is applied to the weak, "sthenic" to the strong human emotions.

and syndramic* faculties of the mind or of instinct are universally found in animals, even the lowliest, and are of the utmost importance in the search for food, and consequently the sustenance of life.

SENSITIVENESS OF THE TEETH.

As far as the dental organs are concerned, passing reference only need here be made to what I have elsewhere noted and described, viz, the several uses of Nasmyth's membrane, of the enamel, dentin, pulp, and periodontal membrane. Suffice to say that it is probably correct to believe that the physical, chemical, and histological constitutions of enamel are such as to allow it to conduct, and to prevent it from generating, sensations of any kind. It is, however, true that the sensitiveness of the teeth, taken as a whole, is extraordinary, "distinguishing, accurately and immediately, between the shapes, proportions, and constitutions of wholly dissimilar foreign bodies, such as shot in game, a crumb of bread, a delicate hair, a piece of thread—silk or otherwise—a fragment of gritty sand or particle of comminuted food; a sensitiveness which causes its rejection or retention; a sensitiveness, too, of degree, whereby differences are at once detected between the comparative softness of a small leaden bullet and the dense hardness of a piece of shell. . . . It would probably be true, however—it remains for future observation to decide —that the nervous. perceptions of a tooth are so high and so complex from a physiological point of view that the pulp may be considered to be a very special sense organ, ranking, not equally, but in some considerable degree or manner, with those other special senses of hearing, of sight, and of taste themselves."

What is a sensation? Karl Pearson ("Grammar of Science," 1900), describes it as follows: "At the brain, what we term the sense impression is formed, and there, most probably, some physical change takes place which remains with a greater or less degree of persistence in the case of those stored sense impressions which we term memories. Everything up to the receipt of the sense impression by the brain is what we are accustomed to term physical or mechanical; it is a legitimate inference to suppose that what from the psychical aspect we term memory has also a physical side; that the brain takes for every memory a permanent physical impress, whether by change in the molecular constitution or in the elementary motions of the brain substance, and that such physical impress is a source of our stored sense impression."

CEREBRAL FALLACIES.

The mind derives its conscious syndramic ideas from external impressions through aisthenic mediums. A sensation is the result of a simple mental operation, brought about by—(1) A stimulus—tactile, electrical, chemical, and so on: (2) a nerve-ending to receive it; (3) a path to the cerebrum, and (4) a center of the brain to receive the impulse and to transfer it to the seat of origin. It—the brain—sometimes makes an error of judgment. For instance, if a foot has been amputated on account of an injury or a disease, a stimulus applied to the surface of the healed "stump" frequently causes the brain to refer it apparently to the toes of that amputated portion of the limb, in which of course a breach of continuity of the parts has been made! A knock on the so-called "crazy-bone"—the ulnar nerve at the elbow—refers painful sensations to the fourth and the medial half of the third fingers!

The sensorium, through the optical

---

* *Syndramic* (σύν, "at the same time," and δρᾶν, "to act") means literally "acting at the same time," and is a combination which is the result of simultaneous actions on the ultimate nervous fibrils. From the point of view of the human mind, aisthenic faculties, derived from the organs of sensation, are most highly developed during the period of youth, say from the ages of six to twelve; the syndramic faculties, derived from simple ideas, from the ages of ten to sixteen.

apparatus, actually subjectively interprets certain changes set up by pressure as *light*. If the finger presses in certain directions the eyeball with the eyelid closed, say over the external canthus of the eye, the brain notices not only the pressure, but also an illuminated ring of light—a "phosphene"—below the internal canthus. Thus it is deceived. Precisely how this occurs has not been expounded by the modern physiologist; the phenomenon was known, too, but never explained, by Aristotle.

In short, the brain generally acts involuntarily; mechanically. As F. W. Hedley says in "Life and Evolution," 1906, "The brain cannot do much, unless it works very largely automatically."

The majority of our ordinary sensations fall about the so-called "range of sensibility," of which the liminal intensity of the sensation, or lower limit of excitation, is the smallest stimulus, and the maximum of excitability, or height of sensibility, is a stimulus so great that the brain is incapable of recognizing any increase in it. This range of sensibility is governed by Weber's and Fechner's laws, which briefly state that sensations increase as the logarithm of the stimuli.

According to Halliburton, the magnitude of the fraction representing the increments of stimulus necessary to produce an increase of sensation determines what is called the discriminative sensibility, which, as far as the mouth is concerned, is for tactile pressure about one-third to one-fourth, for temperature one-third, and for weight one-seventeenth. The homologous stimuli met with in the oral cavity are those of changes produced by actual contact with a body, taste, touch, weight, and alterations of temperature by conduction, not by vibrations set up to a distance.

Original Experiments.

With the view of determining the discriminative sensibility and ascertaining the reactions of the homologous stimuli of the mouth, the following experiments were undertaken for the special purposes of this communication.

Simple experiments were conducted to ascertain the localization of parts of the cavity which were responsive to, first, slight spreading tactile impressions; secondly, localized pin-point impressions; thirdly, temperature impressions.

For descriptive purposes the palate was divided into sutural, dental, and middle regions, while the alveolar processes of the jaws provided tracts for examinations of the surfaces of the external and internal alveolar plates in the maxilla and mandible respectively.

First, the tactile sense, the oldest of all senses, from which all the others have, in course of time, become evolved:

(A) *Light, spreading impressions* were made by means of a soft camel-hair brush and also a heavier bristle brush. In both cases the results were similar.

In the antero- and postero-sutural segments there was slight sensibility, in the mid-sutural segment maximum excitability. In the antero- and postero-dental regions there was slight sensibility, and maximum excitability in the mid-dental area. In the middle territory the anterior and posterior parts showed but very slight susceptibility to tactile impressions, while in the middle portions they were only slight. (See Fig. 1.)

Over the molar regions of the external maxillary alveolar plates these impressions were practically imperceptible, and noticeable to a trifling degree only over the canine and incisor regions; and over the internal alveolar plate they were noticeable only to a slight degree in every part.

In the mandible the tissues covering the external alveolar plate showed the same; but there was a variation on the opposite side of the mouth, being either sensitive or insensitive in certain localities, and those over the internal alveolar plate exhibited identical signs to those found on the maxillary internal alveolar plates.

(B) *Localized pin-point impressions,* such as those produced by the Sieveking or Hammond esthesiometer. In the palate two points 1 mm. apart appeared

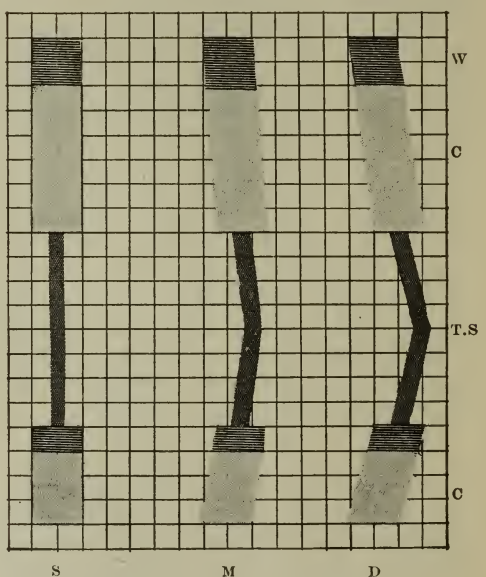
Fig. 4.



Cold and heat resting. (Lettering as in Fig. 3.)

subjectively as one distinct point; two points 4 mm. apart as two points in the incisor region, and one point elsewhere; two points 8 mm. apart were felt as two points generally, but in the molar region varied, and sometimes appeared as one point only.

According to E. H. Weber, 12 mm. is the least distance which can be measured over the "center of the hard palate" at which two points can be separately distinguished.

It is interesting to note that the distances which two points must be apart in order to set up two distinct sensations are 1 mm. in the case of the tip of the tongue, 8 mm. in the red mucous membrane of the lip, and 8 mm. in the middle of the dorsum of the tongue, while in the mid-cervical and mid-dorsal regions of the back it is as much as 62 mm.

In the maxilla both external and internal alveolar plates were tested, and yielded the same results. Thus two points 1 mm. apart appeared as one point; two points 4 mm. apart as one point; two points 8 mm. apart as two points generally, but in the premolar region appeared, on both sides of the mouth, as one point.

In the mandible the sensitive areas of the internal and external alveolar plates corresponded entirely with those in the maxilla.

Prof. E. H. Starling notes in his "Elements of Physiology," 1904, that—"It may be observed as a general rule that in those regions where the tactile sense is best developed the temperature sense is least developed. It is evidently of more importance to the organism," he continues, "that it should feel discomfort by a fall of temperature than it should by a rise of temperature, as shown by the preponderance of social contrivances, sartorial or otherwise, for maintaining the body temperature, over those for cooling the body." While this may be true for dermic territories, it will be presently apparent that, as far as the tactile and temperature senses in the mouth are concerned, the equivalence of the sensorial excitations can be satisfactorily determined by these particular experiments.

In the foregoing observations reliance was not placed solely on personal subjective sensations; fallacies would almost certainly have cropped up. The tongue fails to appreciate the real dimensions of things; a small carious cavity in a tooth seems to be an enormous chasm, a tiny almost invisible vesicle on its surface a mountain! As with regard to size, so with other perceptions; therefore objective help was sought, and the findings are those of such.

(c) *Temperature changes.* The tests for these are necessarily less delicate than those for the tactile sense, on account of the fact that cold and the radiation of heat waves from the instruments employed are apt to be felt by the lips, tongue, etc. As far as both force and sensation are concerned, the discriminative sensibility of the mouth equals, at least, that found in the center of the palm of the hand, the forearm, the plantar surface of the feet, and other parts of the body, even if it is not still more refined, and is greatly in excess of that of the thenar and hypothenar eminences of the hand.

The appended results were obtained by the use of metal pencils, each provided with an insulating holder. One pencil was warmed to 98°C., the other cooled to about 2°C.; raised or lowered above or below these degrees, pain could have been experienced.

The palate. 1. On passing the warm pencil over the sutural surface, warm spots similar to those described by Goldscheider as occurring elsewhere, were discovered at the back and over the *papilla palatina.* (Fig. 2.) The tactile sense only was discernible in the middle of this segment. These impressions remained for quite a minute after the stimuli had been withdrawn. On the external alveolar plate, in both maxilla and mandible, tactile impressions only were received on drawing the instrument over the surface; but on holding it in place in a localized position, these became quickly converted into

those of warmth. II. With two points, one hot, the other cold, at a distance of 4 mm. apart, drawn over various surfaces of the palate, the caloric sense was suspended at the back, cold only being felt, but both cold and warmth at the front. (Fig. 3.) But in regard to stationary points, both were noticed, the cold predominating. (Fig. 4.)

(D) *The weight sense* is difficult to ascertain. If a sensitive organ such as the tongue is practically unable to distinguish degrees of weight—for instance, it cannot detect the radial pulse at the wrist—it is extremely unlikely that the palate and alveolar plates could give other than negative results.

The ability to localize, as in the second set of experiments, tactile sensations, depends chiefly on the number of nerve fibers distributed to a part. According to Weber, the distance between two points is estimated, by the brain, by the number of unstimulated nerve endings which intervene between these points. "A certain number of intervening unexcited nerve endings are necessary before the points touched can be recognized as separate, and the greater the number, the more clearly are the points of contact distinguished as separate." (Halliburton.)

From this we learn that both liminal intensities of sensation as well as maxima of excitation are found in the mouth, and that, generally speaking, its anterior parts and vault are much more sensitive than those of the back and sides, this being probably due to the fact that the naso-palatine and anterior palatine nerves are particularly sensitive to caloric impressions.

Further, it is also clear that its sensitiveness exceeds that of the general integument; that its faculty of nicely distinguishing variations in the tactile and temperature senses is largely developed; and that its physiological attributes are brought about by a very similar arrangement of the end organs and touch corpuscles which are so freely distributed to the mucous membrane of the lips and certain portions of the skin itself.

ORAL ELECTRICITY.

Electrical phenomena are frequently met with in the mouth, and their recognition will often explain the occurrence of otherwise insoluble enigmas. The unexpected fracture of a 16-karat gold clasp on a denture or appliance draws attention to it. If such a band comes into close but not necessarily immediate contact with a metallic filling—say amalgam—electrical currents may be set up sufficiently strong to cause it to break, and the filling to become disintegrated.

Various parts of the mouth should be tested to elucidate these examples of oral electricity. When two metals of different electro-motive force meet or nearly meet in the mouth, electrical currents are induced, if there is an intervening electrolyte present, such as the saliva. This current can actually be appreciated by the gumaisthenic perceptions of the tongue. Two dissimilar metals placed, one close to, the other below the lingual extremity give rise to the sensation of a slightly bitter taste. If the edge of a nickel-plated mirror comes momentarily into contact with a gold filling, and the saliva is sufficiently ionized, the patient will feel a slight shock, which varies in different individuals and at different times. I believe that voltaic currents occur in every mouth, but are so slight as to be usually unnoticeable.

Mere contact with enamel or exposed dentin is not appreciated by the pulp; it is only when two dissimilar metals are brought into contact with an intervening electrolyte, and the current is completed by contact with the mucous membrane of the lip or cheek, that the current is evolved. The pain may be feeble, but at times of even a neuralgic character.

PART II.—PATHOLOGICAL CONSIDERATIONS.

Turning now from the discussion of this highly interesting subject, we pass to the consideration of the question of

painful oral sensations. Excessive excitation of the sensory nerves and undue stimulation of nerve areas, such as we have described, produce a sensation of pain. But it is more than an hypertrophied tactile or temperature sensation. There are many evidences and testimonies that it may be a distinct sensation. Some go so far as to assert that a special set of nerve fibers carries to the brain the sensation of pain.

PLEASURE AND PAIN.

Pain is but little removed from pleasure. The pleasurable delights of toweling one's back after a shower-bath are quickly turned to pain if the rubbing be done too vigorously or too long.

Sherrington and Head have devised an apparatus, to be placed upon the wrist, to show that different sets of impulses travel to the brain side by side. Thus if the hand is plunged into warm water, pleasurable sensations ensue; but, by using the apparatus mentioned, on plunging the hand into the same water pain is experienced. "The hypothesis which can be based upon this experiment"—I quote from my "Introduction to Dental Anatomy and Physiology," 1903—"would lead one to believe that the evolution of the sensory nerves in the human organism has continually been in the direction of the avoidance of giving the human being pain." Pain is a magnificent protection and warning.

At a recent meeting of the County Medical Society held in this College of Physicians, Dr. John B. Deaver said: "Doctors must learn to understand the language of pain, which, although mild, is often of the greatest value in the beginning of serious disease, when prompt treatment has the utmost benefit." The same aphorism applies also to dental surgeons.

OBSCURE FORMS OF PAIN.

It would be a matter of superfluity to deal in this paper with such evident causes of pain in the mouth and teeth as those due to inflammation of the pulp and of the periodontal membrane, osteitis, affections of the lingual nerves when set up by epithelioma, or to pressure of impacted third molars, diseases of the same, pains occasioned by inflammatory conditions of the antrum or fractures of the jaws. Rather is it the obscurer, not the obvious forms of pain, and some observations as to certain little known sensations experienced by the oral tissues, with which we are immediately concerned.

Eliminating the problems entirely connected with the tongue and sensations of taste, as not being quite germane to this subject, attention must now be directed to the teeth themselves. Why does odontalgia arise at times in apparently sound non-carious teeth?

SENSITIVITY OF THE HARD DENTAL TISSUES.

Is enamel sensitive? Is Nasmyth's membrane sensitive? Assuredly, No! Assuming that the sensations of a tissue are due to the presence in those tissues of nerve fibers or their equivalents, it can be stated that the latter is anatomically unfit for the existence within itself of a nervous system. As far as enamel is concerned it probably has no nervous supply. No one has, as yet, succeeded in indubitably demonstrating the finest nerve terminations in its substance. Römer and Morgenstein claim the existence of minute bodies similar to Pacinian corpuscles in the human enamel spindles. Their demonstrations are open to criticism. With regard to dentin, its sensitivity is well known. The work of Römer, Morgenstein, Dependorf, and Mummery must be recalled. In the non-acceptance of their views, I find myself on the side of Charles Tomes, Retzius, Huber, and others. Retzius has abundantly demonstrated the absence of nerve endings in the dentins of *Gobius, Gasterosteus, Salamander maculata, Lacerta agilis,* and *Mus;* Huber, in *Canis familiaris* and *Lepus.*

When Mr. Howard Mummery advanced his views before the Odontological Section of the Royal Society of Medicine

I contravened them for clinical, anatomical, histogenetic, and pathological reasons. The conclusions in his subsequent paper before the Royal Society did not alter my attitude. To my mind, it is inconceivable that, as stated, two nerve fibrillæ occupy each tubule. If that were so, the dentin is supplied with many myriads of nerve endings. The difficulties surrounding the inquiry are only known to expert histologists. Still, in this connection there is just an element of uncertainty which must not be forgotten. The only point of doubt on the clinical side of the problem may arise from the possibility that some molecular changes may have taken place in the dentinal nerves, if there be any, by which they may be rendered insensitive at times, in some recondite fashion.

Adhering to the belief that the fibers in the dentinal tubules, as the peripheral poles of the odontoblasts, possess the properties of sensory nerves, it appears to my way of thinking that here is a sufficient answer to the whole question of the innervation of the dentin. It is a daily common occurrence to find that many cavities are formed in the hard parts of teeth which are absolutely insensitive; that where an area of sensitiveness and pain does exist, a deeper layer of the tissue, that nearer the pulp, on removal with a sharp excavator exhibits none of these subjective symptoms. I am still content to consider that the ultimate ramifications of the non-medullated nerve fibrillæ of the pulp arborize about the odontoblasts, which in their turn act as sensation transmitters or carriers, although they themselves do not partake of the nature of nervous ganglia.

It is frequently asserted that cementum is sensitive, the argument being that the hard tissues below the necks of teeth acutely feel tactile impressions. It is an erroneous supposition, and can be explained by the fact that frequently (in 5 per cent. of sections examined for the purpose) a developmental defect exists in this region, and that instead of the dentin being covered by enamel and cementum at this spot, they fail to meet as they should do, *bout à bout*. No one has shown indubitable proof; the anatomical characteristics of cementum would not and could not allow of the existence of terminal nerve fibers in its substance. Hence it follows that the pulp alone is responsible for pain—for it is supplied with a large nerve plexus which is out of all proportion to its size, but not to its requirements.

There are many examples of the pulps of teeth causing pain when there is no obvious lesion. Occasionally the eating of very sweet or sour bodies will set up excruciating synalgia in sound teeth. Through the glosso-pharyngeal and the chorda tympani nerve sensations are felt by the brain, which as in the case of the amputated foot makes an error of judgment as to the position of the stimulus. In its essence it is akin to mysophobia and certain other systemic morbid emotivities.

Reverting for a moment to this question as an aid to the proper understanding of this reflex act, we know that mysophobia, or the fear of improper or inapposite contacts is not confined to manifestations in the form of a natural aversion to touching disagreeable bodies, or those capable of undergoing decomposition. Many people cannot bear to perceive, by the sense of touch, the surface of fabrics such as velvets or silks, or the external parts of the skins of fruits such as peaches. There may arise in the minds of some fear of contact with metallic objects, such as copper, pins, and needles, or, according to Morselli, pieces of glass. It is possible that derangements of the tactile digital sensibility are partly the cause, for Marcé has described a case in which, through a fear of seeing pins or needles adhering to the fingers, complete insensibility of the skin of the hand was produced. Among other illustrations of systemic morbid emotivity, Morel, quoted by Dr. Charles Féré in his "La Pathologie des Emotions," cites the following: King James II of England trembled at the sight of a naked sword; Erasmus suffered from febrile fits on seeing a plate of lentils; Scaliger was

seized with nervous tremors at the sight of a carafe of water; Bacon experienced the state of syncope during every lunar eclipse.

"SETTING THE TEETH ON EDGE."

The complex series of phenomena constituting that anomaly of sensibility popularly spoken of as "setting the teeth on edge" may perhaps be placed in the same category as the preceding illustration, for, in this case, it is partly the outcome of an innate antipathy on the part of the individual. It is something more than a mere reflex act, inasmuch as it is accompanied and complicated by a mentality which is the effect of the workings of a higher conscious cerebration. This syncinesia, among others studied by John Hunter, Müller, and Gubler, which is purely physiological or perhaps borders on the abnormal, may be caused partly by the action of the auditory nerves and partly by the gumaisthenic or somaisthenic perceptions of the person.

Gumaisthenic perceptions. The phenomenon was known to the Prophets of old whose words recorded in the Bible are as follows:

> Prov. x, 26: As vinegar to the teeth, and as smoke to the eyes, so is the sluggard to them that send him.
>
> Ezek. xviii, 2: What mean ye, that ye use this proverb concerning the land of Israel, saying "The fathers have eaten sour grapes, and the children's teeth are set on edge"?
>
> Jer. xxxi, 29, 30: In those days they shall say no more, The fathers have eaten a sour grape, and the children's teeth are set on edge. But every one shall die for his own iniquity: every man that eateth the sour grape, his teeth shall be set on edge.

Ousaisthenic ideas. Shakespeare declared:

> I had rather hear a brazen canstick turned,
> Or a dry wheel grate on the axle-tree;
> And that would set my teeth nothing on edge,
> Nothing so much as mincing poetry.
> —*1 Henry IV*, iii, 1.

Through the action of the auditory nerves the grating of a dry wheel or stick of schoolboy's pencil on his slate induce it; and not infrequently the tactile sense. When the fingers are rubbed lightly on the surface of a piece of velvet, this curious sensation of pain in the teeth is noticed. Somaisthenic ideas become converted into a modified form of acute odontalgia. If the fingers are rubbed on a piece of glass-paper or a hot metallic surface, the mind appreciates the condition thus induced locally, and pain is felt, not in the teeth, but in the digital extremities themselves.

The explanation of the conversion of the somaisthenic perceptions into pain would seem to be the following:

The simple act of touching the velvet does not *per se* induce pain, and would not do so if the mental attitude of the individual were not an anticipatory one. He has the knowledge that his teeth will ache, and that possibly a cold tremor will pass down his spine, as his fingers are brought into contact with the velvety field. It may be that the brain is unaccustomed to determine the amount of muscular effort set up by the digital movements, or that it is disturbed by the unusual and somewhat naturally repellant act. There is no doubt that there is a great limitation to the capacity of the synthetic action of our minds in appreciating the changes which occur within our bodies, and the mechanism of the brain frequently fails in its estimation and correct interpretation of what is going on.

UNUSUAL FORM OF TRIGEMINAL NEURALGIA.

Bordering upon the line between physiological and pathological pain is a rare affection or disturbance—not a disease—of the fifth nerve, similar perhaps in origin to hemicrania, due to hyperemia of the vessels in the cerebrum. Hughlings Jackson says one form is due to digestive derangements. Here change in the feeding customs of an individual—digestive changes or altered constructive metabolism, due to a newly acquired fasting or semi-fasting habit, may, and do often set up pain in the

jaws and teeth, which puzzle the dental surgeon when called upon to diagnose and treat them. The pain is not restricted to Head's areas; these do not help in the diagnosis. Located and limited to one side of the face, curiously it is always the same side or alternate sides of the face which is affected, as if one of the pairs of the fifth nerve was more susceptible, for some reason, to these changes, and as if the brain was content in indicating the presence of a deep-seated disturbance only by one and not by two routes. It spreads over a large area, not the mastoid region nor the concha of the ear. It is increased on deep pressure outside, over the root of the tongue. The pain is heavy, dull, spontaneous, persistent, deeply planted, apparently in the body of the mandible and maxilla and cheek of one or other side. The soft palate, tongue, and tonsils are unaffected. It may last for a half-hour or less and disappear. No maximum spots of intensity are noticed. Digital pressure increases it; hot and cold objects have no effect, though cold may at times relieve it; pressure as from a soft substance—like a cushion or pillow—produces an exacerbation. It may be accompanied by intermittent frontal headache.

The teeth are hypersensitive. A cold finger gently passed over their crowns increases it; pressure and percussion do not. Occlusion of the opposing teeth does not. The dental surgeon may be deceived by the presence of fillings in the teeth. If they are showing signs of wear or loosening, he will probably remove them and insert others, frequently flooring the cavities with a non-conducting material, or even going so far as to devitalize the pulp of a tooth, all, much to his chagrin, being of no avail to stop the pain.

Excluding migrain, the origin of the trouble appears to be anemia or metabolic disturbances of the sympathetic nervous system, due to slight temporary gastric derangement set up by slight malnutrition or la grippe. A full, easily digested meal will usually act like magic, and relieve the pain, while the exhibition of drugs, such as acetophenetidin in five-grain doses, is also indicated. Tonics and general attention to health will also bring about like results; but in any case it takes time to effect a cure.

Thus the answer to the first problem is partially given; but to complete it one must consider even more definite conditions.

OTHER CAUSES OF PAIN.

Pain arises obviously through some intrinsic vascular changes in the pulp. An elevation or depression of the blood pressure more or less suddenly brought about will cause it.

Pain in sound teeth, due to these vascular disturbances, may be found in women at the periods of puberty, menstruation, and the climacteric. There are many proofs of this fact. Patients will complain of severe odontalgia in teeth which exhibit no visible signs of disease or injury.

An alteration in the character of the chemical constituents of the blood also may set it up. I described in the pages of the DENTAL COSMOS seven years ago an instructive and remarkable case, where the exhibition of calcium lactate to supply a reduction in the amount of the calcium content in the plasma, cured the persistent acute odontalgia in a child of fourteen years. Associated in this particular instance with this deficiency was a structural modification of the teeth only revealed on microscopic examination, which showed an abnormally small though healthy pulp bounded by an extraordinarily thick dentinal wall.

The pressure of pulp nodules on the nerve trunks of the pulp will also occasion it, and may be suspected by the dentist, should they be unidentified by roentgenography, if the patient is inclined to the rheumatic or gouty diathesis.

CONCLUSION.

This paper is the outcome of personal experience and observation. In the First Part there have been narrated some original experiments which, though not

pretending to be complete, are entirely new, save that, years ago E. H. Weber, when noting the localization of tactile spots on the surface of the body generally, found that at the center of the palate two points must be separated by a distance of 12 mm. to appear as two distinct sensations. I have ascertained that a distance of 8 mm. is sufficient.

I have endeavored to add a slight contribution to our common store of knowledge about the mouth, and particularly its discriminative sensibility—one aspect of its functions which has been but little investigated. This may not seem to be of much moment, but assuredly we should get to know as much as we possibly can with regard to the teeth and their associated parts.

Summing up Part II, it may be stated in general terms that there is no local dental lesion if reasonably hot and cold drinks and foods can be taken into the oral cavity without inducing any local reaction of pain; and that it is clear that if no obvious cause of odontalgia is present, such lesion must be looked for elsewhere. Hyperemia of the pulp is indicated, and may be diagnosed if pain is experienced at a localized situation on taking warm fluids, especially if a breach of enamel or dentin is discovered.

If this examination fails, and if pain still persists, the tongue may next be suspected and thoroughly inspected and tested; then general constitutional causes —vascular disturbances due to puberty, menstruation, the climacteric, pregnancy, etc.—conjectured; and finally degeneration, calcarious infiltration, and other retrogressive conditions of the dental pulp may be diagnosed and suitable therapeutic measures taken accordingly. The prompt recognition of these latter changes will be convincing alike to patient and dental surgeon, and the solution of some problems of pain and other oral sensations satisfactorily determined.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

STERILIZING THE HYPODERMIC SYRINGE BY BOILING.

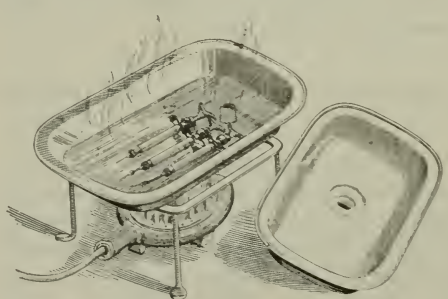
By J. L. ELPHINSTONE, D.D.S., L.D.S., Aberdeen, Scotland.

ASEPSIS is among the most important requirements of local anesthesia. There are unlimited possibilities of infection in the hypodermic syringe.

Two methods of sterilization are possible, boiling and immersion in antiseptic fluid, and as writers have of late favored the immersion method, the object of the present paper is to point out the superiority of the boiling method. No one will contend that immersion is simple, easy, and rapid, or that the method is fool-proof, while for boiling all these claims can be made.

TECHNIQUE OF STERILIZATION BY BOILING.

The following is the technique of sterilization by boiling: An ordinary porcelain-enameled iron chafing-dish with cover is obtained, such as is used in every household for baking puddings,



etc.; also an iron stand and a suitable gas burner for heating (see figure).

All-metal syringes of the well-known

Imperial pattern are used. The leather washers are removed, also the leather piston packing, as this material is destroyed by boiling.

REPLACING LEATHER WASHERS BY TIN FOIL.

The leather washers are replaced by others cut from tin foil of suitable thickness. This metal is an ideal material for making the joints water-tight, as it possesses just the right hardness. The problem of replacing the piston leather packing is more difficult to solve. Nothing is quite so soft and agreeable to the touch as greased leather.

REPLACING PISTON LEATHER PACKING BY ASBESTOS FIBER.

Fiber asbestos is, however, very good. It was suggested to me by Messrs. Ash. The loose fiber is packed tightly around the piston in the groove provided for the purpose. No lubricant should be used; vaselin or other grease only fouls the syringe inside. The moisture absorbed and retained when the syringe is in use is a sufficient lubricant. At first this packing is just a little harsh, but it soon becomes easier working, and almost as soft to the feel as the leather.

Thus prepared, the syringe requires only boiling to secure asepsis, and is then ready for use. The metal syringe has the advantage also that it can be warmed just previous to use, by holding over the Bunsen flame, and the anesthetic can thus be brought in a ready manner to blood heat.

COMPOSITION OF LIQUID FOR BOILING SYRINGES.

The next important point is the composition of the liquid in which the syringe is to be boiled. If iridio-platinum needles are used, clean tap-water will answer all purposes, and I can see no reason for using distilled water. This altogether depends on whether the small quantity of alkaline material which such water may contain is harmful, a question we shall discuss at some length presently.

If steel needles are used, a small quantity of sodium bicarbonate or some other alkali must be added to the water, one grain to the ounce, or as much as can be lifted on a twenty-five-cent piece to the pint will suffice. This is to prevent corrosion of the steel. The syringe should be totally immersed—a protruding needle will rust. A little of the fluid is drawn into the syringe, which is then boiled for ten minutes. Since the adoption of conductive anesthesia, there is no accident more likely than the breaking of a long thin needle in the tissues in a situation where its removal would not be easy. It is necessary, therefore, to be quite sure of the needle each time, and this is best accomplished by making it a routine practice to examine the needle just previous to insertion. The few drops or less of solution of sodium bicarbonate which adhere to the syringe do not precipitate the weak solution of about 1½ per cent. of novocain hydrochlorid with suprarenin, such as is used in dental anesthesia.

EFFECT OF TRACES OF SODIUM BICARBONATE ON NOVOCAIN-SUPRARENIN SOLUTION.

We must examine this matter at some length, as the contrary is a belief widely held. Sodium monocarbonate, Na_2CO_3, is a more serious precipitant, and the monocarbonate forms on boiling the bicarbonate solution:

$$2NaHCO_3 = Na_2CO_3 + CO_2 + H_2O$$

To set the matter at rest, a 1½ per cent. solution of novocain hydrochlorid, with suprarenin hydrochlorid, just as used for anesthesia, was prepared with normal saline solution. On taking a syringeful—2 cc.—of this liquid, and adding to it 5 minims of a 1 : 200 solution of sodium bicarbonate, which is as strong as the sterilizing liquid could become even after long boiling, no precipitate was obtained.

Taking a fresh portion of the same

solution and adding 5 minims solution of sodium monocarbonate—1 : 200 of the dried salt—again no precipitate could be obtained. These experiments closely copy what happens when the anesthetic solution is drawn into a syringe which has been boiled in a solution of sodium bicarbonate. The small residue adhering to the syringe is never enough to cause precipitation of the anesthetic salts. It is apparent that precipitation depends on whether there is enough water to retain in solution the bicarbonate, carbonate, or possibly free base of the alkaloids novocain and suprarenin, which is formed; and experience proves that this is always the case, unless alkaline solutions of excessive strength are used. In any case, the anesthetic is subjected to analogous influences as soon as it mingles with the lymph or blood serum, both of which fluids are alkaline.

We are therefore justified in concluding that it is only necessary to empty the syringe of the sodium bicarbonate solution, but quite unnecessary to further cleanse it by drawing in and ejecting sterile distilled water. Thus we are saved one process in an already elaborate procedure. This is all the more important since only repeated and prolonged cleansing could remove the last trace of alkali if such were indeed injurious.

The following correspondence will be found of interest. The Saccharin Corporation of London, agents for the sale of novocain in the United Kingdom, issue a leaflet from which I quote as follows: "The sterilizing of syringes with an alkaline disinfectant must be avoided, as novocain is precipitated by the slightest trace of alkali."

In answer to a letter asking their grounds for making this statement, which I informed them was not in accordance with my experience, I received the following interesting reply:

> In reply to yours it is within our own experience that unsatisfactory results with novocain have been traced to the use of alkaline disinfectants for sterilizing instruments, and that when their use had been given up complaints had ceased. Our consulting chemists are Messrs. Helbing and Passmore, 81 Queen Victoria st., London, E.C., who write as follows: "It is a well-known property of novocain that the commercial salt—the hydrochlorid—is easily dissociated by alkalis. With liberation of the free base, which is insoluble in water, with caustic alkalis, and carbonate of soda or potash, dissociation takes place, in the cold; with bicarbonate if the solution is boiled. If to a cold 1 per cent. solution of novocain hydrochlorid half the volume of 1 per cent. sodium bicarbonate be added, the solution remains clear; but on boiling, as the carbonic acid escapes, an oily scum appears on the surface, and eventually globules of melted novocain base separate. Practically the whole of the novocain is thrown out of solution, and if excess of alkali be present, further decomposition of the base takes place. At any rate it is impossible to obtain a uniform solution for injection."

The above letter fairly represents the evidence on which is based the case against alkalis.

I repeated the above described experiment, boiling together one syringeful—2 cc.—of a 1 per cent. solution of novocain hydrochlorid with 1 cc. of a 1 per cent. solution of sodium bicarbonate. The precipitate of novocain base was duly obtained, but it was noticed that there was great evaporation of the water during the process. Accordingly, distilled water was added to make up the original volume, when the precipitate redissolved; the contents of the test tube again became clear. The conclusion is therefore justified that in weak solution precipitation does not occur. In the case tested, our solution of sodium bicarbonate was one-third of the total volume, amounting in a syringeful to about 10 minims, and of a greater strength than is required for the sterilizing fluid. The above remarks about sodium bicarbonate apply in full to the sodium monocarbonate, since the former changes into the latter salt on boiling. Moreover, I do not find that a trace of alkali has any immediate bad effect which interferes with the constitution or action of the suprarenin within the short time it remains in the syringe previous to injection.

A few drops of a 1:200 solution of sodium monocarbonate were added to 2 cc., a syringeful, of a 1 : 50,000 solution of suprarenin hydrochlorid—the strength commonly used for injection. Neither precipitate nor discoloration were observed, and on injection the blanching of the gum was the same as usual. In order to confirm the deductions from this experiment, the same experiment, with a like negative result, was also tried with a stronger, viz, a 1:10,000 solution of suprarenin hydrochlorid. However, I most decidedly admit and emphasize that, as pointed out by Drs. Fischer and Riethmüller, undesirable decomposition would have taken place if the alkaline solution had been boiled or kept for any length of time. However, the important fact is that no immediate decomposition was evident.

RINGER SOLUTION VS. NORMAL SALT SOLUTION.

Lately, Dr. Fischer has recommended what he calls modified Ringer solution for dissolving the anesthetic salts.

Ringer solution modified by Fischer:

Sodium chlorid,	0.5
Calcium chlorid,	0.04
Potassium chlorid,	0.02
Aqua destillata, q. s. ad	100.0

The above solution contains one ingredient, calcium chlorid, which is precipitated by sodium monocarbonate:

$$Na_2CO_3 + CaCl_2 = 2NaCl + CaCO_3$$
Calcium carbonate (insoluble)

Accordingly, if we adopt this formula, we must give up the bicarbonate of sodium, and use iridio-platinum needles.

Personally, I adhere to the steel needles and the bicarbonate of sodium, and still dissolve my anesthetic salts in normal sodium chlorid solution. The formula for injection is therefore as follows:

Novocain hydrochlorid,	1.0 or 1.5 or 2.0
Suprarenin hydrochlorid,	0.002
Sodium chlorid,	0.7
Aqua destillata, q. s. ad	100.

STERILIZATION OF ACCESSORY INSTRUMENTARIUM.

Glass cups are often used for holding the anesthetic liquid to be drawn into the syringe, but porcelain cups, which can be boiled in the sterilizer together with the syringes, will be found better, since they will not be fractured by the heat.

A jug of water, sterilized by boiling and allowed to get cold, should be kept at hand for cooling the syringes rapidly if they are required quickly for use before they have time to cool in the ordinary way. The cold water is poured over the syringe held by a forceps.

Forceps, etc., for handling the syringes and cups, and lifting them from the sterilizer should be kept immersed near the sterilizer in a dish of about 2 per cent. lysol solution, or any other suitable antiseptic. Each time after use the syringes, etc., are boiled about ten minutes.

Dr. R. W. Goadby, in Bennet's "Science and Practice of Dental Surgery," states: "For forceps, elevators, and other surgical instruments, boiling for three or four minutes in water with 1 per cent. sodium carbonate is the best, as practically no spore-forming bacteria are to be found in the mouth, and if due care is taken in the way of common cleanliness, no sporing organisms should come in contact with them."

As, however, our piston packing is a poor conductor of heat, it will be safer to give the syringes longer than three or four minutes' boiling. In conductive anesthesia, when more than one injection is to be made with the same syringe, it will be found feasible to return it to the sterilizer, boil, and make another injection, without undue loss of time, if the water in the sterilizer has been kept ready at the boil. In this case the above-mentioned three or four minutes will suffice, since contamination can occur only on the outside of the syringe.

Goadby's proportion of 1 per cent. of sodium bicarbonate is unnecessarily strong for syringe sterilization, although unobjectionable for the instruments

which he names. I have always found 1 grain to the ounce—1 : 480—adequate for this purpose.

STERILIZATION OF THE MOUTH.

There is another factor, the sterilization of the mouth itself as a whole, which is helpful in preventing the gross contamination above mentioned. For this purpose the patient may rinse the mouth with solution of perchlorid of mercury, 1 : 2000 or 1 : 1000. For severe operations in very filthy mouths the stronger solution should be used, since every other consideration must yield to the need of asepsis. Of course this solution cannot be used in the presence of any extensive gold work, such as bridges, since the metallic mercury would be deposited thereon, and discolor the gold. The galvanic taste would also be very disagreeable. Some authorities warn us against using so poisonous an antiseptic. Asepsis, however, is all-important, and I have never been able to understand this objection. Miller declared it the most efficient antiseptic in the mouth; and we want the most efficient. Since the period for which a mouth-wash can be retained in the mouth previous to operation is necessarily very short, a weak antiseptic in such circumstances will not answer our purpose.

When the use of perchlorid of mercury is not desired, the next best antiseptic mouth-wash is the hydrogen dioxid, 3 per cent., diluted with an equal volume of hot water to make it tepid. The patient is handed about 2 ounces of one of these mouth-washes in a colored glass to distinguish it. He is directed to use it mouthful after mouthful until it is finished, working each mouthful well through the teeth, and finally ejecting it into the spittoon. He is warned not to swallow any. The dioxid froths so much that plain water must afterward be used to get rid of the froth, which would obscure the field of operation. When the mouth as a whole has been thus cleansed, the field of operation, and especially the point of injection, is rubbed with a swab of cotton impregnated with tincture of iodin. We thus insure special sterility in this important locality.

If the operation in hand is a large one, the burning taste of the tincture of iodin may be objectionable on account of the large quantity of alcohol it contains. Besides, in the mouth, the fluid naturally present negatives the chief *raison d'être* of the alcohol, viz, the readiness with which it dries. In this case the following watery solution of iodin answers better:

Iodin,	1 part
Potass. iodid,	1 "
Water,	40 parts

The iodin and the potassium iodid are rubbed with a small quantity of water in a mortar until dissolved, then the rest of the water is added.

This solution can be much more freely used than the tincture. Its taste is much less unpleasant. It stains the gum as dark a brown as the alcoholic tincture, and is presumably therefore as efficient an antiseptic, and as readily absorbed into the mucous membrane. While it is granted that the alcohol is also an antiseptic, in the mouth it is so immediately flooded by the copious saliva evoked that its antiseptic influence is negligible, except when it is applied in small quantity in a restricted area which can be kept dry.

USES AND ADVANTAGES OF THE X-RAYS AS AN AID TO DENTAL DIAGNOSIS, INCLUDING THE DIFFERENTIATION OF THE RADIOGRAPHIC APPEARANCE OF NORMAL AND ABNORMAL TISSUES.

By HOWARD R. RAPER, D.D.S., Indianapolis, Ind.

(Report presented to Section IV, Sixth International Dental Congress, London, 1914.)

FIRST let us consider the "Uses of the X-rays as an aid to dental diagnosis," then "Advantages," and lastly, the "Differentiation of the radiographic appearance of normal and abnormal tissue."

USES OF THE X-RAYS IN DENTAL DIAGNOSIS.

The radiograph is an aid in diagnosis in practically all cases of pathologic or abnormal conditions of the jaws, because all pathologic changes or abnormal conditions involve some alteration of normal density of the parts. If this variance from normal density is sufficiently definite, it will register on the radiographic film or plate.

Giving this report in accordance with the rules governing its length, it will not be possible to go into a detailed enumeration of the uses of the radiograph as an aid in diagnosis. We may summarize them as follows: (1) in cases of unerupted or missing teeth. (2) In cases of supernumerary teeth. (3) In cases of partially formed teeth. (4) In cases of pulp nodules. (5) In cases of alveolar abscesses. (6) In cases of tumors. (7) In cases of pyorrhea alveolaris. (8) In cases of necrosis. (9) In cases of disease of the antra. (10) In cases of fracture. (11) To locate foreign bodies. (12) In research work.

Though this summary covers the field fairly well, a casual reading of it will not give the man unacquainted with the subject the correct idea of the almost limitless application of the X-rays as a diagnostic aid. Take the one use, *in cases of tumors,* for example; unless you pause and consider the matter, you will not realize that this includes cases of odontomata, cementomata, osteomata, cysts, and others. Likewise the bland statement—*in cases of alveolar abscess* —gives no idea of the countless circumstances under which the radiograph proves of assistance in diagnosis in such cases. I would also call attention to the fact that we are considering the X-rays as an aid in diagnosis only, not as an aid in the practice of dentistry. To consider the X-rays as an aid in the practice of dentistry would open the big field where the radiograph is used by the operator as an aid in his operative work rather than as a diagnostic aid.

Of all the uses of the radiograph, none seem so important to me, at the present time, as the one *in research work.* The use of the radiograph will finally prove or disprove the contentions of Dr. William Hunter, as set forth in his several papers, but particularly his paper, "The Rôle of Sepsis and of Antisepsis in Medicine," read in 1910; and a careful, honest, scientific consideration of the possible effects of oral sepsis is the most important problem the dental profession has ever faced. If it is true that chronic dento-alveolar abscesses may cause such diseases as arthritis, anemia, endocarditis, and other grave constitutional diseases, then the practice and standing of dentistry will be revolutionized. The radiograph will be used extensively in

this oral sepsis research work. Thus its use is closely linked with the solution of the most serious problem which confronts us.

ADVANTAGES OF THE RADIOGRAPH AS AN AID TO DENTAL DIAGNOSIS.

There is a story told of two policemen who dragged a dead horse along Piccadilly several hundred yards to Bond st. The reason for this laborious transfer of the inanimate beast from one street to another arose from the necessity of making a written report, which involved a statement as to the whereabouts of the animal, coupled with the policemen's inability to spell Piccadilly. The advantages of the radiograph as an aid in diagnosis are often analogous to the advantage a knowledge of how to spell Piccadilly would have been to the policemen.

It has not been, however, the policy of the writer to resort to any of the artifices of writing to prove the advantages of the radiograph as an aid in diagnosis, or to consider the matter in the abstract at all, in fact, but rather to give evidence of the advantages, and let that evidence stand or fall of its own weight. It would be unfitting that I should attempt to cite in this report a number of cases which would prove the advantages of the X-rays in dental diagnosis. Evidence of its recognized value may be shown, though, by observing the manner in which American colleges have made radiography a part of their curricula. In 1910 but one or two of the approximately fifty American dental colleges taught the subject. In 1913 over one-third of the colleges were either teaching or making efforts to teach dental radiography. As this is written, March 1914, I am still receiving replies from letters sent to the colleges which are members of the American Institute of Dental Teachers. To date I have received thirty-two replies. Of the thirty-two which have answered, twenty-eight colleges teach the subject; four do not. Thus it will be seen that the value of the radiograph is rapidly being recognized by our educational institutions.

I cannot pass the subject of the advantages of the radiograph as an aid in diagnosis without calling attention to the fact that the good derived from its use depends very much on the manner in which it is used. It is unfortunate that it is not always used in vain by the man who has no idea of the etiology of the patient's malady, and makes or has made radiographs expecting them to reveal, as on a written page, the disease, its existing cause, and a paragraph or two describing treatment. I say it is unfortunate that the radiograph does not always disappoint this man who expects too much of it, who forgets all other methods of diagnosis, and lazily depends on the radiograph to do all his diagnostic work for him. It is unfortunate because it leads men to believe that the radiograph has arrived to replace all other means and modes of diagnosis, when in reality it has come not to take the place *of*, but to take its place *with* the probe, the history, the symptoms, the signs, and diagnostic tests.

A tentative diagnosis should always be made before the case is radiographed. Thus, for example, from the signs and symptoms, you may suspect a case of pulp nodules. Radiographs are made to verify or disprove this diagnosis. If the diagnosis is verified by the radiograph a great element of doubt as to the correctness of his diagnosis is removed from the diagnostician's mind. If the tentative diagnosis is disproved by the radiograph, an important step has been made in diagnosis by elimination.

Another example: From signs, symptoms, probing, and tests we make a diagnosis of alveolar abscess of an upper canine. A radiograph is made, and we learn that we have not only an abscess of the canine but of the first bicuspid also. The radiograph has verified our diagnosis and elaborated on it.

To epitomize: If you would derive the greatest benefits from the radiograph, use it only to verify or disprove and to elaborate on tentative diagnoses.

DIFFERENTIATION OF THE RADIOGRAPHICAL APPEARANCE OF NORMAL AND ABNORMAL TISSUES.

To be able to differentiate between the radiographic appearance of tissue with any degree of skill, a man should know first the general elementary principles of making radiographs; second, the anatomy of the parts; and third, the pathology of the parts. Nor is this knowledge alone sufficient. To it must be added experience in reading radiographs. Every radiograph is the product of known chemical and physical laws. Misinterpretation of radiographs is due to some lack of knowledge or illogical deduction. The assertion that the radiograph is fallible is misleading. It is our ability correctly to interpret radiographs that is fallible, and our unwillingness to recognize the limitations of radiographs that leads us to assert that we see things in them which they cannot or do not show.

Some of the more common misinterpretations of radiographs are:

(1) To mistake the anterior palatine foramen for a dento-alveolar abscess of an upper central incisor.

(2) To mistake the mental foramen for a dento-alveolar abscess of a lower bicuspid.

(3) To mistake the maxillary sinus for a dento-alveolar abscess of the upper bicuspids or molars.

(4) To assume, from the appearance of single radiographs—not stereoscopic radiographs—that the roots of teeth penetrate into the antrum, when the appearance as of this condition may be due to distortion or lapping of the roots to the buccal or lingual of the antrum.

(5) To mistake the mandibular foramen for osteoporosis due to disease.

(6) To mistake a small cervical filling for a pulp nodule.

(7) To assume that a canal filling in an upper tooth fails to reach the end of the root when this appearance of a faulty canal filling is due to the relative positions of tube, film, and tooth at the time of exposure.

CONCLUSION.

In conclusion, I would say that the X-rays are the most valuable of all our means of diagnosis. Yet this very value seems destined to cause them to fail in their greatest possible usefulness. Men will depend upon them too much, be disappointed, and then condemn them as altogether unreliable. Let us face the fact, in future, that the X-rays will not assist us to a definite diagnosis in all cases, and that unless we exercise the keenest judgment they are often misleading. For, like all other things in the world, they have their limitation and their faults, but withal they remain our greatest single aid to dental diagnosis.

FACTORS OF IMPORTANCE IN THE CONSTRUCTION OF CAST GOLD INLAYS.

By MARCUS L. WARD, D.D.Sc., Ann Arbor, Mich.

(Read before the Toronto Dental Society, February 15, 1915.)

WHEN Dr. Weston A. Price presented a paper to this society on October 27, 1908, entitled "The Detailed Technique for Making Dental Restorations on Artificial Stone Models," he was asked, according to the reports of the meeting, the following question by Dr. Capon: "In referring to that part of the paper where the essayist alludes to restoration in a mesial and distal filling united in one piece through the occlusal surface, he says the contraction will prevent its going to place, and to force it means simply to spread it out at the gingival margins, like the spreading of a horse-shoe. I would like the essayist to explain how Dr. Taggart got such fine work by his methods, and I know from personal experience that dozens of such inlays have been cast and placed into the cavity without that spreading and would bear the closest inspection."

UNCERTAINTY REGARDING THE SUCCESS OF GOLD INLAYS.

The records do not show that Dr. Capon's question was answered at that meeting, nor at any time since by the essayist of that evening, or fully answered by anyone else since that time. The writer has been asked essentially the same question as the one asked by Dr. Capon so many times within the last five or six years that he is certain that, while a great deal has been done along this line of work and a considerable amount written, there prevails a feeling that Taggart's gold inlays have never been excelled by the use of the stone model suggested by the essayist of that evening, by the use of other materials for the cast inlay, or by making use of the results of some valuable scientific research along this line of work. Those to whom Dr. Capon referred that evening have, I believe, continued from that time to the present to insert as beautiful inlays as they did then, and have found but a partial application for many of the theories advanced relative to this work that were not in harmony with the ones they were already practicing. That a most beautiful result is possible in almost every case is the belief of many, but the majority feel that there is an element of uncertainty connected with the construction of about every case they do. This condition of uncertainty, which in many cases is probably due to nothing more than faulty technique, is exaggerated oftentimes by the conflicting opinions that so often appear in the current literature. With the feeling that he has been in a position to investigate the merits of the different methods practiced and theories advanced in this work, both from a practical standpoint in a large clinic and a theoretical one in the physical laboratory, the writer wishes to discuss some of the factors that he regards as of much importance in the construction of the cast inlay.

TAGGART AND HIS IMITATORS.

From the introduction of the cast inlay to the present time there have been many who believe that Taggart had mastered the technique of making gold in-

lays when he presented the process that could not be detected from the foil filling when the two were in close proximity. Unfortunately it has been difficult to get all the methods employed by the designer of the process, and as a result some quite different procedures have been designated as Taggart's. Some have been designated as Taggart men because they use Taggart's machine. The writer has a close friend who uses a Taggart machine but as far as is known he uses no other of Taggart's products nor knows of Taggart's methods. Another is in mind who uses Taggart's products except the investment. The writer was recently designated as a Taggart man before one of the large societies of the country, by a man who is a profuse writer on the subject of casting, because he uses a comparatively cool mold when using the Taggart machine. The fact is, however, that I have for the use of my students, besides the Taggart machine, five centrifugal machines, one compressed-air machine, and one vacuum machine, advising as hot a mold as can be obtained without getting the shrinkage in the investments that occurs with temperatures upward of 1000°F. for use on the vacuum appliance; removal of the mold from the flame as soon as the investing material was dehydrated to the extent that vapor could not be seen rising from the mold and a piece of the same wax that was invested would rapidly disappear when placed upon the surface of the mold, and the cast made immediately, when it was to be done on the centrifugal appliance, and from this temperature to that of the room when using the Taggart machine.

TEST OF VARIOUS CASTING DEVICES.

These machines have been treated as devices for delivering pressure. The amount of pressure available and that actually delivered upon the gold has been taken into consideration when using any one of the types of machines mentioned. The condition of the mold relative to the delivery and maintenance of pressure has been considered. The rapidity with which the pressure could be delivered with the different types of machines, the nature of the casting to be made, the size, location, and number of sprues to be employed, the detail in some castings that can be sacrificed to the benefit of others, have each been studied simultaneously with the delivery of pressure by the machine and the influence of the temperature of the mold upon this pressure.

As a result of these observations we have found that we can produce more satisfactory reproductions of wax models in gold by the use of a technique that has been worked out for the production of the particular casting to be made and the machine to be used.

EXTREMES IN CASTING TECHNIQUE INJURIOUS.

In no instance has the writer advocated the cool mold for all kinds of work nor for all types of machines. In the Cosmos for September 1909 I advocated the cool mold in discussing cast inlays, but did not anticipate at the time of writing that article (February 1909) that there would be any necessity for working out a technique for use with pressure devices that have their efficiency modified by so many parts of the technique necessary to construct a cast inlay as do some of the present vacuum appliances now in the market.

Whether or not Dr. Taggart produced the beautiful results that Dr. Capon referred to by the use of the cool mold, the use of the artificial stone model referred to by Dr. Price, the hot mold referred to by Dr. Van Horn (Cosmos, 1910, page 878), the more recent suggestion of Dr. Price that warm water be used for investing the wax model, the taper walled cavities to be discussed later, or any other particular kind of technique, cannot be stated definitely at this time. The writer ventures the assertion, however, that not only Dr. Taggart but dozens of others can produce cast gold inlays that cannot be excelled at the present time, without the use of

the artificial stone models, the hot mold, or the warm water for investing the wax pattern.

It seems safe to assert that those who have produced the beautiful results that have been referred to have invariably been excellent technicians in other lines of work, and that they have pursued a practice more like that referred to by Ottolengui in Cosmos, January 1915, than to assume that they have been extremists and known in this work by the use of a cold mold or a hot mold, or any other form of extreme technique. Ottolengui says in the article referred to ("The Filling of Teeth with Cast Gold Inlays, and the Present State of the Art in the United States"):

> The true method of casting does not depend upon the utilization, but rather upon the avoidance, of extremes of temperature. The wax should not be chilled; the investment should not be made with cold water, and the mold should not be extremely hot when the cast is made. On the contrary, the effort should be made to work as close to room temperature as possible, the wax and investment thus being neither warmer nor colder than the surrounding air, while the mold itself should be as cool as possible, and consequently as little expanded as possible. Success, indeed, depends more upon a constancy and accuracy of technique than upon the utilization of any extraordinary means of overcoming faults which should not occur at all.

TECHNICAL SKILL A PREREQUISITE.

With the possible exception of Dr. Ottolengui's statement regarding the cool mold, his views relative to the production of good castings, and the assumption that men producing fine results have been fine technicians, seem to answer very largely the question asked by Dr. Capon. In the production of the cast inlay there seem to be several steps, any one of which may contribute to the success of the operation, but in all instances it takes a good technician to get good results. Those who are unfortunate enough to be unable to secure a beautiful wax pattern with well-defined edges need not expect that the casting will be any better. And those who have not mastered the handling of chisels need not expect to be able to get good wax patterns. Whichever of the two types of cavities that will be discussed later the operator chooses to adopt, he must possess and learn to use at least the following instruments from Black's set, viz, Nos. 49–54, 77–85, 99, 100, or must have their equivalent in someone else's set. From personal experience the writer has observed that not a large enough number of the profession have ever followed the teachings of Black and others about outlining cavities to enable them to carve a wax pattern to a definite outline or to finish the margins of a cast gold inlay after it has been inserted into the cavity. Neither has the mechanical work on cavities for inlays been of a sufficiently high order. But the outline of the cavity and the degree of mechanical skill exercised in finishing seem to be factors of first importance. There has been a tendency on the part of many who formerly practiced the laying down of cavity margins on areas that would be cleansed by excursions of the food in chewing to do less extension at the cervical margins, for two reasons: First, because it enabled them in most cases to prepare cavities for the inlay that had inclining walls without excessive extension of the occlusal surfaces of the teeth; and second, because the present demand for better oral hygiene seems to warrant it. There are some, however, who advocate almost if not quite as much cervical extension for the inlay as for the foil and other fillings; which means, according to their teachings, that the cervical portion of approximal cavities in highly susceptible cases is wider than the occlusal portion.

THE PROBLEM OF CAVITY PREPARATION.

While the writer has been, and is now, a firm advocate of extension into areas of relative immunity, the practice of trying to get an accurate wax model in all the cases that are found in a large clinic, where the duration of the operation and comparative weakness of the

finished operation seem to exclude the possibility of inserting a gold foil filling, when there were walls parallel to the long axis of the tooth, or as some advocate, a cavity wider cervically than occlusally, has resulted in such comparatively poor results that it has been abandoned.

The question may well be asked, Why not make the same extension for the inlay as for the foil filling. If accurate wax models could be made equally well in both cases, and if the contraction of gold in castings so shaped was equally well cared for, there would seem to be no reason for the distinction between cervical extension for inlays and cervical extension for foil and other fillings. While some claim that there is little or no necessity for the distinction, it appears that they are in the minority, and are in reality trying to adapt the inlay to the cavity preparation previously used for foil and other fillings. A recent statement by one who has been one of the closest students of Dr. Black's teachings seems to indicate a tendency to take a more rational view of what has appeared to many of the profession's finest cast gold inlay workers as an extreme view of the question of cervical bucco-lingual extension of approximal cavities. The statement referred to was: "I have about decided that when the case seems to demand wide bucco-lingual extension of the proximal cavities cervically, I will accomplish this with something else than the inlay." This assertion admits the inability of this well-known operator to make satisfactory cast gold inlays in cavities of the nature of those mentioned (see Fig. 1) and appears to bring out the limitations of the inlay in this respect. It is doubtful, however, if those of the profession who are most sincere in their advocacy of better hygiene for their patients are always allowing the question of whether an inlay or foil filling shall be inserted to be decided by the amount of cervical extension in a bucco-lingual direction that seems to be advisable. On the other hand, it would seem that better hygiene was being substituted in many of these cases for the former practice of wide cervical extensions; and likewise, the cast gold inlay is taking the place of the foil filling in many of these cases.

DIFFICULTIES IN COMPOUND INLAYS AND CAST BASES FOR CROWNS.

Since the writer has been unable to secure uniformly accurate wax models, or to get some of the most skilled students to do it, from cavities similar to the one shown in Fig. 1, and since the contraction of the gold in cooling in compound fillings interferes to a greater extent with the walls of the cavity nearly parallel than it does when the walls are somewhat more tapered, he has made a study of how much taper could be employed without losing necessary retention form. Obviously, in cavities of the shape shown in Fig. 2, where only inside dimensions are to be considered, as little taper as will permit the drawing of an accurate wax model will be all that is necessary—for the shrinkage of the gold in cooling will facilitate the insertion of such a filling. In Fig. 3 much the same is true, though we have here, besides the internal dimensions of the cavity, two external ones. In Fig. 4 we have the internal dimensions of the cavity and three outside ones. In Fig 5 the gold ring on the mandrel represents a casting entirely encircling the object from which a wax ring was made. It may be seen that the ring does not go down on this mandrel, with a taper of 1/100 inch per inch, nearer than about 437/1000 inch to the place from which the wax ring was removed. Obviously the trouble encountered from the contraction of the gold will be in proportion to the number of outside surfaces to be fitted. In cavities in the occlusal surfaces of the bicuspids and molars there should be little if any trouble in getting a cast gold inlay to place. In proximo-occlusal cavities in the same teeth there should be but little trouble. In compound proximal cavities, however, and in casting copings, etc., for roots of teeth, where the casting nearly or quite surrounds the object

from which the wax pattern was made, a more difficult problem is presented.

Fig. 1.

Fig. 2.

From the beginning the compound inlay and the cast base crown have been the most difficult to construct. At least three of the profession's well-known men have furnished evidence of this, one with a clinic on how to correct the cervical deficiency in gold inlays, another with articles and illustrations and a clinic to show how to construct a cast base crown by first adapting to the root and crown

Fig. 3.

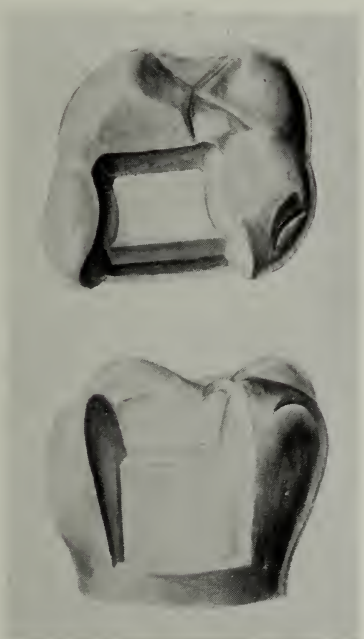


Fig. 4.

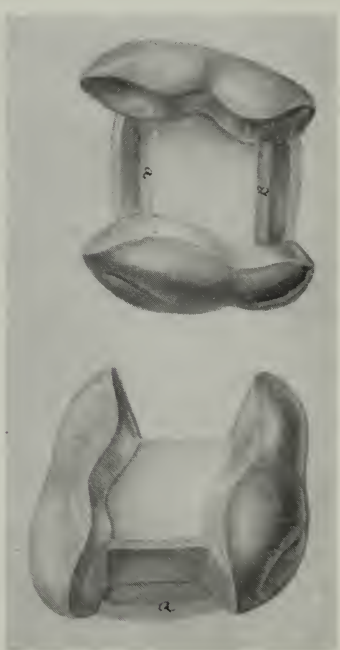


a plate of 24-k. gold. In other words, he is not attempting to adapt wax to the end of a root or a model of it and expecting a casting from this wax pattern to be satisfactory. Before the Lake Erie Dental Society in 1912 (*Dental Summary*, 1913, page 92), Goslee stated that "In the construction of gold crowns by the casting process, however, the fit or peripheral adaptation is, because of the spreading tendency of the wax, always best obtained by previously fitting some form of band to the root and then casting directly to it."

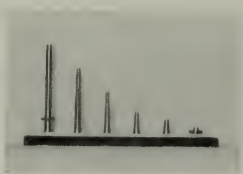
Before the Kentucky State Dental Society in 1913 (*Summary*, 1914, page 104), in discussing the cast base crown, he says: "In the various methods now generally used and advocated, good, accurate results are difficult to obtain, because the very plasticity of wax makes it possess a tendency to spread when subjected to the pressure necessary to mold it to a clean, close adaptation. This tendency has made it practically impossible for me to obtain a satisfactory degree of accuracy of adaptation to the root-end. However, such difficulty may be entirely overcome, and absolute accuracy obtained in all cases, by first adapting a cap of thin pure gold (about 36 gage) to the root-end." Later in the article he says: "Also, such a procedure reduces to a minimum the possibility of any change of form which may result from the warpage or shrinkage of the gold or alloy used in casting, and this is a very important consideration."

Approximately one year later (1914) at Detroit (paper yet to be printed in the *Dental Summary*), in discussing the subject of crown and bridge work he made essentially the same statements as he had previously made at Louisville in regard to the cast base crown.

Under date of January 14, 1915, I have from him a letter in which he says: "Replying to your question, will say that I have not changed my method of technique with regard to crown construction in any respect since my meeting with you in Detroit last year, and am still adapting the cap to the root by means of swaging pure gold or platinum on an amalgam die. An extended experience has convinced me that this is the only method by which I am able to obtain the degree of accuracy in the adaptation of my crowns to the root which I desire to obtain, and in addition to the accuracy obtained by previously swaging the thin cap, its very presence minimizes the warpage and shrinkage of the metal used for casting, hence making possible a better adaptation than might be obtained from the use of wax alone."

We have here repeated statements, covering a period of four years, from

FIG. 5.



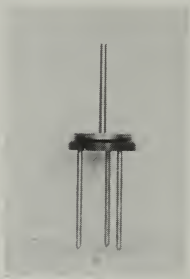
one whose identification with the subject of crown and bridge work is such that his opinion can hardly be counterbalanced with that of any other one man, that he can get a better result by not attempting to construct cast base crowns by adapting wax to either the root or a model of it without first adapting gold or platinum to it. It has been the experience of the writer both in private practice and in handling a large clinic that cast base crowns made by methods other than by adapting gold or platinum (preferably gold) to the end of the root or model have been so unsatisfactory that their construction has been abandoned except as a last resort in a few badly broken down cases. The question, then, of how some men got such beautiful results as were referred to by Dr. Capon without the use of the artificial stone model to prevent the gold from contracting, or the expanded wax pattern recently suggested by Dr. Price, may be answered by the statement that they do not make cast base crowns unless

they have a plate adapted to the end of the root—which method must be considered, first, as a factor in preventing the gold from contracting, and second, a method that insures the presence of the peripheral margin.

OBSERVATIONS ON DIFFERENCES IN ACCURACY OF FIT OF CAST HOODS AND COMPOUND INLAYS, AND THE REASONS THEREFOR.

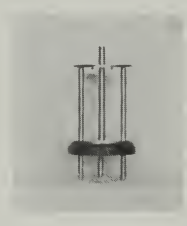
The compound inlay, with three outside surfaces to be fitted instead of four as with the cast base crown, has been done by some of the profession's best technicians by pursuing much the same methods as are suggested by Ottolengui, without the use of the plate that is suggested by Goslee for the cast base crown. The fact that such castings do not entirely encircle the object from which the wax was removed, and permit of a little stretching, must be remembered. Fig. 5 shows a set of hardened steel mandrels; the first and largest one has 1/100 inch taper in every inch, the second has 5/100 inch taper per inch, the third has 10/100 inch taper per inch, the fourth has 15/100 inch taper per inch, the fifth has 20/100 inch taper per inch, and the sixth has 25/100 inch taper per inch. Fig. 6 shows a hardened steel mandrel that is a duplicate of No. 1 in Fig. 5 to the 1/10,000 of an inch, together with a "raising device" (see Fig. 7) for raising a wax ring off the mandrel without distorting it. When a wax ring or washer is raised off the mandrel for this purpose and a gold casting is made from it, it will not go nearer than 437/1000 of an inch (see Fig. 5) to the place the wax came from, owing to the contraction of the gold in cooling. By passing this casting down the mandrels —all of which are of the same diameter at the base—successively tapered from 1/100 in. per inch to 25/100 in. per inch, it is seen that it goes to within 16/1000 of an inch on the 25/100 inch per inch taper (see Fig. 5). The writer has not been able to get a casting to go nearer to the bottom, even with a 25/100 inch per inch taper, than about 16/1000 of an inch. The difference between 437/1000 of an inch and 16/1000 of an inch approximately represents the effect of a 25/100 inch per inch

Fig. 6.



taper over a 1/100 inch per inch taper on a washer with a diameter of one-half inch and a one-fourth inch hole through it, with the technique that we are using. This amount is very plainly seen. The space between the base of the mandrel

Fig. 7.



with the 25/100 inch per inch taper and the gold washer which is approximately 16/1000 of an inch above it is also plainly seen. When compound inlays in molars and bicuspids are constructed with the same technique, however, they will pass to place so closely when made of 24-k. gold that no space is seen, providing the taper in the cavity is approximately 25/100 inch per inch, and especially at the points represented by *a* and *b*, Fig. 4. To eliminate the possibility of the elasticity of the tooth entering into the problem the same cavities have been prepared in steel and porcelain in large enough bulk to resist

any ordinary stress, and the result has been the same. The reasons for the washer not going to place, and the compound inlay going to place, appear to be, first, the shape of the inlay being such that it is stretched when but lightly pressed over a taper; second, the material is capable of being stretched with this amount of force; and third, the linear dimensions of such inlays are smaller than those of the mandrels, consequently less contraction takes place. That all three factors contribute to the placing of these compound inlays at various times, if not all the time, I think there is little doubt.

Cast gold can be stretched when pressed over a wedge with a force of four or five pounds when in the shape of a compound inlay in a thickness not exceeding 125/1000 of an inch. This is an easy experiment to carry out with ordinary measuring instruments. If, however, the compound inlay be made of gold alloyed with platinum or copper, or some other metals, the thickness that can be stretched is reduced in some instances to 31/1000 of an inch, and even less in others. It should be remembered in this connection that when once placed in the cavity the compound inlay is not subjected to the leverage of the wedge on the inlay some distance from the place being stretched, though there is a much larger force than four or five pounds placed upon the inlay in most of such cases. No such stretching of 24-k. gold in approximal or compound approximal inlays has been observed after the inlay has been placed, providing the cavity form had a good foundation and what would be called one of Black's occlusal extensions, except in a few anterior inlays that have been done in raising the bite for men where the conditions would seem to excuse the insertion of gold inlays in the anterior part of the mouth. This has led the writer to believe that those who are so enthusiastic about the use of alloyed golds for making inlays are using a cavity formation that would not be accepted by the students of Black's work or those practicing a somewhat tempered form of it.

Only when students or others doing the work have made the shallow and narrow occlusal formation, or have failed to get a good foundation for the inlay, have we observed the trouble so often described by some. On the other hand, we have observed the stretching of these inlays in a mesio-distal direction, and to take advantage of it in the finishing of the inlay we adhere closely to the beveled cervical margin (see Figs. 4 and 3) so that this thin part of the inlay may be burnished tightly against the tooth.

The third of the factors that appear

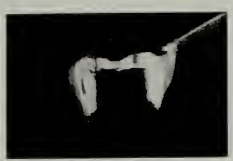
Fig. 8.

to contribute to the close seating of the compound inlay is the difference between the size of the mandrel and the size of the average inlay. The mandrel is 250/1000 of an inch in diameter at the base. In our clinic during the last six years, however, we have never found a compound inlay that exceeded 203/1000 of an inch, and only one that came near to this size. This may be because we are getting smaller teeth to operate on, or because we are selecting our cases more carefully than others, but it does not appear to be either. If the cavity shown in the last *Bulletin* of the National Dental Association, in the article by Dr. Price on page 118 (see Fig. 8) and which he says "reproduced as nearly as possible the actual condition obtaining in the molar tooth one-fourth inch in diameter with an MOD cavity, all walls of which had a taper of one per cent. to a common perpendicular," and if the inlay shown in

Fig. 9, which is a photograph of an inlay recently made at a casting contest where the cavity was supplied by the committee in charge, and if dozens of other similar cases that can be presented can be taken as an indication of what hundreds of the profession are doing in their cavity preparation for the inlay, there is good cause for believing that the reason why we do not get cavities that are one-fourth inch across the step portion is that we are cutting thicker seatings for them.

Whatever be the verdict of the profession relative to the cutting of good deep seatings for the cast inlay, the opinion of the writer will remain that cavities for the compound inlay that are

Fig. 9.



one-fourth inch across the step portion have a poor seating. It seems, therefore, that the contraction of gold as shown by Dr. Price in the cavity that he says represents the conditions that obtain in the molar cavities, and the amount shown by the mandrels that are one-fourth inch in diameter (see Fig. 5) is greater than the amount that will take place in the largest compound inlays for molars if they are prepared with the extensions and seatings recommended in Figs. 2, 3, and 4.

The compound inlay, then, that has a short portion of metal between the proximal portions has less linear contraction when the gold cools down than the one that is two or three times as long, consequently such an inlay will not show the amount of spreading that was referred to by Dr. Price in his paper read before this society in 1908, and which seems to be accounted for by the shape of his and the other cavity previously referred to.

The cavity shown by Dr. Price and the one that was prepared for the casting contest referred to, both show a taper of about 1/100 inch per inch, an amount not visible when the tooth is in the hand except under the most favorable conditions of light and when the tooth is revolved into certain positions. Under the conditions that exist in the mouth it seems impossible for anyone to be sure that there is a taper at all when there is as little as 1/100 inch per inch. If this amount would let one of the compound inlays down as far as the 25/100 inch per inch taper, would it not seem strange that anyone would adopt an amount that he could be sure of under all conditions for the sake of the removal of the wax? The question might be asked, Why are such cavities as shown in Figs. 8 and 9, with little or no taper and practically no seating form, presented as representing actual conditions in the molar teeth? In the case of the one from the committee shown in Fig. 9, I think that it is quite indicative of the general condition that prevails in the profession relative to extensions, seatings, and tapers for the inlay. In the case of the test cavity shown by Dr. Price, I would be inclined to think that he had prepared the most difficult cavity that could be prepared, coming anywhere near to the conditions in the mouth, for the sake of bringing out different methods of technique, were it not for the fact that he suggests that the wax from such cavity be expanded so that the inlay will go to place.

While it is difficult to say exactly why these types of cavities are presented, there appears to be no question about their being presented by a great many because they have never been impressed sufficiently with the matter of extensions and seatings. The question of tapers is one that does not date far from that of the origin of the general use of the inlay method of filling teeth, and it is not to be supposed that everyone has had this feature of cavity preparation for the inlay brought to his attention as it may be with a set of man-

drels with varying tapers. When the writer first began the work with the cast inlay he was under the impression that it was necessary that the cavity have as nearly as possible parallel walls to get the greatest possible retention, leaving little for the cement to do except to prevent the inlay from being drawn up out of the cavity. It had not occurred at that time that the inlay would go down farther on a taper of 25/100 inch per inch than it would on the 1/100, or the least amount that could be seen definitely. Later, however, when he came in contact with one in the same practice who was following the practice of prophylaxis and the treatment of pyorrhea it became necessary that an improvement be made in the condition of the proximal inlays at the cervical margin.

SUGGESTIONS IN REGARD TO CAVITY SHAPING.

This led to a painstaking study, in which it was found that the proximo-occlusal inlays were better in this respect than the compound proximo-occlusal ones. This led to the study of why this was true, and it was found that it was because the compound inlay was spread out, in the manner suggested by Dr. Price in his paper before this society in 1908, at the cervical portion. Immediately a study of the effect of tapers was made, and it was found that from 10/100 inch per inch to 25/100 would allow the inlay to go to place better than the very small amounts that had been used. The question of how much loss of retention there would be with tapers of this amount was then undertaken, with careful records, and it was found that, if the cavity were one that had a normal height from cervical to occlusal, and if a good seating was made and the occlusal portion was made of such width and thickness as would be accepted by an authority on cavity preparation for other materials, tapers of 25/100 inch per inch could be used without trouble from inlays being dislodged. The linear distance of the cavity from cervical to occlusal, the seating, and the size of the occlusal, all appear to have a bearing on the dislodgment of the inlay to as great if not greater extent than the amount of taper up to 25/100 or 30/100 inch per inch.

Since taking up the work in a large clinic these observations have been verified with records that show that not quite ½ of one per cent. of the several thousand inlays inserted have become dislodged when placed in such cavities as shown in Figs. 2, 3, and 4 with tapers of 25/100 to 30/100 per cent. per inch. The adoption of the tapers suggested, however, did not complete the study of how to improve the cervical portion of the compound inlays. The question of how to finish this part of the inlay soon resulted in using a larger bevel at the cervical, so that the inlay could be burnished close to the cervical to make up for the slight amount of spreading that was noticed with even as much as 25/100 inch per inch taper. This bevel may be seen in the cavities shown in Figs. 3 and 4. The burnishing of this part of the inlay to the tooth and the subsequent finishing soon led to the conclusion that 24-k. gold was preferable for these inlays, because it had proved strong enough when in sufficient bulk, and was much easier and better finished in these comparatively inaccessible places.

This experience with a specialist in the treatment of pyorrhea and practice of oral prophylaxis, together with several years' contact in a large clinic with those in charge of the gold foil fillings, who have demanded that inlays to be good for several years must look so near like gold fillings that they cannot be told apart, has caused a close adherence to the shape of the cavity shown in Fig. 4 when inserting the compound inlay, and the use of 24-k. gold. The factors of importance are, a taper of all walls of from 10/100 inch per inch to 25/100 inch per inch, depending upon the linear distance from one proximal portion of the cavity to the other, and a good bevel at the cervical, as shown in Figs. 3 and 4.

THE QUESTION OF BEVELS.

A form of cavity which has been widely demonstrated and written about is shown in Fig. 1. It differs from those shown in Figs. 3 and 4 by having a beveled margin all around the cavity, and it has almost parallel walls. Such cavities have been advocated, and are shown in *Items of Interest* for 1911, in the writings of one of the profession's good gold workers, Dr. J. V. Conzett.

More about the question of parallel walls seems unnecessary. The beveled margin all around the cavity is a subject about which more may be said, however. Dr. Conzett and those following this form of cavity preparation for the inlay seem to claim a better protection to the enamel rods as a result of this bevel. Some of those who have previously taken the same view of the matter have more recently stated that they were able to give the same protection with the cavity formation shown in Figs. 2, 3, and 4, the difference in protection being a question of whether there was the same occlusal extension in both cases. In studying a large number of cases it may be found that this view of the matter is approximately correct, though in some it may be necessary to make the taper to the step portion of the cavity more than 25/100 inch per inch to get the same protection shown in the cavity with the margin beveled all around. The objection to this form of cavity in the writer's hands has been inability in most cases to get the inlay down into the cavity as far as could be done with the form shown in Figs. 3 and 4. Upon examination it has been found that when the casting is made of 24-k. gold, the greater part of it that covers the bevel may be bent with comparative ease, but the junction of the bevel with the main portion of the step is the first to hold the casting from going to place. Inability to produce such angles with investing materials as soft as are now available has caused the abandonment of the bevel in this portion of the cavity, the beveling or rounding of such angles as are shown at *a*, Fig. 1, and the removal of some from the casting at *a*, Figs. 3 and 4, when it appears that a thin edge of investing material was present at this place when the gold was forced into the mold.

BEHAVIOR OF DIFFERENT WAXES USED FOR PATTERNS.

As upon the question of temperature of the mold when the cast is made, much has been written on the behavior of the different waxes used for patterns. Almost simultaneously came reports of experiments by C. S. Van Horn and Weston A. Price in 1910. In discussing the subject of casting, Van Horn says (Cosmos, 1910, page 877):

> It was proved that a pattern (wax cylinder) at the temperature of the water with which the investment was ordinarily mixed (say 54°–56°F.), the temperature of the water used in conducting the first experiments for this paper was some 0.0014 in. *shorter* than was the pattern at body temperature. Now, "It's a poor rule that won't work both ways"—therefore, to neutralize the shrinkage of gold, *expand the wax pattern* by having the investing material and the flask at a temperature sufficiently above the normal body temperature when the pattern is invested, to compensate for the shrinkage of the gold, which is in excess of the expansion of the investment.

Later in the same article he advises using water at the temperature of 115°–120°F. for mixing the investing material. It may be noted that the quotation implies that when wax is removed from the cavity to the investing material there is a reduction in temperature of over 40°F., and a reduction of the wax pattern as a result. To overcome this and to counteract the contraction of the gold he advises the expansion of the wax pattern with water for mixing the investment at 115°–120°. This would seem to be a good basis for the statement of Ottolengui previously quoted, that the "true method of casting does not depend upon the utilization, but rather the avoidance, of extremes of temperature," etc. In Cosmos for 1911, page 266, Dr. Price says of the "factors of error in the Taggart direct method":

"The wax for its pattern is put in the cavity at its workable temperature, which will be for the various inlay waxes from 95°F. to 130°F. It is cooled in the cavity, to render it firm and strong, to about 67°F. and in so doing it contracts, according to its formula, one or two per cent. of its linear dimension. If invested at this temperature an error of this definite amount is already carried forward, to appear in the final inlay, unless it be corrected by some other step." This implies that when a wax is cooled in the cavity it shrinks, and that the shrinkage is not corrected at the margins by the carving of the wax. Again the comment of Ottolengui seems appropriate, for the wax pattern is not smaller at

Fig. 10.

the margins when carved with a warm spatula by a clever technician.

Continuing, in the same article, Dr. Price says:

If the wax of the pattern, when being formed and cooled, surrounds the tooth structure, covering outside dimensions, it will be stretched as it cools, and it would by so stretching apparently correct part or all of the error of contraction from cooling; but all waxes have elasticity, and hence do not remain stretched, which introduces a new uncertainty or error to change the accumulated error. When the wax pattern is invested, its temperature will partly determine its dimension, for on heating from 67°F. to 100°F. or 130°F. the wax will be expanded, and if not carried to the softening point at which surface tension will distort it, or where the investment will change its shape, part or all of the accumulated error due to contraction of the wax may be corrected, and with a certain definite technique, to be explained later, even an error of expansion produced. The ordinary technique will not show the true expansion. Heating the pattern to enlarge it will release its elasticity and allow much distortion.

In the next step, that of heating the investment material, if it be of the best quality we may have an expansion of about one per

Fig. 11.

cent., or if of poor quality we may have a contraction of two per cent., according to our manipulation, and if the investing compound is soft and yielding it can be distorted easily by the pressure of the gold when casting, thus causing an error which is not a uniform expansion.

When the molten gold is forced into the investment, its physical state changes from liquid to solid, and here we have what has heretofore been an entirely unknown factor, but which we will show later to be a very large contraction; and again, on changing temperature from its freezing-point and cooling to normal temperature, it contracts, as

Fig. 12.

the writer has previously shown, over two per cent. (*Items of Interest*, May 1908.) This contraction can be partially controlled by pressure on the congealing gold, thus forcing gold from the sprue, and partially by holding the gold as it contracts, *i.e.* by causing it to surround a strong form, thus preventing the normal contraction.

The relation of the size of this final casting of gold to the original cavity in which

the wax pattern was made may thus vary through a wide range, and the final error is the sum of all the plus and minus changes made in the size of the record of the cavity as it passed through the different materials and processes. We will show definitely the amount of change produced by each step.

To work intelligently we must therefore know the behavior of the materials used for each step, and make the unfixed or variable changes correct the fixed changes.

CRITIQUE OF DR. PRICE'S CRITICISMS OF TAGGART'S DIRECT METHOD.

It may be noted that Dr. Price is discussing "factors of error in the Taggart direct method." First, he points out that wax shrinks when placed into the cavity, but does not point out that the shrinkage is corrected at the margins by the carving. Second, he points out the elasticity of the wax, and implies that a wax which has been stretched again returns to its original form during the construction of the inlay, apparently not recognizing the fact that some of the profession's best technicians are using the water from the same glass to both chill the wax while carving it to carry the wax in from the cavity to the bench for investing immediately and to mix the investing material with, thereby not getting a change in temperature of more than a degree or two before the investing material has hardened. Third, he mentions that investing materials properly made will expand approximately one per cent., but, if of a poor quality, will shrink about two per cent. It may be pointed out that the good ones will also contract rapidly if heated very long at a temperature of 850°F. or higher, hence the reason why Taggart has advocated from the beginning that the mold be removed from the heat as soon as the wax had been melted out of the way for the casting and had a sufficient dehydration to prevent much back pressure in the mold when the hot gold was forced into it. Fourth, he mentions that some investing compounds are distorted when the gold is forced into them, and says that this gives an error that is not uniform expansion. From the beginning Taggart has advocated a nicely regulated low pressure delivered quickly, a feature in which no other appliance to date can excel his. Fifth, he mentions that gold contracts on cooling, and suggests that it may be partially controlled by pressure on the gold during cooling and by using a strong form, such as artificial stone, to cast the gold around.

That such errors as the ones mentioned might occur in the hands of a bungling technician there is little doubt, but to call them "factors of error in the Taggart method," and to suggest that it was necessary to use such radical technique as the artificial stone model, high pressure on the gold while cooling, and an expanded wax to correct the errors seems to show unfamiliarity with Taggart's methods. Later in the same article, and in various parts of the current literature, reference is made to the change in volume of waxes which has been so thoroughly investigated by Dr. Price and presented by him at various times both orally and through the dental journals. The elasticity of wax has likewise been studied and reported in detail by him. A careful review of the articles referred to by Grieves in his report before the Sixth International Dental Congress in *Items of Interest* for October 1914, which includes many of the best ones, will show that many of the profession have encountered much of the trouble that is referred to by Dr. Price, but the writer is of the opinion that there must be some who have never encountered these troubles, because their results cannot be excelled, and they are not using the methods suggested by Drs. Price, Van Horn, Lane, and others relative to the use of hot molds or expanded waxes.

It seems safe to assert that no one can fail to acknowledge the debt of gratitude that is due those who present such detailed scientific data as have been presented by some of those mentioned relative to the behavior of waxes, but it appears to the writer a mistake that the conclusions to be drawn from such research should have been made and advocated to busy practitioners of

dentistry as the corrections for errors which had already been demonstrated to be entirely avoidable.

Therefore it seems unnecessary to consider the change in volume or the elasticity of the wax, if it be invested immediately and be transferred without change of temperature, unless the pattern is to be purposely expanded. The aim should be to avoid a change in temperature that would change the volume of the wax or release the tension placed on it when packing it. This seems to be the most valuable practical lesson to be drawn from the work of Dr. Price on waxes, viz, *invest the wax immediately,* not allowing it to change temperature from the carving to the investing. By obtaining a glass of water at room temperature and using this to cool and invest in as well as chill the wax with, using a good-sized pellet of cotton for the purpose of chilling the wax, the process of carving and investing and carrying the pattern to the laboratory may be carried on without involving a perceptible change of temperature. The expanding of the wax for the purpose of enlarging the casting appears to be an unsafe procedure except when the wax is of a uniform thickness—as in a few saddles for bridge work, etc. In the writer's hands it appears more satisfactory as a laboratory procedure than when used in the mouth. Any amount of releasing of the tension on the wax in the mouth that can be accomplished has not allowed the expansion of it afterward to give a casting true to form.

In the production of the gold washer for the mandrel the expansion of the wax aids materially, but the patterns do not remain true to form when taken from some of the irregular cases that are found in a large clinic. These irregular expansions appear to be due to uneven elasticity, density, and thickness of the wax after packing into the cavity. Whatever be the cause, it does not appear so contributive to beautiful results, in the great variety of cases found in a large clinic, as does the close adherence to the technique previously mentioned.

TEMPERATURE OF THE MOLD AT THE TIME OF CASTING, DETERMINED BY THE CASTING MACHINE USED.

Another subject which has been discussed by several writers is that of the temperature of the mold at the time of casting. An extended inquiry into the methods of a great many who have been known to be reasonably successful with this work has revealed that by far the greater number have favored what would generally be called a hot mold. This has been especially true with those who are using the vacuum principle for delivering the pressure. With one or two exceptions, the opposite has been true with those who were skilful with the Taggart appliance. The difference between the various machines on the market for the purpose of delivering pressure and the Taggart type of machine is very apparent in at least two respects, viz, the Taggart machine has the most uniform pressure of any device that has been presented, and it also permits of the quickest delivery of the pressure, of any device yet offered to the profession. These two features, and especially the latter, permit of using a cold mold without having the gold solidify before it has reached the remote parts of the mold, which are usually acute angles made by the margins of the wax. With a device like most of the vacuum appliances the application of the pressure to the molten gold is not to be compared in quickness of delivery, the Taggart appliance doing this with a spat that is so quick that it is hardly visible. With a recently designed centrifugal appliance (see Fig. 10, p. 524) that has a straight arm with a shield to direct the gold toward the mold, the pressure is delivered somewhat as with the Taggart appliance, though not quite as quickly or uniformly. This device is sold by the Patterson-O'Brien Co. of St. Paul, Minnesota, and is capable of doing very good work if the principles involved in the delivery of pressure by the centrifugal method are taken into consideration. It is obvious that with a vacuum appli-

ance a cold mold will not do for many irregular castings with thin sharp margins, for the gold will never reach such places in the mold. With the gold lying directly over the sprue, as it does in the Taggart appliance, and with the pressure applied with a spat, the gold, in the case of nearly all kinds of shapes of castings for inlays, can be carried to the finest edges in a mold that is at the freezing-point of water.

The possibilities of the two machines in this respect are as different as can be imagined. The centrifugal appliance referred to occupies a middle ground in this respect. The centrifugal appliances that have an arm with a joint that moves outward under varying conditions are not to be compared with the one referred to, either, in this respect. It seems, therefore, that from the standpoint of the delivery of the pressure, the cold mold is permissible only with the Taggart type of appliance and with the centrifugal appliance referred to, or one of the same type. Since more dehydration of the investing material aids in the passage of atmospheric air to the vacuum, the hot mold would seem to be capable of aiding in the delivery of the pressure with the vacuum appliance. It seems clear why those using the vacuum appliance should use the hot mold, though it does not account for the use of the cold mold by those using other types of machines.

In 1908 the writer advocated a cool mold for casting, and pointed out in this connection that gold and other metals do not have the fixed contractions on cooling that were attributed to them, save under fixed conditions. Excess of heat, shape of casting, combination with other materials, and a cool mold were pointed out as modifiers of the amount of contraction that would take place when the casting cooled down. Since that time several men have referred to the statement that a cool mold would produce a larger casting, and each seems to have placed some different interpretation on the word "larger." Apparently none of those who have discussed the subject have tried the casting of gold into a cool or cold mold with an appliance that would carry the gold to the finest angles, and have taken as the basis of their conclusion the contraction that occurred in compound cavities, cast base crowns, etc., where the casting has three or four outside dimensions to fit. There should be no trouble in observing that the distance from one cervical margin to another on a compound inlay is greater with the cool mold than with a hot one, with the Taggart appliance and the pressure regulator set below 6 lb. The best form to illustrate the difference seems to be a discoid with knife-blade shape (see Figs. 11 and 12, p. 524). In this casting, as with most large inlays, much of the shrinkage of the gold in a cold mold is represented by a hole in the casting in the locality of the sprue, or a sprue reduced in size or even disconnected from the casting when the Taggart type of appliance is used with low pressure and a sprue-hole that is small enough to prevent a premature falling of the gold into the mold by any little jar that may be given the appliance at the time of casting. These sizes of the sprue-hole vary from 20/1000 to 40/1000 of an inch. With a larger sprue-hole and increased pressure and with smaller castings the metal is fed fast enough to prevent the formation of the hole in the casting, and the shrinkage appears to be more uniformly distributed throughout the casting. A pressure, however, that will make sure the feeding of a casting of the size of a large compound inlay in a molar with a cold mold will invariably distort the mold, the very thing that we aim to prevent. If, on the other hand, the pressure is maintained and the sprue-hole increased in size for the sake of feeding the cooling casting, the back pressure in the mold produced by the incoming hot gold causes the gold to return against the pressure of the machine. With the centrifugal principle (as in Fig. 10, p. 524) the sprue-hole may be as large as 80/1000 of an inch and the pressure increased according to the following formula $\left(\frac{Wv^2}{32.16R}\right)$, many times that mentioned for the Taggart

appliance, and as a result the gold is held to the remote parts of the mold in most cases against the back pressure, and the casting is fed with molten gold as it contracts. Such castings, however, as are made with the fine silica and plaster-of-Paris investing materials that are now in the market will be untrue to form so often that the method, while it is in keeping with modern practice in allied casting work, must not be compared in accuracy of fit in the casting with castings made under low pressure.

Castings distorted from high pressures that are necessary to feed the molten gold during the cooling may sometimes be fitted to make a very acceptable result, but they must have the fitting. It must be remembered, however, that the feeding of a cooling casting requires heat, pressure, and a sprue-hole that does not cool at the same time that the remote part of the casting does, and by so doing shut off the feeding. The latter is what takes place with the use of the small sprue-former and the low pressures usually used on the Taggart appliance, the result being that the casting is not always fed, and the shrinkage is often represented by a hole in the casting, a sprue that is reduced in size, or one even disconnected from the casting, because the gold is kept a little hotter at this point owing to the heat applied to the investing material in melting the gold, but is not in a condition to be fed to the casting below.

TWO KINDS OF CASTINGS.

Two kinds of castings appear as a result of the use respectively of low pressures and small sprue-formers, and high pressures and large sprue-formers. The former may be known as those that are not always fed with molten metal, depending upon the size, shape, etc., of the filling, and the latter may be known as those that *are* fed with molten metal. With the former, fine margins which often determine linear dimensions are often dependent upon a cold mold that will chill the metal instantly at the margins, thereby bringing into operation surface tension which pulls the cooling metal from the center toward the congealed margins before an appreciable amount of back pressure has had time to form from the hot gold. With the latter, fine margins may be produced with either a hot or a cold mold, though in the writer's hands there is little comparison, in accuracy of fit, between the casting made under low pressure and the one made under high pressure, in any investing material now available. For this reason the low pressures and cool mold have been adhered to with all our machines, which would deliver the gold to remote parts of the mold into the finest margins before congealing, even though there was a hole in the casting—a defect easily corrected with a small piece of lower-karat gold and a blowpipe.

A close study of the "Hadfield process" of making sound steel ingots, by Sir Robert Hadfield, in the Proceedings of the Iron and Steel Institute, and the numerous references to the process by others, the practical suggestions by John Sharp and others, as well as a careful survey of the operations of the foundries where perfect castings are a necessity, will, in the opinion of the writer, convince the present users of hot molds that the problem with a foundryman in most cases is, first, a cool mold, and second, facilities that will feed the molten metal to the casting as it tends to form the hole in the center. Since the present investing materials do not seem to resist the pressure necessary to fill all shapes of castings without distortion of the mold, it appears that the better practice is to adhere to the cool mold for the cast inlay where the fine margins and true form are the important features, and get a pressure appliance that will deliver the pressure quickly and uniformly, allowing the hole to form in some of the castings rather than attempting to feed it.

With castings other than inlays, where the fine margin is not so important a feature, a warmer mold may be permissible, but in no instance does it seem that the quality of the casting nor

the trueness to the form of pattern is improved as a result of the increased heat. Until dentists adopt the use of pressure appliances that are capable of filling a cool or cold mold for a compound molar inlay, to the finest angles, quickly and with uniform low pressure, they will not realize to the fullest extent what a perfect reproduction of a wax pattern is.

INVESTING MATERIALS.

There are on the market a few investing materials that will not permit, in the writer's hands, of the use of the cool or cold mold with any pressure appliance yet devised. Upon examination it has been found that the difficulty lies in the lack of porosity of these products. No amount of pressure obtainable with any of the devices tried would result in the fine margins that could be obtained with other materials. Not only have these materials been the cause of failure in our hands when used comparatively cold, but also when heated thoroughly. This lack of porosity of these products seems to cause the air to become compressed as the gold rushes into the mold, and to prevent the escape of the gas formed from the hot gold.

The introduction of such materials as clay, magnesia, whiting, and others that will become denser with heat appears to furnish contributing if not controlling factors in the cause of the density of these materials. An investing material must allow air and gases formed from the hot gold to pass out readily, if the gold is to reach and to be held in the finest margins. While clay and magnesia both add to the strength of most of these investing materials, as their setting qualities are added to those of plaster, they both shrink under comparatively low heat and make an investing material that is very dense and hard as compared to one made from plaster alone as the binding material.

The writer pointed out in 1908 that the only material then available that could be depended upon to expand regularly upon the application of heat, and thereby counteract to a great extent the shrinkage of the plaster, was silica. It was also pointed out that two or three grades of sizes of silica would eliminate much of the tendency of these materials to crack, because there would be an overlapping of the different sized particles. From that time until now there has been little improvement in the material suggested at that time for inlay work, either by the manufacturers or anyone else. There has been a tendency by the manufacturers to adopt the use of a coarse grade of silica that had round particles instead of the No. 200 flint suggested. This appears as a little improvement over the angular flint suggested at that time.

Two or three grades of silica, with the finer grade predominating, together with plaster of Paris, in the proportions of approximately four of silica and one of plaster, as adopted by the majority of the manufacturers, will permit the use of a cool mold and the pressure devices that are quickest in their delivery of the pressure. Those containing the materials suggested that set or bake hard, however, seem to have no advantage except strength, which seems to be insufficient in importance to counterbalance the objection attaching to them of not being porous enough.

A CASE OF EXTENSIVE ALVEOLAR ABSCESS ASSOCIATED WITH PYEMIA.

By JOSEPH HERBERT KAUFFMANN, D.D.S.,
DENTAL SURGEON TO THE BRONX HOSPITAL DISPENSARY, NEW YORK CITY.

ALTHOUGH many cases of similar nature to the one to be described have probably been recorded, the case under consideration presents so many complex and interesting phases to all interested in oral surgery that it is probably worth noting.

HISTORY.

On March 29, 1913, the patient, Mrs. X., presented at my office for the first time with an inflamed and very painful area in the lower right third molar region. The patient, the mother of one child, was a frail, anemic subject of about thirty-two years of age, affected with palpitation of the heart and occasional fainting spells. She had extremely carious teeth, which had lost their fillings, and her right temporomaxillary articulation was very susceptible to dislocation, no doubt owing to the weakness of the ligaments of that joint.

The patient stated that about four weeks previous to her visit she had consulted a dentist for the extraction of a lower right third molar—which is important to note; but although she thought then that the operation was complete (as she was told), three weeks after, or one week before she presented to me, the region became painful and she described the condition as "a feeling of something still there."

DIAGNOSIS.

The patient's general history immediately caused me to look for one or more roots which might have been left in the alveolus and were already starting to cause an abscessed and necrotic condition. Upon digital examination nothing of that nature could be found, but upon probing in the partly opened and inflamed socket I could feel what seemed to be a root and some necrotic bone surrounding it. In order to make a positive diagnosis, I advised that a radiograph be taken; to this, however, the patient would not consent, saying that she knew something was there without seeing a picture of it. My work, therefore, had to be based upon that presumption, although I regretted the lack of a more positive diagnosis, and my object was to remove as soon as possible the abscessed remaining root.

TREATMENT.

In order to relieve the soreness, I first cleansed the socket with a 10 per cent. silver nitrate solution, followed by a deep application of tincture of iodin, over which I applied orthoform, an anesthetic powder, and told the patient to make up her mind that, since I could not secure an X-ray picture, I would have to treat the case slowly, as I did not care to damage the tissues further, not being able to determine the conditions exactly, especially since there was intense swelling.

For the next week the patient presented each day, and gradually I was able to remove small portions of necrotic bone, although the root was yet obscured and undisturbed. So far, no pus or external swelling was noted. My treatment was confined to a daily syringing of the cavity with a saturated

solution of boric acid and to advising the patient to use the same solution every two hours at home, my intention being to remove the root when the socket became cleaner, as I expected it to be in about ten days, as the pain and swelling subsided. About one week later, her pain being relieved, the patient failed to make any more visits, as unfortunately is often the case.

About one year later, on April 27, 1914, she again presented with a most enormously swollen right mandible and a serious condition of locked jaw, due chiefly to an involvement of the masseter muscle and an extensive osteomyelitis of the adjoining portion of the mandible. It was necessary to make a mouth-prop of modeling compound in order to keep her mouth open, so as to be able to work properly. Of course I could not help immediately recognizing the case as one of extreme osteomyelitis and extensive necrosis due to a slow spreading of the infection resulting from the abscessed root the removal of which had been neglected. This most discouraging condition was aggravated by the fact that the patient was pregnant and expected confinement within a month.

I now prescribed potassium iodid, according to the formula of Dr. Fortiner of New Jersey, for the purpose of relieving the locked-jaw condition. I next resolved to extract the abscessed root at any cost and also removed much loose necrosed bone, but I did not use any force to remove such bone, for reasons to be stated hereafter. It is here necessary to explain that my work had to be done from ten to eleven o'clock at night, because the patient was unable to come during the day, the family sleeping during that time in order to spend their waking hours with the husband, who was working at night.

Two days later, after a most trying local operation without any anesthetic whatsoever, I removed the abscessed root entirely, but not until much destruction had been done owing to neglect of treatment, with consequent later results. My treatment again turned to thorough washing-out with saturated boric acid; I also removed a large portion of necrosed bone, together with the appended sound second molar tooth.

Here, very abruptly, despite great swelling, considerable necrosis, and osteomyelitis, the patient failed again to appear.

On June 20th, seven weeks later, I received a message from the patient's physician asking me to call immediately for a discussion of the case, as she was in a most serious condition. Upon seeing him at her home, I learned the following facts about the case: On May 13th she had given birth to a healthy male child, having had her old family physician in attendance. Before and during the period of her confinement, from the time she had last seen me at my office, she had still been bearing all the conditions attendant upon her abscessed and necrosed jaw, for which she received no treatment. Her first physician being called away, a second physician was called in, who informed her that the abscess treatment could be temporarily disregarded. This discontinuation of treatment was the most unfortunate circumstance of all. Four weeks after her confinement she went out for exercise, meanwhile suffering intense facial pain, due to neglect of treatment. At that time pus was constantly forming as the necrosis increased, and as it formed, automatically increased the necrosis and osteomyelitis. In trying to escape, this pus pressed upon the tissues, causing the patient intense agony. Nevertheless she was told to disregard the condition, and no dentist was consulted. The patient suddenly developed various symptoms of pyemia, and her second physician recognized the gravity of her condition. The patient had failed to realize her becoming a victim of gradual intense autointoxication, due to the incessant ingestion into her system of ounces and ounces of pus containing staphylococci and streptococci which were gradually involving all the tissues and organs of her body. Her physician immediately resolved to cut into her diseased jaw-

bone in order to afford relief, and he lanced the inflamed area, three times, from within; the patient refused to allow him to work further, as he was unsuccessful in his attempt to liberate any pus. The next day, however, after this attempt, the external tissues were perforated by the pointing and escape of the pus itself; about a pint of pus was liberated, and the fistula had completely established itself from within outward, affording great relief locally to the patient. During the next two weeks the constitutional pyemic symptoms became aggravated, and the physician left the case to be attended to by her dentist. On the 19th of June she called in a third physician, who after examining her, sent for me the next day, as stated above.

At that time her condition was as follows: Pains all over her body, especially in the regions of the spleen, kidneys, genital organs, head and neck; intense, diffused, sluggish yellow hue; inability to move the limbs freely; intense thirst; little hunger; inability to swallow or move the jaw; enlarged cervical lymphatic glands; copious discharge of pus both within and without; fairly large swelling; extensive necrosis and contiguous osteomyelitis; temperature of from 103°–105°F.; respiration of about 14; pulse of about 130; periodically severe chills lasting an hour at a time and followed by severe perspiration, which latter symptoms are almost pathognomic of true general pyemia.

As a prognosis, after comparing notes, we decided that we did not think the patient could live another week, especially since she had no nurse or other help in attendance, and as she absolutely refused to go to any hospital, even her husband being unable to persuade her to do so.

We then decided to lay the stress of treatment, as a final hope, upon her jaw alone, although she also had a slight sapremia as a result of neglect during her confinement, which latter affection, however, passed away quickly upon antiseptic treatment. Therapeutic efforts were now concentrated upon her diseased jaw, the physician later prescribing euquinin as a general alterative and antipyretic in strong doses.

After a close examination of the patient's mouth and jaws, I first cleansed the mouth thoroughly with a strong listerine solution, removed as much pus as possible, and advised the use of a strong boric acid solution as a mouth-wash every hour, the former drug being too expensive for her to use. After removing as much pus as possible by palpation toward the cloaca, I injected into the fistula by way of the alveolus five or six drams of boric acid with a hypodermic syringe, and cleansed the fistula by letting the solution find its way out externally.

I absolutely refused to curet any bone —in spite of what the text-books advise in these cases—for the following reasons. First, and most important: The intensely weakened condition rendered it likely that the infection would easily be pushed out beyond the area already involved instead of confining it, by forcing more pus and infected matter into the surrounding tissues, which were now very susceptible to infection. Secondly: There was no visible sequestrum or line of demarcation. Thirdly: The escape of pus and proper antiseptic and prophylactic treatment were sufficient measures, under the circumstances, and served to check further destruction of tissues. Fourth: In order to curet, a general anesthetic would have been necessary, but the patient was too weak for that, especially since her heart action was very poor, as indicated by a pulse of 130.

This simple treatment was followed by inserting a moistened drain of half-inch gauze externally so as to allow an unobstructed exudation of pus; over this I applied a regular surgical dressing held in place by a plain bandage over the head, as any other form of bandage, such as the Barton, was too cumbersome. This procedure was repeated twice a day for eight days, always evacuating by massage as much pus as possible and using a syringe to cleanse the fistula.

Five days after starting this simple antiseptic treatment I noticed a reduction of temperature, cessation of chills, normal breathing, healthier pus, and an improvement in the patient's subjective feeling, the yellow pyemic hue having subsided, a more healthy color taking its place. One week later I reduced the treatments to one a day, and then succeeded in removing much loosened necrosed bone.

Meanwhile, the euquinin, which had served its purpose, began to produce symptoms of cinchonism, consisting in temporary loss of equilibrium, headache, dizziness, and buzzing in the ears, and we discontinued its use entirely. By the 10th of July I was able to see the patient in my office for a better examination. At this visit I removed much proud flesh, necrosed bone, and coagulated blood, the dead bone having a splintery, softened appearance, due to the process of liquefaction necrosis which always accompanies alveolar abscess. I cleansed the fistula with a 2 per cent. phenol solution, the treatment leaving the patient in a somewhat exhausted but greatly relieved condition. A dressing of rubber oil-silk over the cloaca, covered by gauze and adhesive plaster, was now used, so as to dispense with the more annoying bandage over the head.

CONCOMITANT METASTATIC ABSCESSES.

During the treatment described, my attention was called to two small metastatic abscesses in the post-scapular and acromial regions, which had presented because—First: Gravity had drained the pus downward along the lymphatics in these regions. Second: All of the pus, owing to its great quantity, could not escape at the fistulous opening, because of the thick superficial cervical fascia in this region, which prevents pus from drawing through facially, but causes it to ooze downward to the lower limits, posteriorly and anteriorly, of the thickened fascial wall, where the deep cervical fascia prevents it from penetrating inwardly.

These metastatic abscesses were soon disposed of by gently massaging the pus upward to its source and by external application of aconite and iodin, which promoted lymphatic absorption. Most of the pyemic symptoms were now rapidly disappearing and the patient was much more at ease, although the pus still flowed copiously. There also remained, at the end of September, some necrosed bone, which by cleansing and prophylactic treatment had to be taken care of, but was gradually exfoliating. Again the patient exhibited another peculiar determination, and decided that she would be "operated on" for removal of the little remaining trouble (which by simple treatment had now almost been entirely removed), because, she said, "she wanted to have the trouble over with at once." However, although she left me, after I had actually saved her life, she neglected the "serious operation" as she termed it. About a month later she reappeared with a piece of necrotic tissue about a quarter of an inch wide and half an inch long, which had been removed by an operation (?), although she herself admitted that the "operation" was not warranted and that the necrosed bone might have been out long before by nature's aid, had she allowed me to follow up the simple treatment. She again asked me to take up her case, which I told her I would gladly do, but there was nothing left to do, as she had only to continue her prophylactic measures and her jaw would be restored to normal, although it was much deformed, as she had lost practically the entire angle of the mandible through necrosis.

SUMMARY.

In reviewing this case, the chief points of interest, and the deductions therefrom, are:

First, and most important: Every operation for the extraction of a diseased tooth or the roots of a tooth must be complete, and if under any circumstances the operator is not absolutely positive of the completeness of the operation he should so inform the patient,

and complete the work as soon as possible.

Second: In any doubtful case, a radiograph is useful—in fact it is indispensable in the more difficult cases.

Third: Neglected roots, when allowed to remain and to give rise to alveolar abscess, will not alone cause local destruction of tissue, but may become the source of an incessant and most dangerous absorption of virulent bacteria and the accompanying products of putrefaction and decomposition—or, more plainly speaking, of the absorption by the blood and lymphatics, the primary fluids, of pus with its attendant myriads of pyogenic bacteria. These, with other morbid changes, in persons of reduced vitality, react in the most serious form of auto-intoxication known, viz, true general pyemia—as was shown in this particular instance.

Fourth: Such a condition, when present in a pregnant woman, not alone endangers her own life, but by way of the fetal circulation the life of the fetus, causing the child to be born already diseased or even dead.

Fifth: Only the most favorable turn of circumstances and careful systemic treatment, coupled with strict antiseptic and prophylactic local treatment, can save the life of a person thus affected, the usually fatal result of pyemia being well known and recorded in medical literature.

THE RESPONSIBILITY OF THE MEMBERS OF THE DENTAL PROFESSION TO THOSE WHO ARE WITHOUT OPPORTUNITY FOR DENTAL TREATMENT.

By B. HOLLY SMITH, M.D., D.D.S., Baltimore, Md.

(Read before the union meeting of the National Dental Association and the Georgia State Dental Society, June 5, 1914.)

EVER since the days of Cain, the question "Am I my brother's keeper?" has been asked, and has found an answer in organized and individual effort for the protection and uplift of mankind, in the betterment of his social, religious, and physical conditions. Philanthropists have built hospitals, almshouses, and churches; colleges and other institutions of learning have multiplied, that man may be trained in the art of living and serving his fellows. Lawyers and statesmen have drafted statutes which, when enacted into law, restrain and punish the vicious and wicked or give greater scope to the civil and religious liberty of the citizen. Scientists and physicians have made plans for sanitary living, for the prevention of the spreading of contagious diseases, and the purification of the food supply. Farmers all over the country are making an organized effort for good roads; merchants and commercial organizations have formed vast plans for the extension of commerce and the increase of manufactures. In fact, the world is teeming with one grand musical hum in affirmation—"I *am* my brother's keeper."

Accepting this acknowledgment, what are we, as a profession, to do with the statistics and statements of writers and students of the relation of neglected mouths to the economic status of those who possess them? When we are told by perfectly reliable authorities that the mental, moral, and physical efficiency of the child or adult is increased from 50 to 100 per cent. by substituting normal for abnormal mouths; when we read

once again Dr. Osler's so often quoted statement, "If I were asked which did more harm to the human family, decayed teeth or alcohol, I would unhesitatingly say, Decayed teeth;" when we are repeatedly told that less than 10 per cent. of all the people ever receive any dental attention; when in the examination of about one thousand mouths in a Baltimore public school less than three per cent. were found where dental attention was not immediately needed; when the most advanced and enlightened physicians insist at the beginning of the treatment of almost any serious disease that the mouth must be placed in a healthy condition; when the noted surgeon, Charles H. Mayo, says, "The next greatest step in medical progress in the line of preventive medicine should be made by the dentist; the question is, Will he do it?"—we must realize that we are facing a demand as imperative as it seems universal.

I have no doubt in my mind that we will say as individual practitioners, "We *do* do it," and I repel the implication of the great surgeon that we do not. Our private patients all over the country get intelligent and skilful service, and we are more than willing to hear argument from the physician in favor of what we have long contended, that neglected mouths invite disease. We hail with joy the co-operation of our brother medico, and thank God for his conversion even at this late day; but what has this to do with the other 90 per cent., those who have no dental attention and no chance to get it? Why, when the people of Georgia realized that strong drink was degrading her citizens and endangering the safety of her homes, men, women, and children all joined in one mighty effort to prevent its sale, until today, I am informed, you cannot get a drink outside of the Capitol City Club.

Now, if Dr. Osler's words are even partly true, we must feel a deep sense of responsibility that the people should realize the situation. We must involve our municipal and state officials, our preachers and teachers, our social workers, our philanthropists, and other public-spirited citizens. Each individual, as well as each association, must work toward the goal, unceasingly teaching, always pushing the line nearer. First, last, and all the time, however, must the dentist himself keep at the good work; he must be in the van. Only in this way will real advance be made, by our own sacrifice—sacrifice of ease, sacrifice of serenity, sacrifice of time and money.

In all the world's history the march of human progress has been measured by sacrifice. Idleness and self-indulgence caused our first parents to be turned out of the paradise of Eden to wander in barren places, they and their descendants reaping the consequences of their misdeeds in crime and tragedy. Self-sacrifice and devotion to the state built up the mighty Roman and Greek nations to be the most cultivated and enlightened people the world had known, while self-indulgence and love of ease caused their governments to decay, their people to degenerate, and their evidences of culture and refinement to crumble in the dust. The history of the establishment of growth of our own nation, the like of which the world has never before known, has been one long succession of sacrifices, from the suffering and starvation of the colony at Jamestown to the bleached bones that lined the trail out to and over the Rockies.

For every great industry developed, every discovery of science proclaimed, every invention that saves labor and facilitates manufacture, we can see in the background the student, the thinker, the mechanic, the scientist working with the energy of a steam-engine long after average men have gone to rest, proclaiming in the language of an Edison that four hours is all the sleep he ever gets, or of a Schwab that he could set up and run every intricate piece of machinery used in the manufacture of steel; or we might point to the inventor of the linotype, who laid down his life in the perfecting of this invention, which has revolutionized printing.

It is of such devotion as this that

American material prosperity is made, until American wheat, corn, cotton, American machinery, American inventions in all the mechanical arts, have given us a commercial prestige unequaled by any other nation. In fact, our material progress has been so rapid, the growth in the volume of our wealth and commerce so phenomenal, that many persons become dazzled, and see only these in the forces that have placed this nation in the front rank, if not leading the nations of the world. This in part is true, but great spiritual and humanitarian impulses have always preceded and underlain material prosperity. The fact that this country offered to men of independent thought, men striving to worship God in spirit and in truth, an asylum from persecution and bigotry, was a greater inducement to the very class which has been the backbone of our nation than was the opportunity to amass wealth. Of the thousands who crossed the Rockies, the major portion, who went purely in search of the gold of California's mines, were largely unruly adventurers, who did little to develop the country, while Marcus Whitman and the missionaries who followed in his trail dotted the land with colleges and churches, institutions which have developed the men who are today the strength of the West, and who are clamoring more loudly than those of any other part of our country for the rights of men and the protection of women and children. It is on these attainments that we should pride ourselves, because in such accomplishment is to be found the only sure foundation for the permanence and stability of our nation.

In foreign cartoons America is frequently represented by the hog, because of the so-called lack of culture of the American man and the greediness of many of our financiers. But the unselfish qualities of the average man are reflected in our diplomacy which refused to accept more indemnity from China after the Boxer rebellion than was literally needed for reparation, that not only set Cuba free from the yoke of Spain, but banished her most dreaded foe, yellow fever, and as soon as she was able to stand alone retired without one concession in payment. Today our chief executive is giving special emphasis to our big-brother attitude toward the nations near us. It is these things which cause our hearts to glow with pride rather than statistics of our bank clearings, exportations, etc. And in this striving for the ideal rather than for the purely utilitarian, for the altruistic rather than the mercenary, for the good of the profession and through that the benefit of all men, rather than the mere amassing of wealth, the great men of the medical profession always have been marked.

Hundreds of medical heroes, for the improvement of the theory and practice of saving or prolonging human life, have suffered impaired health and even death, have gone into disease and pest-ridden communities at the imminent risk of their own safety, like the hero, the life-saver in every walk of life. Perhaps the most striking instance of this heroic sacrifice for science and humanity occurred when three comparatively young, but certainly very well trained and useful army surgeons—Ried, Carroll, and Lazier—conspired together in Cuba to prove to the world a theory which they themselves had partly developed as to the cause of yellow fever. They agreed that each should be inoculated by a mosquito which had bitten a yellow-fever patient during the first three days of the disease, and had been allowed twelve days for incubation afterward. Ried was called to Washington and did not take his mosquito. Carroll and Lazier contracted yellow fever as a result of their bites, and both died. Lazier was the first to succumb, and Carroll some time afterward. Later Ried, too, died—no doubt as a result of his trying compact and desperate sorrow. As valuable as is a trained human life, the sacrifice which these men made seems amply repaid in the saving of millions upon millions of dollars which yellow-fever epidemics would have cost, to say nothing of thousands of lives they have protected and the freedom from

danger they have secured in the construction of the Panama canal, the most useful and gigantic engineering proposition the world has ever known.

We all recall the wonderful work of Dr. Trudeau at Saranac, N. Y.; he was himself a consumptive, and ill, yet nevertheless established a colony and sanatorium where numbers have been cured of the "great white plague."

There is no gainsaying the fact that professional privileges bring with them very serious, yet, withal, most honorable and ennobling responsibilities. A profession is necessarily benevolent, because of itself and its science being most certainly made up of the benevolence of others; made up of treasures intrusted to its members, as trustees, to be used for the betterment of humanity as a whole.

Less conspicuous perhaps, but not less useful than the medical profession, are the army of men and women, workers in charity organizations, children's playgrounds, visiting nurses' associations, etc., who serve their fellows and bring aid and comfort in times of distress, affliction, and disease. What an unwholesome and uncomfortable place this world would be to live in but for such service, and what a great need there is that it shall be rendered in more abundance! We as a generation are passing, and are today perhaps beyond reclaim, but the child comes on at rapid pace—to make or mar our nation, to elevate or degrade our race.

President Wilson has said:

> The human race is not to be saved by a remnant; the human race is not to be saved by a few instructed persons, but it is to be saved by the consciences and purposes of common men. If you cannot carry the instinct of the common man with you, then you have done nothing to increase the forces or to enhance the hopes of the nation.
>
> And so, in studying the interests of Atlanta, you are studying the interests of Georgia, you are studying the interests of America; you are trying to set yourself the standards which, as they spread from community to community, will call men's thoughts back to these fundamental things for which we live.
>
> We do not live for material success. Not one of us has ever been satisfied for a single moment by material success. We live in order that our spirits may be serene. We live in order that days may come in which, when our work is over, we may look our fellow men in the eyes with unfaltering gaze, and when we shall come to the brink of the grave and go down into its depths, that we may know that we, at least, have done our little parts to see that men are elevated to the uplands of vision and unselfish achievement.

[See also *Discussion*, as reported under "Proceedings of Societies," this issue.]

THE USE OF NITROUS OXID AND OXYGEN FOR PAINLESS DENTISTRY.

By JEROME G. HESS, D.D.S., Lancaster, Pa.

THE active part taken by dentists in the discovery of general anesthesia is a matter of historical record, and it is to be expected, from the painful nature of their work, that they should put forth every effort in perfecting agents and methods for the relief of pain. It is very gratifying, therefore, to observe the results obtained in the use of nitrous oxid and oxygen for this purpose.

Various general and local anesthetics have for many years been in use in dentistry for extracting teeth and for small oral operations, but nothing has been used with success for the relief of pain in the preparation of cavities for filling teeth until three years ago, when the

combination of nitrous oxid and oxygen was introduced for such work. Nitrous oxid has been used in its pure state for the extraction of teeth since as early as 1844, but it could not be used to advantage for a sufficient length of time to do prolonged operations. The discovery of the combined use of nitrous oxid and oxygen is as helpful in modern dentistry for the relief of pain as that of ether or chloroform in surgery.

The fear of pain has kept thousands of people from having their teeth attended to until an exposed pulp, abscess, or some dental disease compelled them to seek the services of a dentist. With nitrous oxid and oxygen the dentist can produce a state known as analgesia. In this condition the patient maintains consciousness, and has full possession of his mental faculties throughout the operation. He sits calmly and restfully in the chair, knowing that the work is being done, but feels no sensation of pain.

This anesthetic is, in the hand of an experienced operator, safe, pleasant to take, and entirely free from after-effects. Analgesia can be varied in depth according to the requirements, and can be prolonged for any desired period of time.

By the use of nitrous oxid and oxygen for the relief of pain, the dentist can thoroughly remove all carious portions from the teeth, impart to the cavities a better retentive shape for the kind of filling selected, and do more work in the same amount of time with a degree of satisfaction which can only be appreciated by that class of patients who have given this method of modern dentistry a trial.

During a period of two years I have given 756 administrations of nitrous oxid and oxygen for analgesia. Ninety per cent. of these analgesias were perfect, nine and one-half per cent. of cases were benefited by its use, and ½ of one per cent. of cases were entirely unsatisfactory. In the last class a few were nauseated, not from the gases alone, but owing to an abnormal physical condition. After the nausea had worn off, most of these patients felt fine, and upon leaving the office continued their regular routine of business for the balance of the day. One patient, whose history showed a low physical and nervous condition for the past few years, was partially exhausted, and showed slight symptoms of hysteria at the close of a forty-minutes administration of this agent, but after several hours regained her usual physical state. In this case the work had been done without any pain.

As illustrating the remarkable results obtained by this treatment, a perfect case, "Miss W.," might be more fully described. This patient was unusually nervous and slightly hysterical, her pulse being 112. In this case, caution and an accurate diagnosis were essential for obtaining perfect results in the administration of nitrous oxid and oxygen, and by one not thoroughly familiar with the various symptoms indicated, difficulties would have been encountered. Four minutes after the valves of the nitrous oxid and oxygen apparatus were opened, perfect analgesia was produced. The operation consisted of the removal of the pulps from the two upper central incisors and the preparation of a large interproximal cavity on the upper left second bicuspid. The duration of the administration was fifty-two minutes. The patient was absolutely free from pain, yet maintained full possession of her mental faculties, which was evidenced by her intelligent response to any suggestions required during the execution of the work. At the close of the period she left the office free from any ill effects whatever. This case, while it is only one of many of similar character, shows the great need of an agent for the elimination of pain in the conservation of teeth which otherwise would have to be neglected or sacrificed.

Nitrous oxid and oxygen anesthesia and analgesia are not confined alone to the filling and extraction of teeth, but can be used to great advantage in oral prophylaxis, especially so in the preliminary treatment of pyorrhea, since thorough cleansing of the teeth in a diseased condition of this character with-

out the use of an agent for the relief of pain is almost unendurable. In subsequent treatments of such pathologic conditions, however, it is usually not required, unless in very unduly nervous subjects, when it will be found of great service in the injection of either emetin hydrochlorid or a vaccine.

EMETIN—ITS POSSIBILITIES.

By Dr. T. F. COYLE, Orange, Texas.

THE article of Dr. Bass and Dr. Johns on "Pyorrhea Dentalis and Alveolaris: Specific Cause and Treatment," published in the *Journal of the American Medical Association* of February 13, 1915 (see "Review of Current Literature," DENTAL COSMOS, April 1915, p. 460), inspires me to sound a warning. While realizing my limitations, in the absence of a stronger defender I am constrained to make an effort to save emetin from its friends.

In my opinion, Dr. Bass and Dr. Johns are over-zealous, and I am afraid that the method they advocate will defeat the ends they seek. Their viewpoint is that of the physician, and while their scientific attainments command the profound respect of the medical and dental world, they do not possess that intimate acquaintance with the condition they seek to relieve that is possessed by the dentist only. This fact could not be better shown than in their incidental reference to dental treatment in the paper referred to: "No doubt proper dental treatment, consisting of cleaning and scaling the roots, removing dead and denuded alveolar process, and cleaning out large pockets, will prove of value. . . . We doubt whether one could find all the small lesions in most cases of pyorrhea, much less make local applications to them." The dentist who has developed that delicate sense of touch, that high order of skill essential to the removal of all foreign deposits from the inaccessible bifurcations of molar roots, will smile at the above quotation.

No case of pyorrhea has ever been cured as long as a particle of calculus remained, as long as overhanging fillings, crowns, or absent contact points were the contributing causes—and these are responsible for almost all primary lesions. Emetin will not remove calcarious deposits, make misfit crowns fit, polish rough and overhanging fillings, nor restore lost contact points.

He who regards dental interference as a remote help, as a possible benefit only, makes a fatal mistake. The physician who invades this field does so totally unequipped to meet conditions. I regard emetin as the most valuable remedy yet used in the treatment of pyorrhea, but the dentist or physician who trusts emetin, and emetin alone, to effect a cure is doomed to disappointment. He may inject one, three, or six cubic centimeters or a gallon of it, and record a failure, through no inherent fault of the drug.

Were I facetious, I would suggest to those who hope to be relieved of the countless hours of soul-trying operative endeavor, that they procure a vessel of ample dimensions, filled with emetin—the per cent. being immaterial—submerge the patient until the bubbles cease to come, and leave him in over night to be sure. When using emetin in that way they will be safe in throwing away their instruments and forgetting their technique.

Seriously, if the dentist does his work skilfully and thoroughly, he may depend upon emetin as a most valuable adju-

vant. I think the exclusive hypodermic use of the drug irrational.

Dr. Bass and Dr. Johns, in the above-mentioned paper, refer to the habitat of the endamœba as being dead and dying tissue. This finding led me to combine the Barrett and Bass-Johns treatments, which in my opinion is a most rational procedure. I am using intravenous injections and local applications in pockets on alternate days, and secure excellent results. I found the subcutaneous and intramuscular use of the drug quite painful, making its continued use impracticable, which suggested the intravenous method. I have employed it in several hundred administrations, and find it most effective, and devoid of its most objectionable symptoms after continued use. I would suggest the more general adoption of this method, which appears to be a most direct means of reaching the endamœbæ in the circulation, while the injection into the pocket destroys those not reached in the bloodstream.

To summarize: For bringing about a cure it is most essential to remove all mechanical predisposing causes. A surgeon would not leave a foreign body in a suppurating wound in any other part of the body and expect favorable results. Pockets must be eliminated to avoid reinfection, and intelligent use and not abuse of emetin be made, which embraces its local and intravenous administration, until complete recovery takes place.

PYORRHEA ALVEOLARIS.

By J. W. NEEDLES, A.M., M.D., D.D.S., Pueblo, Colo.

(Read before the Pueblo County Medical Society, September 29, 1914.)

PYORRHEA alveolaris is one of the most prevalent, if not the most prevalent of human diseases. It is also one of very great importance, both because of the number of teeth which it destroys and the influence which it exerts upon the general health; and because of the serious nature of the complications and sequelæ which are due to it, it is at least as important to the medical profession as it is to the dental profession.

DEFINITION.

According to Dorland, "pyorrhea alveolaris is a purulent inflammation of the dental periosteum, with progressive necrosis of the alveoli and looseness of the teeth." This is a very concise and serviceable definition, and, with proper interpretation, a very accurate and comprehensive one. It is necessary, however, to read into some of its terms very specific meanings, in order to make it cover the most recent and scientific conceptions of the disease. It is distinctly a disease of man, as it is not found in the lower animals, and is experimentally produced in them with difficulty.

ETIOLOGY.

The etiology of pyorrhea is a very much debated question, though it will probably be settled in the very near future. The theories that have been advanced most often in the past have been built largely upon one single factor in the etiology, and have not given full weight to other equally important features. These divergent views are coming to be reconciled by recent studies which show certain factors to be predisposing or contributory, and others exciting. Pyorrhea must now be considered to be essentially an infectious disease due to one of several organisms, the most prob-

able of which are the pneumococcus, the streptococcus, and other pyogenic organisms, or the endamœba buccalis.

The predisposing causes are mechanical irritation of the gums and the peridental membrane by tartar, the rough edges of cervical cavities, trauma from the impaction of food due to approximal cavities or irregularity of the teeth, poorly fitting crowns or protruding fillings. Of the constitutional diseases, gout, rheumatism, diabetes mellitus, nephritis, disordered metabolism, and debilitating diseases may be mentioned as predisposing causes.

Tartar is of two kinds. The salivary tartar is composed of calcium phosphate or carbonate, and mucin or another organic binder. This form of tartar is of light color, massive, and friable. The serumal calculus, derived in part from the blood serum, is composed of urates, triple phosphate, calcium phosphate or carbonate, blood pigment, and an organic binder. This form is dark colored, occurs in smaller masses, and is denser and more deeply embedded in the tissues. Both forms contain bacterial remains and tissue débris. Because of the altered secretions, gout and rheumatism predispose to the formation of serumal calculus. Age is a predisposing factor, as severe cases of the disease are seldom seen in patients below thirty years of age; after this age it becomes progressively more common, so that at the ages of forty-five or fifty very few people are entirely free from it. All the severe infectious diseases, especially pneumonia, typhoid fever, tuberculosis, syphilis, and malaria, favor the contraction of pyorrhea, since they lower the resistance to infection.

The disease is essentially chronic, though it may originate in an acute gingivitis, and is subject to acute exacerbations. It runs a course of from ten to twenty-five years, and without adequate treatment ends with the exfoliation of all the teeth.

PATHOLOGY.

A clear understanding of the pathology of pyorrhea alveolaris requires a somewhat detailed study of the relation of the teeth to their supporting tissues; that is, the histological relation of the teeth to the gums, peridental or pericemental membrane, and the alveolus. The cementum covers the surface of the dentin apically from the border of the enamel, lapping slightly over the enamel at the gingival margin. The function of the cementum is to furnish attachment to the fibers of the peridental membrane or ligament which holds the tooth in its socket. Fibers of the peridental membrane penetrate through the layers of the cementum, and are calcified with it.

THE PERIDENTAL MEMBRANE.

While this tissue performs the function of a periosteum for the cementum and the bone of the alveolus, it differs in structure from periosteum, so that any name including the word periosteum or implying a double membrane should be avoided. It is nothing more than an alveolo-dental ligament, because of the fact that microscopic sections show that it is composed of solid bundles of fibers, which emanate from the walls of the alveolus and go convergently to insert themselves into the cementum of the tooth, thus forming a circular, suspensary ligament. They penetrate deeply in the form of Sharpey's fibers into the bone of the maxilla as well as into the cementum, similarly to what takes place in other tendinous insertions.

THE ALVEOLAR PROCESS.

This is not a bone distinct from the maxilla, but a part thereof. "The socket is nothing more than an enlarged medullary space of the maxilla with a thinned-out edge forming the alveolar process."

The disease begins as an inflammation of the gum margin, and gradually involves the peridental ligament or membrane and the alveolar wall, which latter becomes necrotic. The process is then in the nature of a chronic alveolar osteomyelitis. The general and me-

chanical causes of the disease have been discussed, leaving only the infectious. The mechanical causes are by far the most important in starting the disease, but less important in keeping it up. It is the local infectious causes, on the other hand, that are the most important in continuing the process.

All of the common pyogenic organisms have been isolated from cases of pyorrhea, and indeed nearly all cases exhibit a mixed infection. The most logical micro-organism to suspect as the cause of pyorrhea, because with careful technique it is found in nearly all cases, and because in other parts of the body it produces lesions of a similar character, is the pneumococcus. As found in this location, it occurs as a diplococcus or in very short chains. Medalia found it 107 times in 112 cases. He describes it as the pneumococcus in chains, or as the streptococcus lanceolatus pneumoniæ. The germ is very difficult of growth, and has only a low degree of virulence. There is a close relationship between this form of pneumococcus and the streptococcus. E. C. Rosenow and Frank Billings, in studying the etiology of gastric ulcer and chronic arthritis, have shown that there are several types of streptococcus, and that these may be changed from one form to another by varying the cultural conditions. Three of the strains taken from rheumatics have been changed into typical pneumococci. These strains may also be isolated from pyorrhea pockets and the crypts of the tonsils. This shows a possible relationship between pyorrhea and gastric ulcer, chronic arthritis, endocarditis, pericarditis, pneumonia, and similar infectious processes. Rosenow showed a similar infectious origin in 35 out of 38 cases of arthritis deformans. Crile, Roswell Park, John B. Murphy, and many others emphasize the connection between joint infections and infections of the tonsils and gums. A similar indication of relationship is shown by the greater severity of pyorrhea following pneumonia. Many of these diseases show very marked improvement following treatment of the pyorrhea, especially when autogenous vaccines are used. In pyorrhea, other pyogenic germs are frequently if not always associated with the pneumococcus.

Two notable contributions to the pathology of pyorrhea have been made within the last few months. One by M. T. Barrett and Allen J. Smith of the pathological laboratory of the University of Pennsylvania (Dental Cosmos for August 1914, p. 948), the other by Professor Chiavaro of the dental department of the University of Rome (Dental Cosmos, September 1914, p. 1089). These two series of experiments were conducted entirely independently, though they have been announced almost simultaneously and verify each other to a remarkable degree. Drs. Barrett and Smith show that in forty-six cases of suppuration affecting the gums and the peridental tissues which they examined up to the time of their report, in every case an actively motile parasitic amœba was found. This endamœba they have identified as the endamœba buccalis, which had previously been described by several writers. In several apparently healthy mouths which they examined they were unable to find the organism. To determine any causative relation which the organism might have, they decided to try emetin hydrochlorid as an amœbicide, because of the results obtained with this drug in amœbic dysentery. The pyorrhea pockets were irrigated with a ½ of one per cent. solution of emetin hydrochlorid. In several of the thirteen cases thus treated, the pus disappeared completely in twenty-four hours; in all, after three daily treatments. After the second or third treatment, the tissues took on a more healthy appearance, the teeth became firmer, and the endamœba disappeared. In the short time since this article was published I have been able to find the endamœba in pyorrhea, and also to demonstrate the improvement following emetin treatment.

The article by Professor Chiavaro deals with the relationship of the endamœba buccalis to pyorrhea, and calls special

attention to the morphology and the life-history of the organism; but while Barrett and Smith regard the endamœba buccalis as highly pathogenic and one of the exciters of the inflammatory condition present in pyorrhea, Chiavaro considers the endamœba as a scavenger, owing to its phagocytic activity, and believes it to assist in protecting the tissues of the mouth against bacterial invasion. The correctness of the opinion of Barrett and Smith, however, in regard to the pathogenicity of the endamœba buccalis has been confirmed not only by a new series of experiments and abundant clinical experience of these writers (Dental Cosmos for December 1914, p. 1345, and January 1915, p. 101), but by the microscopic and clinical findings of Bass and Johns (Dental Cosmos, January 1915, p. 101; February 1915, p. 223), and the clinical experience of a rapidly increasing number of dental practitioners who are giving emetin hydrochlorid a thorough test.

SYMPTOMS.

The main symptoms are an inflammation of the peridental membrane, bleeding of the gums at the slightest touch, a tendency of the teeth to elongate and to be painful to pressure, often associated with a dull, continuous ache. Loosening of the teeth in their sockets, accumulation of tartar about the teeth, the formation of deep pockets between the gums and the teeth, discharge of pus from these pockets, and an occasional abscess, a foul breath, and a coated tongue are characteristic of the disease; constipation and intestinal putrefaction are almost constant.

DIAGNOSIS.

Pyorrhea must be distinguished from acute gingivitis, which it often follows, also from necrosis of the alveoli due to lead poison, scurvy, and mercurial stomatitis. The lesions of syphilis and tuberculosis are sometimes found in the mouth.

PROGNOSIS.

The destruction of the alveolus and the looseness of badly affected teeth cannot be remedied, but the active process can be stopped, and teeth which are not too badly crippled can be made comfortable and useful for many years. Early cases and those without too much destruction of tissue yield as high as 90 per cent. of cures under local treatment and autogenous vaccines; advanced cases give about 40 per cent. of cures. Relapses or recurring attacks often take place, as the constitutional and predisposing causes may remain unchanged.

Prophylaxis is of the greatest importance, as the disease may be entirely avoided, or, if recognized early, very much more successfully treated. The prevention of the disease depends upon scrupulous cleanliness of the mouth and in having the teeth kept in the best condition. Regular visits to the dentist at least once a year for the removal of causes of local irritation and the overcoming of any incipient trouble are very important.

TREATMENT.

The treatment consists in thorough cleansing of the teeth by mechanical and chemical means, removal of any local irritation, such as broken roots, rough edges of cavities, or protruding fillings, poorly fitted crowns, and so forth. The after-treatment consists in keeping the pockets washed out with mild antiseptics and local applications to stimulate healthy granulations and to overcome infection. It is sometimes necessary to support the teeth by splints of various kinds. Massage of the gums is very valuable, both as a stimulant and as a means of producing auto-inoculation. Systemic treatment is necessary to overcome faulty metabolism. Predisposing constitutional diseases often need treatment. At the present time, autogenous vaccines combined with local measures give the best results. The treatment with emetin hydrochlorid may prove to be almost a specific.

CONCLUSIONS.

(1) Pyorrhea alveolaris is in reality a chronic alveolar osteomyelitis; it should be known and treated as such.

(2) Mechanical causes are responsible for starting the disease, while systemic diseases and local infection are responsible for keeping it up.

(3) Pyorrhea is a specific disease, though its etiology cannot be ascribed to any one single organism.

(4) A great many rheumatic diseases, so called, and a great many gastro-intestinal conditions, are directly related to pyorrhea. The importance of oral sepsis to constitutional disease is just beginning to be appreciated.

(6) The treatment of pyorrhea, especially with autogenous vaccines, with proper attention to diet, relieves or cures these systemic conditions, as well as cures the pyorrhea.

(7) The near future promises to bring forth a more exact knowledge of the etiology, and possibly a more effective treatment of pyorrhea alveolaris.

CORRESPONDENCE.

DR. BUCKLEY'S DESENSITIZING PASTE.

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—Allow me to give you a brief history of my experience with Buckley's desensitizing paste. I used it for some time without any disagreeable results, but of late, and with the same material I at first used, I have had many cases of pulp hyperemia and a few cases of devitalization. I would not think of using it in the cavity very near a pulp, for it is almost sure to devitalize the tooth when so used, but I have had not a few cases of severe pulp irritation—some transient and some persistent—even when it was used in shallow cavities.

There is no question as to its efficacy in obtunding dentin in any cavity, but it seems almost impossible to determine when it is safe to use it and when not. I believe thoroughly in the honesty and good intent of Dr. Buckley, but I fear that his statement in regard to the impossibility of the paste causing devitalization was rather premature.

I think you will find others have had a similar experience to mine, and I write this as a warning to those who are experimenting with this material, to use it with great caution. I was very enthusiastic about it at first and used it a great deal, but I must confess that I am now somewhat disappointed in it. I

have never had so many cases of pulp irritation on hand as I have had lately, and am thoroughly convinced that this is due solely to the use of the paste.

Dr. Buckley has done much for dentistry in teaching us the advantages of the formocresol treatment, and he deserves unlimited credit for that discovery or propaganda, but I fear he has made a mistake in claiming so much for the desensitizing paste.

"SYMMETRIC CARIES."

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—I trust it will not be considered hypercritical if I call attention to what seems to me to be a rather superfluous and unacceptable theory of symmetric caries. I refer to the article by Dr. Wechsler, "Symmetry in Dental Caries," in your March issue, page 270.

The explanation of this condition seems to me to be simpler than the very vague one advanced. Were caries endogenous, the sympathetic theory might carry some weight, but who can suppose that any nervous irritation is able to alter the susceptibility of enamel to the external agencies which we know to cause decay? An analogy is drawn between this condition and optic neuritis which does not hold good, as, supposing that the eyes were affected from without, as from germ-laden dust, resulting in inflammation, should we assume that first one eye was affected and the other became affected by way of sympathy, or should we accept the more rational explanation, *i.e.* that both were acted upon by the same common cause?

Once we allow that germs cause decay, what is more natural than that "twin" teeth, the follicles of which are formed at the same time, erupt at the same time, and are subjected in the mouth to the same environment for a given period of time—what could be more natural than that they should succumb to the same disease? Of course, exceptions are very numerous, sufficiently so to almost dispose of any central cause, and they are easily explained by the habits of the patient, especially in the use of the brush and in mastication, also by accidents to the teeth and by slight anomalies of formation and position.

Furthermore, the writer of the article in question does not explain why it is that these impulses of irritation, when carried to a central ganglion, are thrown out to the *mate* of the tooth affected rather than to *any tooth* on that side of the jaw?

Respectfully submitted,

W. A. KERRISON.
REARDAN, WASH., March 15, 1915.

"A PROBLEM IN ANCHORAGE."

TO THE EDITOR OF THE DENTAL COSMOS:

Sir,—In the March 1915 issue of your journal, Dr. Lawrence W. Baker of Boston presented a paper entitled "A Problem in Anchorage." (See pp. 249, 250.) The doctor concludes his article by stating, "I bring this method before you this morning as a *contribution to the principle of anchorage* in orthodontia." [Italics mine.]

I have read the article, and fail to find any references to similar "contributions" in our literature. Now, if you will turn to page 196 of the January 1909 issue of *"Oestr.-Ungar. Vierteljahrsschrift f. Zahnheilkunde,"* you will

find an excellent illustrated description of the "principle of anchorage" of which Dr. Baker writes, by Joseph Grünberg of Berlin. Several other writers have described this principle in similar fashion, and I regret to see it brought out now as though it were new.

"How long, oh! how long" will it be before men will take the time to learn something of the history of our art? I cannot help but conclude that this is another evidence of the pernicious "handicap on thought" which orthodontic orthodoxy has produced. Will we ever rid ourselves of the narrow viewpoint of the "systems"?

B. E. Lischer.

St. Louis, March 12, 1915.

INFORMATION REGARDING THE ARMY DENTAL SURGEONS CORPS.

To the Editor of the Dental Cosmos:

Sir,—In replying to Dr. Scheiman's inquiry, published in the Dental Cosmos, January 1915, p. 72, I shall endeavor to answer briefly his questions regarding the army dental corps.

As to the exact nature of the services that the members of the army dental corps are called upon to render, they are required to do all that any general practitioner in civil life would have to do, provided they are stationed at a large post and furnished with a complete equipment. When in the field, or traveling with a field equipment from one small post to another, the scope of the army dental surgeon's work is of necessity limited to oral prophylaxis, the filling and treating of teeth, and such minor operations as his limited time and equipment will enable him to perform.

Of the ninety-two candidates who presented themselves for the past three examinations, eleven failed physically, eight withdrew, forty-four failed either in mental or clinical work, and twenty-nine passed. The actual length of time spent in civil practice by these twenty-nine averaged two years and eight months. The law requires that a man be not over twenty-seven years of age when entering the dental corps. At the last examination held there were ten successful candidates, but it was possible to give contracts to only seven of them, as the act of Congress making appropriations for the fiscal year ending on June 30, 1915, made provision for only forty acting dental surgeons. The report of the Adjutant-general, United States army, June 30, 1914, gives the strength of the army as 92,877 enlisted men and 4883 officers. The law allows one dental surgeon to each thousand men of the actual enlisted force of the army, so that, if the corps were filled on the basis of the 1914 report, it would consist of ninety-two dental surgeons, sixty of whom can become first lieutenant dental surgeons, the balance remaining acting dental surgeons until a vacancy occurs.

S. D. Boak, M.D., D.D.S.,
Dental Surgeon U. S. Army.

PROCEEDINGS OF SOCIETIES.

DENTAL FACULTIES ASSOCIATION OF AMERICAN UNIVERSITIES.

Special Meeting, held at Philadelphia, February 24 and 25, 1915.

FIRST SESSION.

A SPECIAL meeting of the Dental Faculties Association of American Universities was called to order on Wednesday, February 24, 1915, at 10 o'clock A.M., by the president, Dr. Hoff, in the Evans Institute, Philadelphia, Pa.

Dr. Breene was on motion made secretary *pro tem.* in the temporary absence of Dr. Kirk.

Members present during the sessions were Dr. Alfred Owre, University of Minnesota, College of Dentistry; Dr. F. T. Breene, University of Iowa, College of Dentistry; Dr. N. S. Hoff, University of Michigan, College of Dental Surgery; Dr. Edward C. Kirk, University of Pennsylvania, School of Dentistry; Dr. E. H. Smith, Harvard Dental School; Dr. J. H. Kennerly, Washington University, Dental School.

During the different sessions the following visitors were present: Dr. C. R. E. Koch, Northwestern University Dental School; Dr. W. P. Cooke, Harvard Dental School; Dr. L. M. S. Miner, Harvard Dental School; Dr. H. M. Semans, University of Ohio Dental School; Dr. Hermann Prinz, University of Pennsylvania School of Dentistry; Dr. Eugene S. Talbot, Chicago.

Dr. HOFF read the call for the meeting, setting forth the objects of the present special meeting, as sent out by the Executive Committee.

The president, Dr. N. S. HOFF, then read his address, as follows:

President's Address.

By N. S. HOFF, D.D.S.

Members of the Dental Faculties Association of American Universities meeting in Special Session,—We are convened in special session today in response to the call of our Executive Committee, to further consider the resolution adopted at our last annual meeting in Minneapolis, March 21, 1914, in the matter of extending the college curriculum to four years; and also to consider such other pertinent matters as may properly come before us at this time.

In view of the fact that our dental announcements are usually printed in June, there can be no sufficient notification to prospective students until June 1916, too late to enable them to prepare for the course. For this reason your Executive Committee thought it necessary to call this special meeting at this time and place. I trust every college holding membership in this association is represented by a duly authorized delegate who has come prepared to act definitely on this important question now before us for final decision. This is necessary before we can intelligently discuss the details of administration.

At the annual meeting a suggestion was made that the action taken by this body and the advisability of similar action by all dental colleges should be brought to the attention of the National Dental Association and the National Association of Dental Examiners. This I

believe our secretary did in a formal communication, and your president had a personal interview with the president of each of these organizations, in which he urged them to make such recommendations as they deemed the cause justified, in their respective addresses to these bodies. As you are all doubtless aware, the matter received much favorable comment in both of these organizations at their annual meetings. We have also done what was possible by personal interviews and correspondence with various executive officers of colleges and other dental organizations that are especially interested in this subject, and there seems to be no difference of opinion in the minds of the majority of thoughtful teachers and professional men as to the necessity for more time for the administration of a proper and adequate course of instruction that shall qualify for the practice of modern dentistry.

The National Dental Faculties Association, at its annual meeting recently held, decided, after a careful and rather strenuous debate, with final and practical unanimity, to inaugurate a four-year course of instruction, beginning with the college year of 1917–18.

Two of our dental editors have editorially commented on this proposition adversely. We have not seen or heard any other adverse comment. It would seem from these facts that our action last year was timely, and that we should complete the initial move by adopting such further measures at this time as may be needed to carry our resolution into effect.

It has been suggested that it might be diplomatic, and that we should serve our cause more effectively, should we postpone the inauguration of the four-year course another year until all the schools were ready to join in the movement. This would undoubtedly give us more time to perfect our plans, and would also give time for the necessary amendment of our registration laws to conform with the new course. This would also make it easier for some colleges to prepare for the change, and give the prospective student a chance to make his preparations.

On the other hand, the seven schools of this association have, tentatively at least, committed themselves to the course for the session of 1916–17, and two of them have actually announced it. Also the Northwestern University Dental School has decided to start a four-year course, beginning with the session of 1916–17. In view of these facts and our published action, would it be wise for us to hesitate? Can we afford to lose the time and risk the possibility of a reversal of the action taken by the other schools? Have we any assurance of favorable legislation unless we first demonstrate to the profession the value of more time for instruction, and its practicability?

No doubt we have all been looking forward to this four-year course as a means of making our teaching work more efficient, and I am aware that much time and thought has been spent in formulating a more efficient course of study by several of our executive officers, with the hope of definite action at this meeting.

Our Educational Committee presented a suggestion for an ideal curriculum at our meeting last year, which with new suggestions may serve at this time as a basis for our discussion. We should all have well-conceived ideas that may be helpful in arriving at the best conclusion, and it is only by the exchange of ideas and their critical examination that we shall be satisfied with the action we may take in regard to this most important movement. In other words, we should have a full and free discussion of this matter from every standpoint—the pedagogic, the practicable, and most of all, from the ideal. If it should become possible for us to devise a practicable and ideal curriculum we shall have accomplished, it seems to me, all that this time and occasion demands.

It is the tradition of this body, based upon an article of our constitution, that the largest possible freedom of internal

management shall always rest with the individual membership. Therefore we can and should discuss this problem unhampered by any possible legislation that may lead to personal embarrassment to any of our members.

Owing to the fact that a full representation of the membership of this association may not be possible at the regular annual meeting this year, because of the great distance, it may seem desirable for us to consider at this meeting some items of business that should more appropriately be deferred to the annual meeting. By the unanimous consent of those present it seems to me that it would be proper, and we should feel competent to take any action that may be necessary at this meeting to effectively forward the interests of the association. Any or all such actions may and properly should be submitted to the annual meeting for ratification, or for reconsideration if occasion demands.

Your president has taken the liberty of inviting to this meeting representatives from the dental colleges connected with Ohio State University, Illinois University, and Northwestern University. As these schools are qualified for membership in this association, and are not connected with any other similar body, and as each has expressed a desire to extend the curriculum to the four-year course, I felt that we should have the benefit of their counsel on this occasion. I trust it may be the pleasure of this body to extend a cordial invitation to the representatives of these, and any other such representatives as may be present, to join us in our deliberations as to ways and means for putting into effect, in the best possible manner, whatever advance in the dental curriculum we shall see fit to adopt.

Dr. Owre moved and Dr. Smith seconded that the Address of the President be accepted and approved. [Motion carried.]

With regard to the action of the president in extending invitations to the University of Illinois Dental Department, the University of Ohio Dental Department, and the Northwestern University Dental Department to send representatives to the meeting, Dr. Kennerly moved that the action be indorsed by the association. [Motion carried.]

Dr. Smith moved that the gentlemen representing these schools invited be given the privileges of the floor. [Motion carried.]

The next order of business was the reading of the report of the Secretary-Treasurer, as follows:

Report of the Secretary-Treasurer.

By Edward C. Kirk, D.D.S., Sc.D., LL.D.

Mr. President and Members of the Dental Faculties Association of American Universities,—As Secretary-Treasurer I have the honor to report that the subject which formed the principal topic of discussion at the previous meeting of our association, namely, the desirability of lengthening the dental curriculum to four years, has been the subject of correspondence, indicating an increasing interest in the problem and a wholesome degree of activity favorable to the addition of another year to the time of the present curriculum.

Pursuant to the instructions of this association, expressed in a resolution at the Minneapolis meeting, directing the secretary to communicate the views of the association favoring the plan of lengthening the course, to the president of the National Dental Association, the president of the National Association of Dental Examiners, and the president of the Pennsylvania State Dental Society, communications were sent by the secretary to each of the officers designated, setting forth the principal reasons why our association, generally speaking, was favorable to the adoption of an additional year, and asking that the subject be brought before the respective associations for consideration. The president of the National Dental Association, Dr. Homer C. Brown, embodied the main features of the argument as presented by your secretary, in

his annual address, and after discussion by the National Dental Association the question brought forth an expression of opinion favorable to the plan suggested, which was embodied in a resolution by our National body expressive of its approval of the suggestion to make the standard dental curriculum of dental study four academic years in length.

The president of the Pennsylvania Dental Society, Dr. Howard S. Seip, in his annual address strongly recommended favorable action by the Pennsylvania State Society, and a similar vote of approval was passed by that body.

No acknowledgment of the receipt of your secretary's letter was received from the president of the National Association of Dental Examiners.

Copies of the correspondence involved in the foregoing are on file for your consideration if desired.

From the University of Minnesota, College of Dentistry, through its dean, Dr. Owre, your secretary received notification under date of August 21st that at its meeting on June 10th, the board of regents of the University of Minnesota adopted the following resolution:

VOTED, That it is the sense of the board that if the majority of the dental colleges in the Association of University Dental Faculties decide to adopt a four-year course, the University of Minnesota will be favorably disposed toward such an extension of the dental course.

Dean Owre has forwarded to the secretary several communications having an interesting bearing upon the question of the four years' curriculum. Dean Owre has sent to the secretary a detailed exhibit of a proposed distribution of work over the several years of the four years' curriculum, copies of which have doubtless been received by all of the members. A consideration of the plan proposed by Dr. Owre may properly be the subject of discussion at the present meeting.

As bearing upon the question of admission requirements, the University of California Dental Department, through its dean, Dr. Millberry, forwarded to the secretary under date of November 18th the report of the Council of the University of California, embodying a statement of advanced requirements for admission to the College of Dentistry of the University of California, to become effective at the beginning of August 1917. The report is not sufficiently clear in itself, requiring for its interpretation reference to the official announcement of courses of the university for 1914–15. A detailed exhibit of the character and extent of the advanced entrance requirements authorized for admission to the Dental School of the University of California is on file with this report for your consideration.

Your secretary has received communications from the registrar of the University of Alberta, Canada, also from the secretary of the Manitoba Dental Association, making inquiry into the status of American dental colleges, with a view to the preparation of a selected list of schools in the United States the educational work of which may entitle them to recognition by the licensing bodies of the Canadian provinces named. Information concerning the schools in the membership of our association was furnished in answer to these inquiries, and for information regarding those outside our membership the correspondents were referred to the secretary of the National Association of Dental Faculties. The correspondence in connection with this matter is on file for your consideration, if it be desired.

Also a communication from Dean Kennerly of the Washington University Dental School, with reference to the possibility of granting credit for work done toward the Bachelor of Science degree and agricultural course to apply to advanced standing in the dental course, the work done by the applicant having included certain credits in chemistry, physics, biology, and bacteriology. An opinion adverse to granting advanced standing in the case cited was transmitted to Dr. Kennerly, he concurring in the decision. Report of this corre-

spondence is made, as the point involved may be deemed worthy of official consideration in order that a definition and precedent may be established in such cases.

The secretary has received repeated requests from the authorities of the Panama-Pacific Dental Congress requesting that a definite date be fixed for our meeting in San Francisco, and your secretary would suggest that action be taken upon that question at the present meeting.

Through correspondence with Dr. Hoff, invitations have been sent to authorities of the Universities of Ohio and Illinois to send representatives to be present at this meeting.

The secretary has received a letter from Mr. Frederic G. Hallett, secretary of the Conjoint Examining Board of England, requesting information with regard to the status of the Dental Department of the University of Illinois. A letter has been sent to President James by the secretary, its receipt being acknowledged, with answers to certain inquiries made by the secretary and promising to send further information, which has not yet been received.

The secretary would direct attention to certain matters which by resolution at the Minneapolis meeting were laid over for final action at the present meeting: First, the following resolution:

RESOLVED, That undergraduate students of reputable medical schools, who have completed at least two years' work and who have credits for the full requirements in chemistry, anatomy, histology, physiology, and bacteriology, may be given credit on examination for these studies, and be advanced to the second year in the dental curriculum.

Also a report by Dean Eugene H. Smith of Harvard, as a committee of one upon his suggestion made in writing at the Minneapolis meeting with reference to the promotion of research work within the colleges of our association membership.

The financial condition of the association is set forth in the following detailed report of the Secretary-Treasurer:

Receipts:

Balance from 1913–14	$289.91	
Receipts for dues 1914–15	350.00	
Total receipts		$639.91

Expenditures:

Clerical service	$200.00	
Printing Transactions	54.61	
Stationery	2.50	
Postage	2.48	
Total expenditures		259.59
Balance 1914–15		$380.32

Respectfully submitted,

EDWARD C. KIRK,
Secretary-Treasurer.

Motion was made and carried that the report be accepted.

Dr. EUGENE H. SMITH, appointed by the association as a committee of one to report upon the question of "organized research work with the schools of the association, acting in a reciprocal way, rather than through the medium of dental societies," reported as follows:

Some five years ago, Miss Harriet N. Lowell bequeathed to the Harvard Dental School the sum of twenty-five thousand dollars, the interest of which was to be devoted to research work along dental lines. To carry out the provisions of this bequest we appointed men of research ability as a Committee on Research, and that committee has formed among the student body what is known as the Harriet N. Lowell Society for Dental Research. The object of this society is to interest students in research problems. We have at present two students doing research work along the line of pyorrhea. We are taking in as honorary fellows of the society and honorary members of the Research Committee men not affiliated with the school, but who have shown by their work their interest in the question of research. It seems to me that this can be made an important feature in our schools, and what I hoped to bring about was similar organization among dental students for research work in other schools, to the end that reciprocal arrangements might be made for the interchange of ideas, and by that means bring about better results than we could if this work was done under the direction of various dental societies.

Dr. Owre moved that the report be accepted. [Motion carried.]

Dr. Hoff read the following telegram from Dean Millberry, of the University of California College of Dentistry:

Dr. N. S. Hoff: Faculty in accord with any action leading to fourth year as preliminary or in dental curriculum. Impossible for us with present facilities to provide fourth year of dental instruction. Can do nothing without regents' action. Matter now pending in regents' committee.—Guy S. Millberry.

The next order of business was the report of the Committee on Education by Dr. Owre, chairman, as follows:

Report of the Committee on Dental Education.

By Alfred Owre, B.A., M.D., C.M., D.M.D.

The committee has found hearty support of the action of this association last year in extending the course to four years. Since then the criticisms and suggestions received as to the contents of the curriculum have led us to recommend some modifications in it.

It has been the aim of the committee to economize the student's time and energy, hence it has often been found wise to introduce studies which prepare him for a fuller appreciation of a subject rather than to lengthen the present hours devoted to it, although this has also been done in several instances. The committee has in all cases guarded against a superficial skirmish with important subjects.

We have also felt that it would be advantageous to have a program which would allow credits to be gained to some extent in accredited colleges. The studies should be designated with enough electives to develop men of power; this also allows the latitude necessary in a country where preliminary education, as well as environment, varies appreciably.

The committee has agreed upon dental faculty control of the curriculum, although the teaching of some subjects must of necessity be done as at present by the other units of the universities.

The total number of hours are increased as compared with last year's proposal, but there is a more even distribution of subjects requiring home study.

The committee has conferred widely with educational experts in allied callings, and the freshman-year program is essentially the result of such conference. While some change might easily be made in this year to make it more specifically dental in character, yet the committee feels that final action in this matter should come only after wider discussion among dental teachers and dental societies. For instance, descriptive anatomy might be given in the second semester of the freshman year, leaving out either rhetoric or the history, economics, or language group. This should be followed by offering histology and embryology in the first semester of the sophomore year, which in turn would allow operative technique to be taught in the second semester of the same year. This would, of course, also increase the available hours for practice. On the other hand, our anatomists prefer that the course in general zoölogy should be completed before beginning the study of the human body; technical drawing should also be completed before much dental work is started, since it economizes time and energy to such a large degree. Therefore if any shift is made in anatomy, it might be well to have this subject completed in the first semester, providing this is pedagogically wise. It will be noticed that substitutes are allowed in animal biology and technical drawing—we recommend in the former instance botany, and in the latter case physics. It may be advisable to substitute physics for technical drawing, or one of the cultural subjects. Furthermore, in regard to substitutes, some latitude must be given to the matriculation committee in each school, in order to meet the educational variations in different localities.

It is the hope of the committee that the universities will make an extraordinary effort to agree on a general plan; deviation from it should only take place as a result of local conditions which cannot be immediately adjusted.

Four-year Course.

[The requirements for admission are graduation from a four-year high school, or the same as for admission to the freshman class of the College of Science, Literature, and the Arts, and should include one unit of General Chemistry. Manual Training is recommended.]

One credit hour may be either one recitation hour through one semester, two laboratory hours with outside work, or three laboratory hours without outside work.

One semester = sixteen weeks; one week = forty-eight hours.

* See Appendix [next page] for description of courses.

APPENDIX.—*Numbers and descriptions of courses according to University of Minnesota Bulletins.*

General Zoölogy Nos. 1, 2. A survey of the animal kingdom, emphasizing the principles of structure, physiology, embryology, classification, and evolution of animals. Text-book, lectures, and quizzes.

Botany Nos. 1, 2. Laboratory study of the structure of flowering plants, their organs and tissues, followed by a brief study of common types of flowerless plants, leading to the origin of the flower and seed habit; greenhouse study of the behavior of plants; field work, classification of trees and shrubs and of spring flowers.

Advanced General Chemistry and Qualitative Analysis Nos. 3, 4. Lectures and laboratory work. A discussion of the general chemical theories and laws with qualitative analysis.

Composition and Rhetoric Nos. 1, 2. Practical training in the art of writing; the principles of structure and analysis of specimens of good prose.

Technical Drawing Nos. 21, 22. Theoretical and practical graphics, the reading and making of working plans. Projection, sketching, lettering, conventions, renderings and translations.

General Physics No. 1 (3 credits). Mechanics of solids and fluids, sound and heat. Treatment experimental rather than mathematical; the fundamental principles. First part of a general course. Should be taken in conjunction with Course 3, but may be taken separately.

General Physis No. 2 (3 credits). Light, electricity, and magnetism. Treatment experimental; the fundamental principles, including those of radio-activity, ionization, X-radiation, and the electrical constitution of matter. The second part of a general course in Physics. Should be taken in conjunction with Course 4, but may be taken separately.

General Bacteriology No. 58. A study of the biologic and chemical problems of bacterial life; the classification of bacteria; methods of isolation and culture; the composition of germicides, antiseptics, disinfectants, etc.; the bacterial examination of water and the purification of sewage.

Organic Chemistry No. 32. An outline of the chemistry of carbon, including the preparation of some of the more important organic compounds. Special emphasis is laid on those substances used in medicine.

General Pathology No. 51. The study of pathologic processes, including anemia, congestion, embolism, thrombosis, infarction, degeneration and necrosis, inflammation. Study of processes of regeneration and repair. Discussion of causation, classification, and history of tumors. Examination of tumor structure in various types.

In connection with the freshman-year program, we wish to emphasize that it allows the student to change from dentistry to other courses almost without waste of any kind.

The committee also recommends that the four-year course should be started in 1916, which was the time tentatively agreed upon at our last meeting.

Dr. KIRK, as a member of the committee, said he was in agreement with Dr. Owre's idea of preparatory training with a view to developing the highest intellectual efficiency, or what he had called "spiritual development," but he thought that this should not be incorporated in the dental curriculum. He was in full accord with the plan of adopting a four-year curriculum, but he felt that the additional year should provide for strictly technical and professional instruction in dentistry.

Dr. SMITH, as the third member of the committee, agreed with the plan of making the dental course four years, and also suggested that a plan be devised by which a man might be able to take both the medical and dental courses in, say, five years. He thought in this way many medical men might be attracted to dentistry, and that altogether it would make for a better educated class of men in dentistry. His plan was to have men enter the medical school as at present, and in the third year have the medical schools accept dental studies as elective toward the medical degree, and at the end of five years allow the man to graduate as an M.D. and D.D.S or D.M.D.

The report was on motion received and placed on file.

After further discussion of the subject by Drs. Owre, Kirk, Smith, and Koch, the association adjourned until the afternoon session.

SECOND SESSION.

The meeting was called to order at 2 o'clock by the president, Dr. Hoff.

The order of business for the afternoon session was the continuation of the discussion of the four-year curriculum.

Dr. PRINZ thought that the educational conditions in foreign countries were so different from ours that they could not be accepted as guides for this country. He also objected to the plan of carrying on education for dentistry in medical schools, and cited conditions in France and Austria where this plan was in force.

Dr. KENNERLY thought the question of adopting the four-year course should first be settled, and the curriculum decided upon afterward.

Dr. BREENE said the sentiment of his faculty was in favor of the four-year course, and when that was put in force they wanted to recommend one year in arts as a preliminary requirement. He thought, however, that the principal thing needed at this time was more time in which to teach dentistry, and he did not think that the proposed curriculum met this need.

Dr. SEMANS of the Ohio University Dental Department said the school with which he was connected was in full accord with the plan of making the dental curriculum four years, and that they proposed to put this into effect in 1916. He said also that his object in attending this meeting was to get information with regard to the feeling of the association on the matter of the four years' course, and to receive some moral support for the action his school was about to take.

Dr. HOFF read a letter to the Association from Dr. Moorehead, dean of the Dental Department of the University of Illinois, in which he advocated making the requirement for admission to the dental school one year in the college course, rather than increasing the dental course to four years. Dr. Hoff added that the sentiment of his school was the same as that expressed by Dr. Moorehead.

Dr. KIRK called attention to some of the subjects included in the proposed curriculum, and thought that these might more properly be incorporated in the entrance requirements, rather than to devote time in the dental course to teaching these subjects. He thought that more time should be afforded for the teaching of dental subjects pure and simple, and for this reason objected to the proposed curriculum as being an increase in time only, and that time devoted to teaching subjects which should not be included in the dental curriculum.

Dr. KOCH agreed with Dr. Kirk in regard to the subjects suggested, and thought they could be obtained in high school and should be made preliminary requirements instead of being taught in the dental school.

Dr. SMITH asked if Dr. Kirk would be willing to accept his plan with regard to the combination of the medical and dental courses.

Dr. KIRK objected to this plan for the reason that he did not think it advisable to put off too long the training of the manipulative skill of the student. As to the teaching of the medical subjects to dental and medical students together, he thought it best to teach anatomy, chemistry, and physiology especially to the dental students from the dental standpoint.

Dr. SMITH moved, and Dr. Breene seconded,

THAT we increase the length of the curriculum by one year, making it four academic years in length.

The motion was carried.

Dr. KIRK moved, and Dr. Smith seconded,

That this rule go into effect not later than the academic session for 1917–18.

Dr. OWRE said that he had sent copies of the proposed course to the different schools, and had found from correspondence that a majority of them were in favor of starting the course in 1917.

Dr. KOCH urged that whatever conclusion was reached at this time should be confirmed by the National Associa-

(Alternative) Four-year Course.

† Students who are advanced in practice should be allowed to specialize in any part of the curriculum, especially in the second semester.

tion of Dental Examiners, and that they be urged to use their efforts to have this carried into effect in the statutes, and also that the action be confirmed by the National Dental Association, so that a declaration might be made on behalf of the profession.

Dr. KIRK agreed with Dr. Koch, and suggested that it would be well for each member of the association to use his individual influence in having this action and the action of the National Association of Dental Faculties backed up by statutory legislation throughout the different states.

Dr. COOKE said that the National Association of Dental Examiners at their recent session had passed a resolution favoring legislation for the four-year course.

Dr. Kirk's motion was then put and carried.

Dr. OWRE asked for an informal expression of opinion of the members of the association in regard to beginning the four-year course in 1916, and the following reported in favor: Pennsylvania, Iowa, Michigan, Minnesota, Dr. Koch for the Northwestern University, and Dr. Semans for the Ohio University.

The question of setting a date for the meeting to be held in San Francisco was taken up for discussion, and Dr. KIRK moved that when the association adjourn, it adjourn to meet at the call of the Executive Committee. [Motion carried.]

The association then adjourned until Thursday morning at 9.30 o'clock.

THIRD SESSION.

The meeting was called to order Thursday morning at 9.30 o'clock by the president, Dr. Hoff.

Dr. COOKE presented the following resolution:

MOVED, That we ask the medical schools connected with the universities represented to arrange and adopt a curriculum by which the degrees in medicine and dentistry may be earned at the end of a five years' course.

The resolution was discussed by Drs. Owre, Kirk, Smith, Cooke, Miner, after which Dr. KIRK moved, and Dr. Owre seconded, that the resolution be adopted.

Dr. COOKE explained that this resolution did not interfere with any other plan suggested, but was simply offered as one method of training men in dentistry.

Dr. OWRE moved that the four-year curriculum be adopted as proposed by the Educational Committee [see p. 553], with such readjustments as are found necessary in each institution.

The motion was seconded by Dr. Kirk.

Dr. KENNERLY suggested that another meeting of the association be held early in the spring of 1916, and that each member of the association work out a curriculum following as nearly this plan as possible, and that final adjustments be made at that time.

Dr. KIRK thought that all of those subjects not strictly dental should be eliminated from the curriculum.

Dr. OWRE then presented as an alternative curriculum, one containing strictly dental subjects—the curriculum outlined at the previous meeting. [See opposite page.]

The motion was further discussed by Drs. Smith, Prinz, Hoff, Cooke, and Kennerly, after which the motion was carried.

Dr. KENNERLY then moved that the dean of each school be requested to forward to the Educational Committee an exhibit of the proposed curriculum which his institution proposes to put into practical effect, so that the Educational Committee may compare the various suggestions and tabulate the differences and agreements, and report to the association at the next meeting.

The motion was seconded by Dr. Kirk and carried.

It was the sense of the association that a meeting should be held in January 1916.

Dr. HOFF then declared the meeting adjourned subject to the call of the Executive Committee.

ACADEMY OF STOMATOLOGY OF PHILADELPHIA.

Regular Monthly Meeting, held January 26, 1915.

THE regular monthly meeting of the Academy of Stomatology was called to order on Tuesday evening, January 26, 1915, at eight o'clock, by the president, Dr. J. C. Curry.

The essayist of the evening, Mr. ARTHUR HOPEWELL-SMITH, Philadelphia, was introduced by the president, and read a paper entitled "Problems of Pain and Other Oral Sensations."

[This paper is printed in full at page 494 of the present issue of the COSMOS.]

Discussion.

DR. OTTO E. INGLIS. There are some points in this valuable paper the explanation of which did not seem to convey to my mind convincing proof of the *modus operandi* of the production of pain in some of the cases described, and I would be glad if Mr. Hopewell-Smith, in closing the discussion, would elucidate these a little more. In discussing the sensitivity of enamel, the essayist spoke of the differentiation by the teeth of semi-soft substances taken between the teeth, such as shot, or still softer substances such as the crust of bread, and hard substances such as pins. It does not seem, unless the enamel has a certain degree of sensitivity, that it would be possible for it to differentiate these. So far as I have been instructed in this matter, it seems that all such tactile sensitivity is practically referable to the pericemental tissue. It has been claimed that, while the pulp can feel pain, it is devoid of real tactile sense; it does not locate its own pain, and such sensations as we feel about the teeth, due to contact with their exterior, are localized by the pericementum, which, judging at least from clinical experience, seems to have a sense of touch. In several cases which I have observed myself the enamel was unquestionably sensitive, and in view of the enamel spindles shown in the essayist's illustrations and the demonstrated fact that the dentinal fibrils extend into the enamel, any sensitivity of the enamel is in all probability due to these sensitive fibrils being touched.

As regards "setting the teeth on edge," the essayist's explanation did not seem to be very clear. Our knowledge of the process of dental caries and Williams' demonstration of the effect of hydrochloric acid on thinly beveled enamel specimens seem to offer a sufficient explanation for the phenomenon of setting the teeth on edge. I think the essayist gave this explanation himself when he spoke of "sour grapes." I am sure that acids or substances of decided acidity when taken into the mouth dissolve a certain portion of the interprismatic cement substance of the enamel, and as a result the enamel rods remain higher than the cement substance, so that a somewhat serrated surface, microscopically minute, is present on occluding teeth, and the rasping of such teeth over each other produces the phenomenon of gritting. This unevenness is quickly worn down, and the teeth again become smooth.

A propos of the galvanic shock induced by a dental mirror touching a filling, I would like to relate a little incident. On one occason I placed a filling in a lower right third molar, and a few days later the patient reported that she had not the slightest sensation upon mastication or upon applying heat or cold, that she could touch the filling with a pin or fork without producing

pain, but that a little tin mirror of about two inches in diameter, when placed against that tooth, would produce a shock. I told the patient that on one occasion a man came to Dr. Garretson's clinic and said, "Doctor, when I move my arm into any of the ordinary positions, I do not have any pain, but when I raise it high above my head, I feel pain." Dr. Garretson said, "What in the devil do you do it for?"

Dr. G. C. Kusel. I have listened to the essayist with a great deal of interest. In connection with the illustration of thrombi occurring in the pulp, the thought occurred to me that possibly here might be an early manifestation of what is known as arterio-sclerosis, and I would like to know if the essayist has associated these conditions, and at about what age these thrombi occur.

I would like also to have him explain to us why we have more sensation in gingival cavities than in cavities in other portions of the tooth. We find so often that of two cavities requiring preparation in a tooth, the one at the gingival portion is more sensitive than the one at another portion of the tooth.

In illustrating the referring of a sensation by the brain to another portion of the body, the essayist said that, when a foot or arm is amputated, the brain constantly refers sensations of pain to the amputated limb. This may be explained by the fact that the center for conveying sensations to the brain from that region had developed as the person developed. The brain, if the impression be referred from the ideo-motor center to the automatic center for the member in question, very naturally recognizes the lost member, because it is by reason of the existence of these centers that we are cognizant of the possession of such limbs, although not entirely so; hence the loss of such limbs does not mean the loss of function in either of these centers. It is our visual and tactile impulses associated with reasoning that cause us to recognize their absence or presence, and not the centers in the brain connected directly by nerve fibers. When members have been lost, as in intra-uterine amputations, these centers do not develop, and in such cases there can be no subconscious references. Possibly the brain is not so much at fault after all.

Dr. Hewitt. Referring to Dr. Inglis' suggestion that the interprismatic substance is dissolved and causes the teeth to be set on edge, I would say that this does not explain the instances where the teeth are set on edge from placing the hand on soft velvet or similar substances.

Dr. Gaskill. One question came to my mind when the essayist said that the sensation of pain, when eating a fig, is purely mental; that there is no actual pain in the teeth themselves, but that it is referred to the teeth as a purely reflex sensation. I cannot reconcile myself to that statement. It seems that there must be some irritation in the tooth, because we know there is a stimulus to the nerve terminals from the sugar of figs and some other dried fruits, which is very active at times. Moreover, these nerve terminals of the teeth are more susceptible at some times than at others; so there must be some actual local manifestation in the nerve terminals in the teeth, rather than in the soft tissues as stated by the essayist.

Mr. Hopewell-Smith (closing the discussion). The question of the sensitivity of the teeth is very difficult to answer in anything like a satisfactory manner. Some believe that sensations in the teeth are due to osmosis in the dentinal tubules, but that is pure hypothesis, and it is difficult to explain or account for sensations in this way. I cannot myself conceive of dentin acting as an osmotic membrane. No one knows much about it.

In reply to Dr. Inglis' remarks in regard to the sensitivity of enamel, I gather that he considers that, when a tooth detects the presence of such things as crumbs of bread, the sensation must be referred to the periodontal membrane. If that be true, this tissue must be frightfully sensitive.

Dr. Inglis. Would that not be a matter of education, or perhaps some

mental idea as to how shock would feel in the teeth?

Mr. Hopewell-Smith. Memory and experience may come in as important factors; but I am now speaking more from the histological point of view. If we knew more about the nerve supply of the periodontal membrane, we might be able to speak more definitely.

In regard to the phenomenon of setting the teeth on edge, I do not think there is any dissolution of the enamel. As Dr. Hewitt suggested, that explanation does not account for the sensation when touching soft velvet and other similar objects.

Dr. Inglis. Does that set the teeth on edge?

Mr. Hopewell-Smith. Surely.

Dr. Inglis. Is it not that the person grits the teeth because of a nervous impression?

Mr. Hopewell-Smith. I think they do that on account of the pain felt in the teeth. I am sure that is the case with myself.

One of the speakers asked if arteriosclerosis was present in the patients from whom these specimens were taken. As a matter of fact I do not know, but it never struck me that there were any general sclerotic changes. I do not think that the patients from whom these teeth were extracted were at all susceptible to those changes, because these specimens were taken in the regulation department of the Royal Dental Hospital of London from patients whose ages varied from eight to twelve years. There may be sclerosis there, but I did not investigate that point. We know that degenerative changes in the teeth are seen in early life, but I do not think that in the cases I examined there were any constitutional causes for thrombosis.

Dr. Kusel asked why teeth were more sensitive at the gingival than at other portions of the tooth. The reason for that is the closer proximity of the gingival portion to the pulp, and the shorter distance which a sensation has to travel from there than from the periphery of the tooth. Dr. Gaskill suggested in regard to the pain induced by a fig that I might have been mistaken, and that there may have been a cavity in a tooth. I do not believe that was the case, because I know that my teeth were all right. Then again, if that had been so, I should have felt the sensation of pain several times, whereas it occurred only once, and since that time, years ago, I have had the same experience perhaps twice only. If it had been from local dental causes, the pain would have occurred every time I ate a fig or took sugar of a similar character.

Dr. Mershon. I think the Academy appreciates fully the valuable paper which Mr. Hopewell-Smith has presented to us, and I move that a vote of thanks be extended to him for his paper. (Motion carried.)

The society then adjourned.

NATIONAL DENTAL ASSOCIATION—SOUTHERN BRANCH.

Sixteenth annual meeting of the Southern Branch of the National Dental Association, and the forty-seventh annual meeting of the Georgia State Dental Society, held at Atlanta, Ga., June 4, 5, and 6, 1914.

(Continued from page 453.)

FRIDAY—*Morning Session.*

The next order of business was the reading of a paper by Dr. H. W. MORGAN, Nashville, Tenn., entitled "Dental Education," as follows:

Dental Education.

By H. W. MORGAN, M.D., D.D.S., Nashville, Tenn.

What is education? has and always will be a live topic. Yet at the risk of being considered an "educational bore," I shall, at the outset, try to point out what education is not. Quoting from a recent paper: "First of all, it may be said that education is not on the part of the subject the mere acquisition of knowledge, or on the part of the educator the mere impartation of knowledge." We are told by Mr. Huxley, who wrote upon this subject nearly fifty years ago, that "In the newly awakened zeal for education, we run some risk of forgetting the truth that, while under-instruction is a bad thing, over-instruction may possibly be a worse. Success in any kind of practical life is not dependent solely or indeed chiefly upon knowledge." For, to quote Mr. Huxley again, "The great end of life is not knowledge, but action. What men need is, as much knowledge as they can assimilate and organize into a basis of action; to give them more of it may become injurious. One knows people who are as heavy and stupid from undigested learning as others are from overeating of meat and drink." An oriental proverb has expressed the same idea:

Who learns and learns, but acts not what he knows,
Is one who plows and plows, but never sows.

Of course the acquisition of knowledge is essential to education, but not its prime object, though it is in this limited sense most commonly used. Educators of today insist that education aims not at mere knowledge or mere power, but at knowledge and power put to right uses. They define education as "any effort to assist the development of an immature human being toward the proper goal of life."

THE PRIME OBJECT OF ALL EDUCATION.

The prime object, then, of education is power, ability to cope better with men and things, to become more efficient in the great struggle for existence. True education increases the student's strength to grasp, to hold, to utilize—especially to utilize. Practical ability to meet issues, to solve difficult problems, is the test of power. It does not matter how much you know, how much theory you have stored up in your mind; if you cannot marshal your knowledge at will and concentrate it upon the weak place, you are an impractical man. You must make every bit of your knowledge practical, or it will not avail you when the trial comes.

That man is educated who is trained in his perceptive faculties, in his analytical powers; so trained in all his abilities that, when surrounded by difficulties, he will be able to see where he is, able to understand what the occasion

demands, and able to master his conditions instead of being overwhelmed by them. The man overcome by his condition is not educated. Useless knowledge, then, is not education. Practical, live, comprehensive command of one's abilities and the full development of one's native resources constitute true education.

We make a serious mistake when we limit our efforts to professional training. Our duty to society is not, therefore, fully discharged when that obligation is met. Education means the development of the person, the training of the affections and the will into an earnest and loving desire to move in harmony with the laws of nature. Learning is not wisdom nor vital energy nor a substitute for common sense. Colton says, "It is better to have wisdom without learning than learning without wisdom." A student may have a head full of facts, and come out of school almost as weak as when he entered. He may rank high, and yet not have half the power of the slow, lazy boy, who ranks low.

A college course is called, by courtesy, "an education." A college course is not an education, it is only the beginning of an education. It is the foundation—and it should be a *good* foundation—for the student to build on for the rest of his life, and he should be taught that the superstructure will be determined solely by his own application and abilities.

A college course cannot do more than touch upon the rudiments of the science of dentistry, and the student cannot too soon learn that college training merely prepares him to study intelligently. A diploma does not stand for a great deal of learning; after all, it only certifies that the holder has taken a stipulated course of study in the college which gave it.

The dental degree stands pre-eminently above all others in that its possession is evidence of practical work satisfactorily done, and the claim that a dental graduate is better prepared to begin the active duties of his professional life than the graduate of any other profession is based upon this important fact. When a young man goes into dentistry, he must fight his way up step by step, each beset by all manner of temptation, petty jealousies and evil influences, which discourage and retard his progress. It is the college course that has furnished the theoretical knowledge of the principles, the practical training, the moral strength, the cultural equipment, and the friendships. I cannot too emphatically insist that no amount of knowledge and discipline will avail a man if he is not moral and honest.

DENTAL SCHOOLS' FACULTIES.

After these observations, we come now to the practical part of this paper. We are living in a scientific age, and with the increase of science relating to our profession has come the multiplication of instructors and subjects taught until the faculties list of some of our American dental schools looks like a young city directory.

There are eleven hundred and thirty names in forty-three college announcements, according to the last report of the American Institute of Dental Teachers. One school is put down as having nine as the lowest; two have fifty-eight, one sixty-six, one sixty-nine, and another eighty-eight. This may be meeting the demand for higher education, but the element of personal contact, if not entirely eliminated, is so remote that it is inappreciable.

The writer does not take these lists seriously to mean that these institutions use all these men in giving instruction, but would protest against the use in school catalogs of the names of men not called on for services. It is a padding process that educational ethics should not tolerate. Professional schools should live up to the standard of ethical conduct which they hope will govern their graduates.

INADEQUATE ANNUAL NUMBER OF DENTAL LICENTIATES.

The conviction seems to be growing that dental schools, notwithstanding

their splendid success and increasing progress, are not educating enough men to recruit the ranks of the profession. It is estimated that there is a five per cent. loss each year on account of death and retirement; that about two thousand licenses should be granted each year to fill up the ranks. This allows nothing for the increase in population nor the increased demands for dental service. In 1913 twenty-one hundred students were graduated; of these but thirteen hundred and fifty, according to the report of the National Association of Dental Examiners, were licensed.

The proper recruiting of the profession is a matter of great moment to the public, and to boards of examiners as well as to dental schools. The public is demanding more and more dental service each year. The care of the state's dependents, the unfortunate inmates of penitentiaries, insane asylums, institutions for the feeble-minded, is a call to humanity that is going to do much to impress the necessity for dental services upon the public mind, and will, in the near future, tax the profession to its utmost, and it is the joint duty of these boards and schools to be ready to meet the call when it comes. In our efforts to "elevate the profession" let us not forget that the public has an interest that must be recognized. Let us acknowledge our responsibility by encouraging young men to prepare themselves for this service.

Every dentist should feel equally this duty, earnestly warn young men of the fatal mistake of entering upon this great work without the proper equipment, and urge the great need of well-trained men and their thorough preparation before entering the profession. Such a course will strengthen the efforts of the educator and make the duties of the state boards less difficult.

THE QUESTION OF ADEQUATE COMPENSATION. DENTAL SCHOLARSHIPS URGED.

There is another aspect of this question of professional education in regard to which dentists have not yet realized their obligation. This is a financial one. Education is the only thing which I know is still sold for less than it costs. We may raise an adequate supply of young men, we may improve our teaching faculties, we may inspire young men with the ambition necessary, but men must live while they are being educated. Many struggle for their preparation but to find a dental education beyond hope of attainment. There is never a year that numerous cases of this kind do not apply for assistance. The dental profession should be willing to make a liberal offering to aid in developing worthy young men for their chosen life-work. Scores of men within the sound of my voice know worthy young individuals who would go into dentistry today, to become bright ornaments to the profession, if this financial obstacle were not in their way. Many of them will come, but not until they are advanced in years, and are handicapped by the taking up late in life a work which requires supple, young fingers, as being the quickest in mastering a difficult and complex technique.

Financial aid in the form of "tuition scholarships" and "loan funds" have proved very beneficial in our academies, colleges, and universities. The University of Pennsylvania in 1906 assisted students to the amount of $4244; Harvard had 260 scholarships ranging from $60 to $400 each. I have been teaching thirty-five years, and during all that time but one man has ever asked me if any dental student ever needed financial assistance. I do not believe the student who earns his way through school can get the best out of it. A few do earn their way, but they are not the leaders. There is an obligation here. May I ask, Will the dental profession ever meet it?

Discussion.

Dr. Homer C. Brown, Columbus, Ohio. The essayist has very ably presented a vital subject. Education, in its broadest sense, is the development of the individual mentally, morally, and

physically, to the end that he may be more efficient, and contribute his services to mankind in a manner that will be worth while.

Education is only secondary to health. In my opinion the question of the physical man is one for first consideration, since it would not profit him in the fullest measure to be educated to the highest possible degree, if he had no physical constitution to apply that education. The college course, as Dr. Morgan has so ably said, should be only the foundation for future education, and no graduate should accept his diploma from a dental or any other college, except as a credential for further study and greater usefulness. I was very much impressed with the essayist's statement regarding the forty-three dental colleges which carry a list of 1130 names of professors, instructors, special lecturers, etc., and to note the very great difference of from nine in one to eighty-eight in another institution. I do not know whether both these institutions maintain membership in the same organization or not, but if so, there certainly is an opportunity for the criticism of the one or the other of these colleges, or of the organization in which they hold membership. If nine men are sufficient to teach the dental student all that he should be required to know, eighty-eight is entirely too large a number, and there naturally will be more or less confusion resulting therefrom. I am inclined to think that nine is entirely too small a number, and that eighty-eight would probably be getting into each others' way some time during the college year.

Dr. Morgan appeals to the dental colleges to practice more ethics in their faculties, their catalogs, and their curricula, and I commend him for the stand which he has taken with reference thereto. Recently I addressed a letter to the dean of each dental college in our country, inclosing a circular letter addressed to the 1914 graduating class, and requested that these deans present this appeal and supplement it with such suggestions as they thought proper in order to stimulate the young men coming into the profession at this time to an increased interest in our dental organizations in the various sections of the country, to the end that we may secure their co-operation in everything that means progress in dentistry. I am of the opinion that if the practitioner of dentistry needs the assistance of our various organizations at any period in his life, he needs it in the first few years of his practice. This is becoming recognized more and more, and the tendency of men to wait until they feel able to attend meetings, join societies, etc., is most reprehensible.

The fact that twenty-one hundred persons were graduated from our dental colleges in 1913, but only 1350 were licensed by the various state boards, is most remarkable. There are examining boards in practically every state in our country, and if such a high percentage of graduates are unable to pass the various examining boards, it would seem that the students are not fully equipped when they graduate, or possibly that the requirements are too strict in some states.

Dr. Morgan. May I interrupt just a moment, to say that Dr. Brown's conclusion is not exactly correct? Many of the 2100 graduates were foreign students, and did not have to apply for license, while many others had degrees before they went to the colleges; that will account for some, but not for all, by any means.

Dr. Brown. I thank the essayist for this suggestion.

Dr. Morgan emphasizes the necessity for an increased number of dentists. I am fully aware that a shortage of dental practitioners, if it does not already exist, will soon exist, and this is another phase worthy of most careful consideration. On the other hand, I wish to emphasize the essayist's statement that the dental student should be more thoroughly equipped in regard to preliminary education. The greatest regret of my professional life has been that my preliminary education was so limited that every step of progress I have made

has only been accomplished under a positive handicap.

The essayist referred to the question of finances, so important to the dental student, and presented some figures that are more or less appalling. I can see the advantage of the establishment of scholarships, and think this should be encouraged wherever possible. I can appreciate, from my own personal experience, under what handicap a student is placed by lack of financial means.

Dr. J. P. Corley, Sewanee, Tenn. Unfortunately I did not hear this paper by my stepfather in dentistry, but Dr. Brown's discussion suggested a thought in reference to the appalling number of dental students who fail to pass the state board examinations. What is there left for them to do? It occurs to me that the dental college might incorporate in their curriculum a course in public dental education and prophylaxis, and require that their students should become efficient in the presentation of illustrated lectures on this subject, using the faculty and the student body as their audience upon whom to practice. Then if a man failed to pass the state board examination there would be a tremendous field left open to him, one ten times greater, and, if you will allow me to say it, of one hundred times greater importance than if he were commissioned to practice and do technical work for suffering humanity. It seems to me that this would afford the colleges an opportunity to use material which otherwise they could not use. There are young men who cannot qualify technically to save aching molars, but who might prove to be geniuses in the field of platform work, and who by lecturing before the thirty millions of public school children in the United States would be instrumental in saving hundreds of thousands of first molars. There is no law so far against a man speaking in public schools on prophylaxis; probably the time will come when we will have licensed men to do that, but at present the field is open. So instead of paying money for a dental equipment, the student might buy a lantern and lantern slides.

Gentlemen, this is not a dream. I realize that I am open to the criticism of having been a dreamer all my days, but this is practical common sense, and it seems to me a not unreasonable request to make of the dental colleges of the United States.

While I am on my feet, I want to pay tribute to the dental teachers of this country. If there is any class of men in dentistry that humanity should take off its hat to, it is the dental teachers. I know what they have sacrificed in order to do their work. I know what it costs them to give their best ability and best thought to the education of young men who may succeed them.

Dr. H. H. Johnson, Macon, Ga. The essayist's paper has already been thoroughly discussed from every standpoint. The subject of dental education is a very broad and interesting one. We all have our individual views along these lines. With the essayist, I believe in practical and scientific education. He struck the keynote when he said that little education is not much worse than over-education. I believe there can be too much schooling, too much training. The times and conditions are changing; new sciences are evolving; the world is broadening, new fields are being discovered, and no human mind can grasp them all. This is an age of specialism, and any man who perfects himself in one specialty during his lifetime has done well. The man who tries to master all science only gets a smattering of many subjects, and not enough of any one to be of practical value. When a patient presents in a dental office he wants to know whether the dentist can give the service required, whether he has perfected himself in that specialty, even to the exclusion of other broadening sciences. I believe in practical specialism, practical knowledge, practical education toward the occupation which a man has selected for his life-work.

Dr. B. Holly Smith, Baltimore. Taken in its broad sense, education is

never complete, but there is a growing appreciation of its value on the part of those who have passed the meridian of life and have given sober judgment to the facts. Schopenhauer says something like this: "In our infancy or early life, we look forward to great events as approaching us in a military parade with brass bands; but when we have gone over the hill, we look back and see that the really great things that come into our lives, come in by the side door, unheralded, quietly." And so it is with education. It has been my observation that the training of youths in colleges and schools has not consisted merely in the acquisition of knowledge, but of such training and mental equipment as enabled the student to think and to act better on any question. Like my distinguished friend, Dr. Brown, I can make a personal comparison between my opportunities and the opportunities which I had the privilege of extending to my own children by giving them the chance to see the disadvantage of the uncultured mind and the great advantage of a thorough education. It is not that one remembers Henry VIII, the Greek roots, or the Latin synonyms of English words, but that one's mind has been so trained that it enables him to meet a problem face to face and to judge it fairly. It is to such training that we owe the achievements of the great men of our profession.

Dr. Morgan (closing the discussion). I wish to express my hearty thanks to the gentlemen who have so kindly discussed my paper. I wish to emphasize that there is no such thing as the perfectly educated man; there never was and never will be, in my opinion. As I have pointed out, college education is simply the training of the heart and mind of the man to put forth the best that there is in him, and the superstructure depends entirely upon his application. Dr. Brown emphasized the idea of physical training. The old Greeks spent just one-half as much time in the gymnasium as they did in the schoolroom, and they were right. I wish every institution in this country had a system of physical examination before permitting students to enter. I believe the time will come when men who go to dental schools will be examined physically with as much care as applicants for entrance into the navy or the army. Then we shall practice true eugenics. We shall have material to work upon, and shall begin to develop it in the grammar schools. We shall then have the desired physical culture, and produce a race of people superior to the ancient Greeks.

Motion was then made and carried to adjourn until the evening session.

Friday—*Evening Session.*

The first order of business for the evening session was a lantern lecture by Dr. Carroll H. Frink, Jacksonville, Fla., on "Surgery of the Mouth, Teeth and Jaws," illustrated with models, drawings, etc.

The next order of business was the reading of a paper by Dr. T. P. Hinman, Atlanta, Ga., entitled, "Modern Crown and Bridge Construction."

[This paper is printed in full at page 491 of the present issue of the Cosmos.]

Discussion.

Dr. H. H. Johnson, Macon, Ga. Dr. Hinman has presented to us a most excellent paper. He has advanced an idea that I believe to be entirely original and extremely valuable. I refer to his suggestion that receding gums may be caused by the hammering of food particles against the dental ligament during mastication, due to improperly constructed crowns. If we stop to think a moment of the anatomy of the tooth, we know that at the rounded termination of the enamel at the neck of the tooth there is a folding of the gum under this sheltering ledge, giving protection to the ligamentous attachment at that point. Despite our knowledge of this anatomic condition, we have failed to reproduce it in our artificial work.

The essayist's method of producing cusps in gold crowns by casting is entirely correct, and I see no reason why we should still resort to the clumsy technique for obtaining correct occlusion that we have had to pursue in years past, when we can so simplify it by molding the cusps in wax, taking the occlusion in the mouth, investing and casting, thus making a complete crown in one operation. I believe, however, that 30 gage gold is too thin for bands in molar crowns, and in many instances for bicuspid crowns, especially if we intend to attach bridges with these crowns as abutments. I have seen that demonstrated many times, when the band, not being able to bear the strain of mastication, was torn away, and the bridge had to be removed for extensive repairs. I believe that 28-gage would be better in those cases. The profession has become so economical, however, that it is difficult to procure 28-gage gold plate, as the supply houses keep only 30-gage. It is poor economy to weaken the bridge foundation in order to save ten cents' worth of gold.

I differ with Dr. Hinman in regard to the size of the pin in his method of making a Richmond crown. I believe that 16-gage wire is too small. For laterals 15-gage would be better, and even 14-gage in canines and other large teeth. Dr. Hinman spoke of the form of crowns and bridges on the lingual and palatal sides, eliminating the so-called self-cleansing spaces. Evans in his "Crown and Bridge Work" calls attention to this idea. Time has demonstrated that saddle bridge work, if properly fitted and held rigidly in place by substantial abutments, may be cemented in place, even if it covers a considerable area of gum tissue, which will remain healthy for years.

Twenty years or more ago, Dr. E. Parmly Brown of New York made porcelain bridge work on this principle, resting on platinum saddles, and it was successful. I have seen porcelain bridge work constructed by Dr. Brown, the saddle covering a square inch of the gum surface, which was cemented in place, the gum having remained in a sanitary condition for years.

A townsman in 1895 applied to me for a piece of anterior bridge work, consisting of four incisors which were to be attached to canines. There was a great deal of resorption of the gums and process, and the constructing of a bridge after the methods in use at that time would have meant an unsightly piece of work, with considerable projection of the teeth. The patient's attention was called to this. Knowing the difficulties and objections, I made for him a little plate instead. I could restore the lost gum tissue with plate work, but it could not be done with the bridge work in use at that time. When on a visit to New York, the patient consulted Dr. Brown, who made a platinum saddle covering an inch of the gum surface, baked on four teeth, including a portion of pink gum, the bridge being fastened in the canines with platinum pins held in place by gold fillings, the whole appliance constituting a beautiful piece of work. On his return, the patient showed me this bridge, which I, in good faith, condemned as not being sanitary. To my utter surprise, the patient wore the appliance for years. I saw it constantly, as he came to have other work done. The gum remained perfectly healthy, and the condition sanitary so far as I could judge. That convinced me at that time that saddle bridge work could be successfully made. We are now perfecting those ideas which were started so long ago. These methods did not seem reasonable, and we took hold of them with fear and doubt, but now we confidently cement bridges in the mouth with large saddles resting over the ridge of gum. If fitted properly, such bridges are sanitary, hence the bridge work of the future will be more efficient, more correct anatomically, and more lifelike and healthful.

Dr. W. E. Lambright, Atlanta, Ga. I wish to ask Dr. Hinman a few questions. In regard to shell crowns, does a shell crown cause more recession than the modified Morrison crown? Again, does the essayist believe in using coarse

disks to round off the corners of teeth which are being prepared for the reception of crowns? How many sprues are used in casting a crown with platinum base?

Further, I would like to thank Dr. Johnson for his remarks about saddle bridge work. I have been experimenting quite a good deal in that direction, and I was pleased to hear his comment.

Dr. R. C. Young, Anniston, Ala. I would like to say that the two worst curses that ever came to the dental profession are the rubber plate and the gold crown. I do not know of anything except the extracting forceps that is more abused than the shell crown. The practitioner who puts a gold shell crown on a tooth without previous devitalization is almost guilty of malpractice. I know that this statement will be strongly resented, but that is my honest opinion.

The question has been raised as to whether it is better to use a Morrison or a Richmond crown. It has been my misfortune to see a number of good healthy roots split by the use of the Morrison crown, and I do not think that the Morrison crown has any place in restorative dentistry. On the other hand, we realize that a certain amount of recession of the gum is due to the use of a band. Platinum, however, seems to have the property of preventing this recession of the gum, as has been stated by Dr. Hinman. We have had today a most beautiful illustration of the usefulness of porcelain as a restorative means in dentistry, and I cannot conceive why it is that porcelain is not more universally used. But I want to reiterate that, if there is one curse in dentistry, it is the contemptible abuse of the gold shell crown.

Dr. H. H. Johnson. I would like to reply to Dr. Young in regard to his statement that it is malpractice to place a gold crown upon a tooth without devitalizing the pulp. I believe I have made crowns and bridges for as long a period of time as any practitioner in Georgia; in fact, I believe I can prove that I made the first bridge that was ever made in Georgia. I do not advocate the devitalization of all teeth which are to be crowned with gold crowns, and I have the following good reasons therefor. A patient presents to me for a piece of bridge work; he has one molar and some front teeth serviceable as anchorages. This molar is not devitalized. A crown is placed over the molar, the frontal abutments are prepared, and the bridge is cemented in place. Cement is not invulnerable, and in time dissolves from under the molar crown. The patient begins to feel a sensitivity at that point, and returns for examination. The bridge is removed, repaired, re-cemented in place, and is as good as ever. If the molar has been devitalized before placing the gold crown on it, the telegraph wires are destroyed which give the patient protection. If the tooth is devitalized, and the cement dissolves, as in the example described, the patient is not aware of it, and it is a matter of common knowledge that a tooth under a loose crown decays four times as fast as one under ordinary conditions. The patient after a time returns saying that the bridge has become loose in the rear, which immediately informs the experienced bridge worker that upon removing the bridge he will find a piece of soft cartilaginous substance which now represents what was once a good tooth. That was the last tooth the patient had on that side, probably his last means of mastication, and its loss to him is beyond estimate. Had that tooth not been devitalized, the bridge and the molar might have lasted ten years or more longer. Even if it had been necessary to devitalize it at the beginning of the second period, it would have rendered a long period of service afterward. There are cases, of course, where considerable grinding is to be done, and the teeth become so sensitive that, in order to prepare the abutments properly, the teeth have to be devitalized, but to advocate the devitalization of every tooth to be crowned is malpractice, in my opinion.

Dr. J. G. Reid, Marion, N. C. I fully agree with Dr. Johnson. I have

constructed bridges that have been in the mouth for fifteen years, and the abutment teeth are still vital. I think every practitioner who is not a crank on the subject of devitalizing teeth knows that no root-canal filling is as good as the natural pulp. One of our best bridge workers in North Carolina said that unless we devitalized the pulps in all teeth to be crowned, we were doing criminal work; his brother, who is a very good operator and is associated with him, told me that he does not devitalize any teeth unless he has to.

Dr. YOUNG. I am surprised that a man of Dr. Johnson's technical ability could put forward such a lame proposition as to say that he wants the sensitiveness of the teeth to act as a warning signal to tell him when bridge work fails. Dr. Johnson is a magnificent workman, but such men as Rhein of New York have spent years in order to demonstrate the fact that the insertion of a gold crown upon a vital tooth causes a degeneration in the pulp which has no apparent outward manifestation, but will make its impress on some vital portion of the body. We have been told that infections from such sources have resulted in endocarditis, abscesses in the liver, kidney trouble, and hosts of other dangerous lesions. The sooner we realize that fact the sooner we shall become better therapeutists. By overcoming this all-absorbing mechanical trend of the profession, we shall hasten its progress. Excuse me from the man who is solely mechanical. We must combine science and mechanics for the best good. And when we substitute a lost tooth with a bridge, let us make it by no means a menace to life and health. I defy any practitioner to crown a tooth by cutting away sufficient tooth structure for a perfect adaptation of a shell crown, and not have the pulp undergo degenerative changes.

Dr. JOHNSON. I agree with Dr. Young in regard to the statement that the gold crown has been a curse. I know that it has been abused, and that the profession has suffered for that; but that is not the question we are discussing. I know Dr. Rhein personally and am familiar with his manner of operating, and while he may at times have discovered pulp stones in teeth that had been crowned, I have seen the same in teeth which have not been crowned. I have seen just as many pathological conditions in teeth that had been filled as Dr. Young and Dr. Rhein have seen under crowns, and I do not attach so much importance to these so-called discoveries. Of course, when an operator makes an ill-fitting crown, we may be sure that trouble will follow, no matter whether the tooth is devitalized or not.

Dr. YOUNG. This is a question of vital importance. We know, Dr. Johnson, that you are a magnificent operator, and that you are not guessing, but how are we to present this problem to the student?

Dr. JOHNSON. Let us discard the ill-fitting crown. You will admit that it is impossible to construct a gold crown with a band fitted so well that the gold will touch every surface of the tooth?

Dr. YOUNG. Yes.

Dr. JOHNSON. You will admit that there is a considerable film of cement between the gold crown and the tooth?

Dr. YOUNG. Yes.

Dr. JOHNSON. Then your contention and Dr. Rhein's contention that the contact of metal causes the trouble is disproved.

Dr. YOUNG. It is the cement, not the metal. I believe that glacial phosphoric acid will kill any pulp.

Dr. JOHNSON. I am glad you make that contention, because it strengthens my position. You admit, then, that after the tooth is crowned, even if it has been accurately shaped for the reception of a gold crown, you have not approached the pulp as near at any point as you would in a carious cavity of medium depth. Your contention is that cement is absolutely unfit as a filling material for any tooth, because it is closer to the pulp than when used for cementing a crown in position. I suppose you have never capped a pulp?

Dr. YOUNG. Never, except with arsenic.

Dr. Holland. What do you line cavities with?

Dr. Young. That is a different proposition from the trimming of a tooth for a crown, robbing it of that marvelous substance of nature, enamel, which is not found in any other portion of the body. No other part has such a protection by an absolutely inert compound as the enamel rods afford, and when you scale this off and replace it with glacial phosphoric acid in sufficient amount to set a crown, you will cause disturbances in the tooth. As to lining cavities or capping pulps with cement, if this material is placed in a tooth *close* to the pulp, we might just as well place arsenic in the tooth, because sooner or later the tooth is going to die. That is the point, and I do not retract one iota.

Dr. Johnson. What do you fasten gold inlays with?

Dr. Young. Cement.

Dr. Johnson. Then you subject the tooth to the same possibility of trouble from the contact of phosphoric acid with dentin and at a nearer approach to the pulp, and your contention as to the gold crown is inconsistent.

Dr. Young. That is not a comparison.

Dr. Hinman (closing the discussion). I shall try to take up the points at issue *seriatim,* and discuss them as briefly as possible.

Dr. Johnson prefers 15 or 14 gage wire for pins instead of 16 gage, which I use more than any other. In some cases it would probably be better to use 14 or even 12 gage wire, but, as a general rule, the 16 gage wire seems to be satisfactory.

Dr. Lambright asks if I find more recession due to shell crown than to a Morrison or disk crown. A shell crown causes no more recession if its construction is correct than a pin-and-disk crown. The reason why gold crowns cause so much recession is that they are incorrectly shaped. The reason for so much recession from the ordinary pin-and-disk crown is that, in restoring the lingual surface, it is made concave instead of concavo-convex. I believe that the pin-and-disk crown, if properly contoured and adjusted, has all the strength requisite for an individual crown, but not for a bridge abutment. As for the Richmond crown, if the technique I spoke of is followed, and the root surfaces are restored in metal, no recession will ensue.

The question of degenerative changes in the pulp underneath a crown has caused much discussion. It is a demonstrable fact that, as soon as a tooth is filled with any material whatever, a degenerative process will take place in the pulp, no matter how small the filling be. This physical fact is easily demonstrable. The matter of putting a crown over a vital pulp is a question of individual judgment. Of course trouble may be caused by cutting the tooth down too far, and, as I said, whenever the pulp is approached too closely, it is a safe plan to devitalize the tooth and fill the roots. That, however, is a matter of individual judgment and technique. A great many vital teeth have been crowned with gold, and have given no trouble for many years; but it is also true that in a great many teeth which have been crowned with gold, the pulps have died. Therefore we have to use judgment in each individual case. In controversion of what Dr. Young has said about cutting off the enamel and replacing it with an artificial substitute, my experience has been that a shell crown or porcelain jacket crown does not cause any more disturbance in the pulp than a metal crown. It is not the grinding-off of the enamel covering, nor the fact that we place cement under the crown that causes the pulp to die. It is true that degenerative changes occur, and that the pulp begins to protect itself, but the real reason why the pulp dies lies in the fact that, when we grind the tooth down, the mouth being filled with germs, the tubuli of the teeth become filled with these germs, which pass through the tubules into the pulp, causing infection and death of the pulp. The way to overcome this is to wash the tooth thoroughly with alcohol before the crown is set.

There are several methods for cutting down hypersensitive dentin. We have

nitrous oxid and oxygen analgesia, for which I do not care—and I will diverge here for a moment to say that I believe this to be one of the crazy waves that come over the profession now and then, and soon pass off. Analgesia may have its place in the hands of some operators, but it has no place with me. I am not condemning it entirely, but am simply giving my views in regard to it. With the use of novocain injected properly by the Fischer method, I can extirpate the pulp of or cut down any tooth painlessly.

I hope you have all had an opportunity to see and criticize the work I have passed around; I wish you to notice one or two items particularly, namely, that the lingual, buccal, and labial surfaces are anatomically correct; also that the saddles are very small. The technique of making these saddles I did not have time to describe in detail.

The next order of business was a talk by Mr. F. O. Foster, Atlanta, Ga., on "New Appliances and Improved Methods During the Past Year."

Motion was then made and carried to adjourn until the Saturday morning session.

Saturday—*Morning Session.*

The meeting was called to order on Saturday morning, June 6th, by the president, Dr. Dean.

The first item on the program for the morning session was the reading of a paper by Dr. B. Holly Smith, Baltimore, Md., entitled "The Responsibility of the Members of the Dental Profession to Those Who are Without Opportunity for Dental Treatment."

[This paper is printed in full at page 534 of the present issue of the Cosmos.]

Discussion.

Dr. Homer C. Brown, Columbus, Ohio. In beginning the discussion of this paper I will say that as a member of the dental profession I fully appreciate the many sacrifices which the essayist has made along the lines indicated in his paper. I referred yesterday to the pioneers in dentistry, and what they have accomplished. Dr. Smith has been one of these pioneers. I personally know of sacrifices which he has made in his home city in order to develop an interest in dental matters among school boards, among medical men, and among the laity, and I wish to take this opportunity of expressing my high appreciation of the men of his caliber for the sacrifices which they make in order to put our profession on a higher plane.

Some are fortunate in the possession of wealth; some are called to positions of honor and influence; some are blessed with a surplus of energy and time, and some are qualified to formulate plans and execute progressive policies for the good of the masses. And he who gives of his purse, his influence, his energy, his time, with a view to improving the present or future generations, is generously contributing to a worthy cause, and his closing days will be brighter for his having rendered some real service for the uplift of humanity.

In doing such work as the essayist has presented in his paper, we are receiving increased support from the medical profession, from educational interests, from philanthropic and from civic organizations, such as we could not have hoped for five years ago. This support has been rendered possible by the work of the pioneers to whom I have referred. I am grateful for the privilege of being present this morning, and thus enabled to call attention to the opportunity which confronts the profession in Georgia at this particular time, as indicated in Dr. Huff's report with reference to the public health bill pending in the legislature of the state. I think it is very important that the profession of your state give loyal support to this bill, and that you impress upon the members of the legislature the advantages to be derived by your co-operation, thus not only securing the enactment of this bill, but enforcing it.

First, we must recognize that the individual is a unit of society; second, that society can be divided into two classes,

producers and non-producers; third, that the progress of a municipality, state, or nation depends primarily upon maintaining a high percentage of productive units; fourth, that health is the first essential in establishing and maintaining a high productive standard; fifth, that by healthy children taking advantage of the liberal educational opportunities, and later the favorable vocational conditions, such as exist in our country, we are justified in assuming that the percentage of productive units can be increased, and that such means should be employed as may be necessary to accomplish this end. If our state and municipal authorities are going to force education upon us—and we certainly know that they are not doing this any too soon—it is just as important for them to keep a child in fit physical condition to receive this education as it is to expend money in educating the child. When this question is properly appreciated, school and municipal authorities will look to the individual for efficiency, and whatever means are necessary to equip the child for highest efficiency in its future life should be employed. In considering the item of expense the public should understand that such increased expense as would naturally be caused by the maintenance of free dental clinics for the indigent is amply offset by what it costs to keep "repeaters" in school an additional year.

Dr. Frank Holland, Atlanta, Ga. I do not feel equal to discussing a paper like the one we have just heard. The essayist has set forth many truths that appeal to us all, one of his strongest arguments being unselfishness. The unselfish man is he who accomplishes things in this world, who does things for the benefit of his fellow man. It devolves upon us to make up our minds to apply as fast as we can the truths which the essayist has set forth. If you show me an unselfish dentist, I will show you a successful one, who is a benefit not only to his *clientèle* but to his profession as well, and who will make himself felt in his community as a valuable citizen. If you show me a selfish dentist who looks upon the sordid dollar as the only object worth seeking, I will show you one whose accomplishments have been so meager that he is never thought of, and who, after all, has accomplished nothing for himself except the few dollars he may have accumulated.

Dr. H. H. Johnson, Macon, Ga. I appreciate very much the honor of being called upon to discuss this admirable paper, but hardly know where to begin. I heartily agree with Dr. Holland that selfishness is the root of all evil. We always admire those characters in history who have devoted and sacrificed their lives for the good of mankind and for science. We have recorded in the history of Atlanta the life of a man who practiced dentistry here, Dr. J. B. Bean, whose career evokes our admiration. Dr. Bean, during the civil war, devoted his services as best he could to hospital work in the Confederate army. Afterward he was called by the government to make some investigations in Switzerland, and in pursuing his investigations among the snow-capped mountains in unexplored regions, he was lost, and realized that he must die from starvation and cold. Immediately on discovering that he was freezing, that life must end, he took from his pocket a tablet and pencil, and until the cold palsied his hand wrote down the sensations of a person dying from cold, so that this description might go down as a contribution to science. It is this kind of character that we admire. The beautiful sentiments expressed in the paper animate not only other noble lives, but the essayist's own.

Dr. N. A. Teague, Augusta, Ga. We cannot but admire the men enumerated by Dr. Smith in his paper who gave their lives for science. What a difference between the lives of these men and the sordid life of the man who is working for the dollar only! I do not feel capable of discussing this admirable paper, but wish to express my sincere appreciation. It is worth a trip to Atlanta to have heard the essayist's beautiful sentiments.

Dr. J. P. Corley, Sewanee, Tenn. I do not wish to discuss the paper, because I am not qualified to do it justice. This

essay deals with fundamentals. In the mind of the great Architect who built this universe there were thoughts which the human mind, up to the present time, has not been able to comprehend. The paper shows that there are two diametrically opposed forces, for which we cannot account. On the one hand we have love, unselfishness, devotion to principle and self-sacrifice, and on the other their antitheses. I believe the unselfish devotee of idealism has in many instances sacrificed and ruthlessly wasted his efforts, and died before his time. Since we are developing in every domain of civilization logical plans for efficiency, why not consider the question of philanthropy in dentistry. Instead of one individual sacrificing himself, scattering his forces and making a wreck of his finances on the one side, while another individual meets with but indifferent success, why not let us evolve a scientific plan like other philanthropic organizations, and employ a trained expert in this line. Then the dentist could, out of his meager funds, contribute to the support of such an expert, and his earnings would yield greater dividends, and he would not have to sacrifice himself. Some of my best friends —and Dr. Smith is one—are killing themselves for their fellow men. Can we not conserve our forces? We have with us an expert who is available for just this work, and I would like to ask that the courtesy of the floor be extended to Mr. Jones, who for twenty-five years has been a salaried specialist in advancing philanthropic enterprises throughout the country.

Mr. M. Jermain Jones, Washington, D. C. This is my first attendance upon a convention of dentists. It was my pleasure to travel with the essayist from Washington, to become acquainted with him. to read his paper, and to feel the magic of his message of altruism and learn his interpretation of what we may call the new social spirit in America. It is not inane flattery when I say that the personal touch with you men from Tennessee, Texas, Florida, South Carolina, Georgia and Atlanta, has convinced me of the high sense of responsibility, of unselfishness, of what I may call social conscience that exists in your body, and of your desire to give expression to this idealism in some practical form. This, gentlemen, is the age of the social question; it is the age of transition from the selfish to the social ideal of life. That spirit is being shown in a thousand ways and I need not dwell upon it, as Dr. Smith has beautifully portrayed it in the examples set before us this morning. But I do want to say that your essayist's interpretation of the dentist's duty toward humanity, of his attitude as a citizen in the community, as a factor in society, is but one more evidence of the conscience that is stirring men and women of our time with the obligation of altruism. We talk about conscience. Is there such a thing as conscience for self? What is conscience, if not an expression of one's obligation, not with a view merely to one's self, but with a view to his relation to others? I was struck, as I listened to the essayist, with the story of altruism expressed by the lives of these men. You are asking the question, "What shall we do?" "How shall this beautiful ideal which our essayist has spoken about so feelingly be attained?" The question which you are bound to solve is, how you may in your community do what has been done in Baltimore, in Rochester, in Cleveland, Detroit, Cincinnati, and other cities. I have been a student of the social question and have been practicing in this field of social engineering a good many years. I have felt the impact of this question, and I have been giving my life for a good many years to the service of the Young Men's Christian Association. I know of no other field of education that I should prefer to devote myself to than social service. Somehow or other there has come to me the opportunity to join hands with the organization which was created as an auxiliary by the National Dental Association four years ago, known as the National Mouth Hygiene Association. That organization has its headquarters at present in Cleveland, and will probably have other headquarters in Washington. With the co-operation which

Dr. Smith has outlined as ideal, and the practical results which in many communities have already been attained by the counsel and direction of men interested in this movement, by organized publicity, by a lecture bureau, and other feasible means, we hope that we may not be content until we shall have reached the byways and highways of our country with this campaign for school clinics.

Mr. President, the question you are asking is—What shall we do? The question which Dr. Smith raised of how the ideal may be made practical, how the uplift of humanity may be realized, that question we hope we shall be able to help you to answer.

Dr. H. W. Morgan, Nashville, Tenn. It may seem bold to attempt to add to the most interesting discussion we have heard, to say nothing of the essayist's beautiful prose poem, but this great work which Dr. Smith has so forcefully outlined is one which is strongly impressed upon us at this time—"the brotherhood of man and the fatherhood of God." The essayist asks, "Am I my brother's keeper?" and proceeds to point out how not only individuals but legislative bodies are providing for protection of human life, and are endeavoring by various movements to enlist the sympathies of everyone in the misfortunes of the masses. During the year ending in July 1913, a commission in charge of the factory operatives in the state of Massachusetts reported no less than eighty-four thousand accidents in the various manufactories in that state. All the efforts toward the introduction of machinery that would protect human life did not avail to prevent these numerous accidents. The world's attention toward the conservation of life is nowhere more beautifully illustrated than in the great work done by the Rockefeller Foundation toward the eradication of the hookworm. I want to suggest to the members of the National Mouth Hygiene Association that Dr. Wycliffe Rose, who is at the head of that work, would surely be able to offer most valuable suggestions for working out the plan which the National Mouth Hygiene Association has in hand. While not a doctor of medicine, this educator was called to that work, and notwithstanding the great opposition which it met with in the beginning, the work has been so effectively and successfully carried on that thousands and thousands of lives have been saved from the enervation and lethargy incident to that disease. He is now, I believe, abroad making a canvass of the entire world, for the hookworm is not a local condition in the South, as it was believed when that great Methodist divine raised his voice against it, and presented his objections through your Atlanta papers a few years ago. We are heading in the right direction. The Forsyth brothers in Boston and Dr. Julius Rosenthal in Chicago have done what we as a profession could not do, and state after state will fall into line, until the time will come, I believe, when the poor unfortunates who have no knowledge of their conditions, the inmates of our insane asylums, our penitentiaries, etc., will be provided with sufficient dental service to meet their great needs. I mentioned yesterday several instances in two states where this has already been accomplished, and let me say that these appointments have not been made owing to any pressure exerted by the dental profession, but through the interest of a few medical men who have been aroused to the importance of this work. As soon as we are able to convince the physicians of the importance of mouth hygiene, the necessary state aid will follow as a matter of course.

I congratulate Dr. Smith and the association upon his most magnificent presentation. He says that it is self-sacrifice that counts; that our lives are worth nothing, that we leave nothing behind us, unless we render services to our fellow men. The great Agassiz, when asked why he did not, instead of devoting himself to natural history, devote himself to medicine or some other calling, that he might make for himself a fortune, said, "I have no time to think about making money."

Dr. Smith (closing the discussion). It is very difficult, because of my warm

affection for those who have been so complimentary in their comments, to avoid in closing this discussion some thought of loving appreciation for the compliments that have been tendered me. But in our efforts for the advancement of our profession and the increase of our usefulness within that profession, selfish considerations, even of warm appreciation or commendation, must be eliminated. As a body of professional men we should keep ourselves in the background, while we establish in the minds of all whom we can reach the value of such a propaganda of dental education as shall bring home to the common people, who have hitherto regarded our services as out of their reach, the absolute importance and necessity of dental attention.

That so much self-sacrificing effort has been made by the members of our profession for the extension of this propaganda of oral hygiene is most commendable, and the results have been truly remarkable. In the last few years we have achieved recognition of the necessity of our work from large corporations, manufactories, from the navy and army, to say nothing of our great sister profession, medicine. Indeed, in my home city the leaders of that profession will not attempt treatment without previous examination of the mouth and its proper treatment. This growth in general esteem is most gratifying, especially to those of us whose memory carries them back to early and very different conditions. We have labored early and late to reach our present status, and the reward is the consciousness that we have projected our service into fields which really did not invite them, but in which our helpfulness has been appreciated after our visit.

I cannot take my seat without recalling some of the incidents that have occurred in the various foregatherings of the distinguished men who have carried on the activities of this Southern Branch of the National Dental Association. I cannot feel with equanimity that this is the last meeting of this association. The deepest sentiment of loving appreciation fills me when I think of the opportunities that have been afforded me for commingling with the great men who have made this association useful in its work for the profession and for the community. I recall the characters, often unique, often picturesque, of the men who have stood as leaders in the thought and action of the Southern Association. I wish that you gentlemen who are members of this association had not taken action toward its disbanding. It seems to me that the sacred memory of the activities of this professional organization, the thought of the men who have come in and out of our meeting, leaving their impress not only upon us individually but upon professional thought generally, should have withheld such a decision. Out of respect to these memories it seems to me that it would have been better to have the association reconvene at the call of the Executive Committee. I have never approved of killing, in fact I have killed very few people or things in my life, and I am not at all in the frame of mind to commit suicide. I loathe death, and I wish earnestly that we might rescind the action taken, and at least allow this association to remain in a state of suspended animation. There may occur a time when we might want to reconvene; there may be some celebration or some anniversary, some occasion when we would want the members to reassemble. I have talked with some of the members who voted for the disbanding of the Southern Branch of the National, however, and I acquiesce in their judgment.

I do not want to project my own views on the thought of this body, but I do wish there could be some way by which we could so modify the action taken that the present Executive Committee would have the privilege of calling together this association if, as I say, a special occasion warranted the call.

Mr. Chairman, I want to thank you for the courtesy extended, and my loving friends for their kind words of appreciation.

THE DENTAL COSMOS

A MONTHLY RECORD OF DENTAL SCIENCE.

Devoted to the Interests of the Profession.

EDITED BY

EDWARD C. KIRK, D.D.S., Sc.D.

PUBLISHED BY

THE S. S. WHITE DENTAL MFG. CO., PHILADELPHIA, PA.

SUBSCRIPTION PRICE, including postage, $1.00 a year to all parts of the United States, Hawaiian Islands, the Philippines, Guam, Porto Rico, Cuba, and Mexico. Canada, $1.40. To other foreign countries, $1.75 a year.

Original contributions, society reports, and other correspondence intended for publication should be addressed to the EDITOR, Lock Box 1615, Philadelphia, Pa.

Subscriptions and communications relating to advertisements should be addressed to the BUSINESS MANAGER of the DENTAL COSMOS, Lock Box 1615, Philadelphia, Pa.

PHILADELPHIA, MAY 1915.

EDITORIAL DEPARTMENT.

THE FOUR YEARS' CURRICULUM.

AFTER years of agitation and the educative effect of experience, which have fully demonstrated the inadequacy of the standard three years' curriculum as preparation for dental practice, the sentiment of the dental profession in America seems to be ready to support an increase in the time of the dental curriculum to four years. Indeed, the National Dental Association, the National Association of Dental Examiners, the National Association of Dental Faculties, and the Dental Faculties Association of American Universities, have each and all officially committed themselves by resolution as favorable to the advanced standard.

Dental educators have for years felt that the three years' curriculum was overcrowded to a degree which made efficient teaching in all of the required subjects of the curriculum almost impossible. Boards of examiners who have had to pass upon the products of our educational system under the three years' standard

have complained of the insufficient preparation of candidates—all of which, with the steadily increasing data which make up the sum total of dental knowledge required for successful practice, has combined to make the demand for additional time in preparation for dental practice imperative.

In anticipation of the official increase in time of the dental course, much attention has been given to the consideration of the manner in which the added time should be utilized, and a variety of suggestions to that end have been made, among the most striking of which are suggestions which have been variously proposed for the incorporation in the new curriculum of cultural studies such as languages, rhetoric, history, economics, psychology, ethics, the principles of art, public speaking, freehand drawing, and the like. These suggestions have been made not only in good faith, but in clear recognition of an existing cultural need in the average dental student. No one can successfully question for a moment the immense value and utility of these cultural subjects as part of the education of the dentist, and it is doubtless because so many dental students are defective in the culture which these studies are believed to develop, and do develop when they are faithfully and intelligently pursued, that dental educators, realizing the intellectual deficiency which lack of training in these subjects entails, have proposed to remedy the defect by incorporating them into the dental curriculum. We are in sympathetic agreement with those who realize the need of proper cultural development of the dental student, but we are wholly opposed to the means suggested for obtaining that kind of cultural training. The only logical way to obtain it is to demand proficiency in the group of subjects referred to as a part of the entrance qualification required for admission to the dental course.

In one of the proposed curricula published in this issue, forty-eight hours are given to materia medica and therapeutics, while to anatomy and its subdivisions are assigned a total of four hundred and forty-eight hours in this arrangement of time. Not only is undue emphasis given to anatomical and histologic study out of all relative proportion to its importance in the dental curriculum, but on the other hand, materia medica and therapeutics, which should involve adequate training in pharmacology, is minimized to a degree which would render the education of the dental stu-

dent in that subject well-nigh worthless. Similarly, ninety-six hours are assigned to general bacteriology, with no provision for the special bacteriology of the mouth and its relations to mouth infections and systemic diseases. It is doubtless valuable and important for a dentist to know something if not all about the bacterial examination of water and the purification of sewage, but it is more important for him to know a great deal about the microbiology of the mouth and the bearings of that subject upon the question of local and systemic disease. It is questionable whether in sixteen hours a student can secure more than a superficial smattering of dental metallurgy, and it is equally questionable whether in one hundred and fifty hours of combined lectures, laboratory, and practice he can secure more than a superficial smattering of orthodontia.
